This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

EDITORIAL NOTE.

The last volume of the new edition of the Reference Handbook having now been completed, it becomes a pleasant duty to acknowledge my indebtedness to those who have been associated with me and who have done so much to bring this great undertaking to a successful conclusion. The number and nature of the articles contributed by each of them may be learned from the List of Authors and their Contributions, which is published at the end of the present volume. This list, however, conveys only an imperfect idea of the amount of time and labor which some of these writers have bestowed upon their tasks. Indeed, only those who have themselves done work of equal magnitude can form a correct estimate of the credit which belongs to each one of the men and women whose names appear in this list. Whatever usefulness the Handbook possesses as a whole is due to the intrinsic value of its component parts. If a large proportion of these articles were not of a high order of merit the Handbook as a whole would not have met with the appreciative reception which has been accorded to it by the medical profession of the United States and Canada, and I must in fairness state that a great deal of the credit for the organization of this mass of useful information belongs to my associates; the major part to the Department Advisers, a list of whose names appears at the beginning of Vol. I. While all of these gentlemen took, in the beginning of the enterprise, an active part in the selection of topics and of the individuals best fitted to write authoritatively upon them, a few of their number have continued to give me most efficient aid throughout the entire progress of the work. I refer particularly to Aldred S. Warthin, of Ann Arbor, Mich., Edward O. Otis, W. T. Councilman and Henry R. Stedman, of Boston, Mass., John Green, of St. Louis, Mo., Col. Charles Smart, U. S. Army, and Henry H. Rusby, William H. Park, George T. Jackson, and Robert Lewis, Jr., of New York. I am also under obligation to many of the contributors for undertaking, at short notice, work which had originally been assigned to other writers, who, owing to illness or for other reasons, had been obliged to abandon their tasks. I should be glad to mention the names of all of these gentlemen did space permit me to do so.

The elaborate and carefully prepared general index is the work of Dr. R. J. E. Scott, of this city.

A. H. B.

New York, February 1st, 1904.

LIST OF CONTRIBUTORS TO VOLUME VIII.

A. A. ABALLI, M.D.................Havana, Cuba.

SAMUEL W. ABBOTT, M.D.. Newton Centre, Mass.
Secretary of State Board of Health of Massachusetts.

CHARLES WARRENNE ALLEN, M.D..New York, N. Y.
Professor of Dermatology, New York Post-Graduate School; Consulting Dermatologist to the Randall's Island Hospitals.

FRANK BAKER, M.D., Ph.D....Washington, D. C.
Professor of Anatomy, Medical Department, Georgetown University, Washington, D. C.; Superintendent, National Zoological Park, Smithsonian Institution.

FRANKLIN GREENE BALCH, M.D........Boston, Mass.
Surgeon to Out-Patients, Massachusetts General Hospital; Visiting Surgeon, Carney and Faulkner Hospitals; Assistant in Clinical and Operative Surgery, Harvard University Medical School.

FREDERICK AMOS BALDWIN, M.D..Ann Arbor, Mich.
Assistant in Pathology, Medical Department, University of Michigan.

WILLIAM BARNES,* M.D...........Decatur, Ill.

DONALD McLEAN BARSTOW, M.D...New York, N. Y.
Clinical Assistant, Department of Medicine, Vanderbilt Clinic, College of Physicians and Surgeons, Columbia University.

WALTER ARTHUR BASTEDO, Ph.G., M.D...New York, N. Y.
Instructor in Materia Medica and Therapeutics, College of Physicians and Surgeons, Columbia University; formerly Torrey Club Lecturer on Botany at the New York College of Pharmacy.

HENRY D. BEYEA, M.D........Philadelphia, Pa.
Instructor in Gynæcology, Medical Department, University of Pennsylvania; Assistant Gynæcologist, University Hospital; Associate Surgeon, Gynecean Hospital.

ROBERT PAYNE BIGELOW, Ph.D.........Boston, Mass.
Instructor in Biology, Massachusetts Institute of Technology.

W. P. BOLLES, M.D..................Boston, Mass.
Professor of Materia Medica and Botany, Emeritus, Massachusetts College of Pharmacy; Attending Surgeon, Boston City Hospital.

MAJOR WILLIAM CLINE BORDEN....Washington, D. C.
Surgeon, United States Army.

MARK A. BROWN, M.D...........Cincinnati, Ohio.
Professor of Hygiene, Miami Medical College, Cincinnati; Pathologist to Presbyterian Hospital, Cincinnati.

WILLIAM SOHIER BRYANT, M.D.....New York, N. Y.
Instructor in Otology, Medical Department, Columbia University.

HUGH CABOT, M.D...................Boston, Mass.
Assistant in Operative Surgery, Harvard University Medical School; Surgeon to Baptist Hospital, Boston, Mass.

EMILE MONNIN CHAMOT, B.S., Ph.D.....Ithaca, N. Y.
Assistant Professor of Sanitary Chemistry and Toxicology, Cornell University; Lecturer on Toxicology, New York State Veterinary College, Ithaca, N. Y.

JOSEPH WILLIAM COURTNEY, M.D......Boston, Mass.
Assistant Physician for Diseases of the Nervous System, Boston City Hospital.

ALFRED C. CROFTAN, M.D.........Chicago, Ill.
Professor of Medicine, Post-Graduate Medical College of Chicago; Pathologist, St. Luke's Hospital, Chicago.

JAMES K. CROOK, M.D..........New York, N. Y.
Adjunct Professor of Clinical Medicine and Physical Diagnosis, New York Post-Graduate Medical School; Attending Physician, New York Post-Graduate Hospital.

EDWARD CURTIS, M.D..........New York, N. Y.
Emeritus Professor of Materia Medica and Therapeutics, College of Physicians and Surgeons, Columbia University.

ARTHUR R. CUSHNY, M.D.....Ann Arbor, Mich.
Professor of Materia Medica and Therapeutics, University of Michigan.

ROBERT H. M. DAWBARN, M.D..New York, N. Y.
Attending Surgeon, City and Polyclinic Hospitals, New York.

D. BRYSON DELAVAN, M.D....New York, N. Y.
Professor of Laryngology, New York Polyclinic; Consulting Laryngologist, General Memorial Hospital and Hospital for Ruptured and Crippled, New York.

EDWARD K. DUNHAM, M.D....New York, N. Y.
Professor of General Pathology, Bacteriology, and Hygiene, the University and Bellevue Hospital Medical College, New York.

GEORGE THOMSON ELLIOT, M.D.....New York, N. Y.
Professor of Dermatology, Cornell University Medical College, New York City; Assistant Attending Physician and Pathologist, New York Skin and Cancer Hospital; Consulting Dermatologist, St. Luke's, Columbus, and the New York Lying-in Hospitals.

J. HAVEN EMERSON, M.D......New York, N. Y.

HAROLD C. ERNST, M.D...........Boston, Mass.
Professor of Bacteriology, Harvard University Medical School, Boston.

LIST OF CONTRIBUTORS TO VOLUME VIII.

EUGENE ELLSWORTH EVERETT, M.D...Boston, Mass.
Instructor in Bacteriology, Harvard University Medical School, Boston; Assistant Gynæcologist, Boston Dispensary.

CYRUS WEST FIELD, M.D.......New York, N. Y.
Assistant Bacteriologist, New York City Board of Health; Pathological Externe, Presbyterian Hospital; formerly Assistant in Pathology, College of Physicians and Surgeons, Columbia University, New York.

CARLOS J. FINLAY, M.D...........Havana, Cuba.
Health Officer, Port of Havana, Cuba.

EDWARD MILTON FOOTE, M.D...New York, N.Y.
Instructor in Minor Surgery, College of Physicians and Surgeons, Columbia University; Visiting Surgeon, City Hospital, New York.

JAMES M. FRENCH, M.D.........Cincinnati, Ohio.
Lecturer on the Theory and Practice of Medicine, Medical College of Ohio; Attending Physician, St. Mary's Hospital; Consulting Physician, St. Francis Hospital for Incurables.

J. RIDDLE GOFFE, M.D.......... New York, N. Y.
Professor of Gynæcology at the New York Polyclinic; Visiting Gynæcologist to the City Hospital, New York; Assistant Visiting Gynæcologist to New York Skin and Cancer Hospital.

JUAN GUITERAS, M.D..............Havana, Cuba.
Professor of General Pathology and Tropical Medicine, University of Havana, Cuba; Director of Las Animas Hospital; Member of the Superior Board of Health; President of the Commission on Infectious Diseases.

NORMAN B. GWYN, M.D.......Philadelphia, Pa.
Instructor in Medicine, University of Pennsylvania.

WINFIELD SCOTT HALL, M.D.......Chicago, Ill.
Professor of Physiology, Northwestern University Medical School, Chicago.

WILLIAM FAWCETT HAMILTON, M.D.......Montreal, Canada.
Lecturer in Medicine, McGill University; Assistant Physician, Royal Victoria Hospital, Montreal.

T. STUART HART, M.D..........New York, N. Y.
Clinical Assistant, Department of General Medicine and Diseases of the Nervous System, Vanderbilt Clinic, College of Physicians and Surgeons, Columbia University, New York.

GEORGE HAVEN,* M.D..............Boston, Mass.
Junior Visiting Physician for Diseases of Women, Boston City Hospital; formerly Physician to Out-Patients, Boston Lying-in Hospital.

WILLIAM BARKER HILLS, M.D...Boston, Mass.
Associate Professor of Chemistry, Harvard University Medical School.

GEORGE WOODRUFF JOHNSTON,* M.D...Washington, D. C.
Professor of Gynæcology, National Medical College, Washington, D. C.; Gynæcologist to the Central Dispensary.

RUFUS A. KINGMAN, M.D...........Boston, Mass.
Gynæcologist to St. Elizabeth's Hospital, Boston, Mass.

DANIEL SMITH LAMB, M.D....Washington, D. C.
Pathologist, Army Medical Museum at Washington, D. C.; Professor of Anatomy, Medical Department, Howard University, Washington, D. C.

HENRY LEFFMANN, M.D.......Philadelphia, Pa.
Professor of Chemistry and Toxicology, Women's Medical College of Pennsylvania; Pathological Chemist to Jefferson Medical College Hospital; Honorary Professor of Chemistry, Wagner Free Institute of Science.

FREDERIC T. LEWIS, M.D...........Boston, Mass.
Instructor in Histology and Embryology, Harvard University Medical School.

WARREN H. LEWIS, M.D..........Baltimore, Md.
Instructor in Anatomy, Johns Hopkins University.

LEO LOEB, M.D.................Philadelphia, Pa.
Assistant Demonstrator of Pathology, University of Pennsylvania.

WILLIAM GEORGE MacCALLUM, M.D......Baltimore, Md.
Associate Professor of Pathology, Johns Hopkins University; Resident Pathologist, Johns Hopkins Hospital.

ERNEST LEWIS McEWEN, M.S., M.D....Chicago, Ill.
Associate Instructor in Dermatology, Rush Medical College, Chicago.

FRANKLIN P. MALL, M.D.........Baltimore, Md.
Professor of Anatomy, Johns Hopkins University.

MATTHEW D. MANN, M.D.........Buffalo, N. Y.
Professor of Obstetrics and Gynæcology, Medical Department, University of Buffalo; Attending Gynæcologist, Buffalo General Hospital.

WILLIAM PITT MASON, Ph.D.........Troy, N. Y.
Professor of Chemistry, Rensselaer Polytechnic Institute, Troy, N. Y.

CHARLES HENRY MAY, M.D...New York, N. Y.
Chief of Clinic and Instructor in Ophthalmology, College of Physicians and Surgeons, Columbia University (1890-1903); Adjunct Ophthalmic and Aural Surgeon, Mount Sinai Hospital, New York.

LAFAYETTE BENEDICT MENDEL, Ph.D....New Haven, Conn.
Professor of Physiological Chemistry, Yale University.

HENRY CHILDS MERWIN, Esq.....Boston, Mass.

CHARLES SEDGWICK MINOT, M.D., LL.D...Boston, Mass.
Professor of Histology and Human Embryology, Harvard University Medical School, Boston.

BENJAMIN MOORE, M.A....Liverpool, England.
Professor of Biochemistry, University College, Liverpool, England; Formerly Professor of Physiology, Yale University, New Haven, Conn.

GRACE PECKHAM MURRAY, M.D....New York, N. Y.
Adjunct Professor of Gynæcology, New York Post-Graduate Medical School.

ALBERT GEORGE NICHOLLS, M.D....Montreal, Canada.
Lecturer in Pathology, McGill University; Assistant Pathologist to the Royal Victoria Hospital, Montreal.

CHARLES P. NOBLE, M.D.......Philadelphia, Pa.
Surgeon-in-Chief, Kensington Hospital for Women; Clinical Professor of Gynæcology, Women's Medical College, Philadelphia.

FREDERICK G. NOVY, Sc.D., M.D....Ann Arbor, Mich.
Junior Professor of Hygiene and Physiological Chemistry, University of Michigan.

LIST OF CONTRIBUTORS TO VOLUME VIII.

OSCAR OLDBERG, Ph.D. ....Chicago, Ill.
Professor of Pharmacy, School of Pharmacy, Northwestern University, Chicago.

EDWARD OSGOOD OTIS, M.D. ......Boston, Mass.
Professor of Pulmonary Diseases and Climatology, Tufts College Medical School; Visiting Physician, Free Home for Consumptives, Boston; Physician to the Department of Pulmonary Tuberculosis, Boston Dispensary.

JAMES PEDERSEN, M.D. ....New York, N. Y.
Assistant Attending Surgeon, Department of Genito-Urinary Diseases, Bellevue Hospital; Adjunct Professor, Venereal and Genito-Urinary Diseases, New York Post-Graduate Medical School and Hospital; Chief of Clinic, University and Bellevue Hospital Medical College.

W. F. R. PHILLIPS, M.D. ....Washington, D. C.
United States Weather Bureau, Washington, D. C.

WILLIAM RICE PRYOR, M.D. ....New York, N. Y.
Professor of Gynæcology, New York Polyclinic; Consulting Gynæcologist, St. Elizabeth's and City Hospitals, New York.

WILLIAM ALLEN PUSEY, M.D. ..... Chicago, Ill.
Professor of Dermatology, Medical Department, University of Illinois.

HUNTINGTON RICHARDS, M.D. ...Concord, N. H.

HENRY H. RUSBY, M.D. ....Newark, N. J.
Professor of Botany, Physiology, and Materia Medica, New York College of Pharmacy; Professor of Materia Medica, University and Bellevue Hospital Medical College, New York.

DANIEL E. SALMON, D.V.M. ...Washington, D. C.
Chief, United States Bureau of Animal Industry, Washington, D. C.

R. J. E. SCOTT, M.D. ....New York, N. Y.
Attending Physician, Bellevue Hospital, Out-Patient Department; Gynæcologist, Demilt Dispensary, New York.

FRANCIS J. SHEPHERD, M.D. ..Montreal, Canada.
Professor of Anatomy and Lecturer on Operative Surgery, McGill University; Senior Surgeon to the Montreal General Hospital.

GEORGE ERETY SHOEMAKER, M.D. ...Philadelphia, Pa.
Gynæcologist to the Presbyterian Hospital and to the Pennsylvania Epileptic Hospital and Colony Farm.

BEAUMONT SMALL, M.D. ....Ottawa, Canada.
Attending Physician, St. Luke's General Hospital, Ottawa; Consulting Physician, the Children's Hospital, Ottawa; Late Examiner in Materia Medica, College of Physicians and Surgeons, Ontario.

BRIG.-GEN. GEORGE M. STERNBERG ..Washington, D. C.
Surgeon-General (Retired), United States Army.

EDMUND W. STEVENS, M.D. ....Denver, Col.
Formerly Instructor in Diseases of the Eye, Philadelphia Polyclinic.

WILLIAM H. THOMSON, M.D. ....New York, N. Y.
Visiting Physician, Roosevelt Hospital, New York.

CHARLES W. TOWNSEND, M.D. .....Boston, Mass.

HENRY BALDWIN WARD, Ph.D. .....Lincoln, Neb.
Dean of the College of Medicine and Professor of Zoology, the University of Nebraska.

ALDRED SCOTT WARTHIN, M.D. ....Ann Arbor, Mich.
Professsor of Pathology and Director of the Pathological Laboratory in the University of Michigan, Ann Arbor, Mich.

HARRY GIDEON WELLS, M.D. ....Chicago, Ill.
Associate in Pathology, University of Chicago.

ERNEST BOYEN YOUNG, M.D. .....Boston, Mass.
Assistant in Gynæcology, Harvard University Medical School; Assistant Physician for Diseases of Women at the Boston Dispensary; Third Assistant Visiting Physician for Diseases of Women at the Boston City Hospital.

PHILIP ZENNER, M.D. ....Cincinnati, Ohio.
Clinical Lecturer on Diseases of the Nervous System, Medical College of Ohio.

---

* Deceased since the issue of the first edition.

A REFERENCE HANDBOOK

OF

THE MEDICAL SCIENCES.

UMBELLIFERÆ.—(*The Parsley Family.*) This large family, of nearly two hundred and fifty genera and at least fifteen hundred species, is distinguished for its aromatic properties. Elsewhere in this work we have discussed the drugs ammoniac, angelica, anise, asafœtida, caraway, carrot, conium, coriander, fennel, sumbul, etc., besides certain poisonous species in a separate article on poisonous plants. These drugs have been selected for individual treatment, not because they are more efficacious than many others in the family, but because custom has given them a more permanent position in medicine and commerce. What has been written of the constituents and properties of those drugs agrees, in general, with the facts regarding all others in the family. The so-called constituents are volatile oils, oleoresins, and gum-resins, but the active portions are in almost every case the volatile oils, the resins, in a few cases only, possessing activity. Their properties incline more toward antispasmodic and carminative than toward antiseptic or expectorant effects, and they are specially valued for their pleasant aromas and flavors.

Of *Parsley* (*Apium Petroselinum* L.) both the root and the fruit are quite largely employed. The former, as it occurs dried, in commerce, closely resembles a carrot in form and size, except that it is usually split longitudinally into quarters. It is of a light orange-yellow color and somewhat annulate externally, and pale-yellow internally, with a dark zone of resin tissue near the centre. It is usually rather tough and elastic, but becomes brittle when very dry. It is fragrant and of a pungent and sweetish taste. Besides the uses named above, it has considerable repute, mostly unprofessional, as a genito-urinary stimulant. The oil of this fruit contains *apiol* ($C_{12}H_{14}C_4$) in larger quantity than does that from other parts. Pure apiol is a white crystalline body, but that usually sold is in the form of a yellowish-green thick liquid. Its special use is as a stimulating emmenagogue, in doses of 0.2–0.5 gm. (gr. iij –viij.). Parsley oil is given in doses about twice as large, and the root and fruit in doses of from 1 to 4 gm. (gr. xv.–lx.).

Celery fruit (*Apium graveolens* L.) is closely related to parsley, resembles the fruit of the latter, has similar properties, though less active, and is used in about the same doses. Probably its chief repute depends upon the very extensive advertising of proprietary preparations bearing its name, but not of its nature.

Thapsia, or *False Turpeth Root*, is the dried root of *Thapsia Garganica* L., a tall perennial of the Mediterranean region. Sometimes the entire root is used, sometimes only the very thick fleshy bark. It contains a highly irritant yellow oleoresin on which its properties depend. Its use has been revived from time to time for its counter-irritant effects, being either rubefacient or vesicant, according to the method of application. As an emetic poison it acts very much like mustard, though it is more active, and in large doses it is a violent irritant cathartic. As a rubefacient, a plaster is commonly employed containing five per cent. of its resin, combined with turpentine, Burgundy pitch, wax, etc.

We cannot do better than to conclude by reprinting the classification of the drugs of the family published in the preceding edition of this work.

First Group.—Yielding agreeable, or not offensive, oils from their fruits (which are mostly the parts used); stems and roots sometimes eaten, often fragrant and slightly resinous; generally, European species growing in open dry places, long cultivated, and not poisonous. The most typical examples are highest on the list.

Name.	*Constituents* (*oils and stearoptenes*).
Anise	Fluid and solid anethol.
Fennel	Hydrocarbon and anethol.
Caraway	Hydrocarbon (carvene) and carvol (liquid).
Ajowan	Hydrocarbon and thymol (cryst.).
Coriander	Two oils, probably hydrates of $C_{10}H_{16}$.
Cumin	Two oils, "cymol" and "cuminol."
Dill	Anethene and carvol.
Parsnip	Essential oil and miscellaneous substances.
Celery	Essential oil and apiin (an inert glucoside).
Parsley	Oil and cryst. stearoptene, apiin, and apiol.
Imperatoria	Oils—peucedanin.
Carrot	Oil, coloring matter (carotin).
Angelica	Oil, angelic acid, resin (has colored juice).
Lovage	Oil, resin (has colored juice).
	Etc., etc.

Various species of Eryngium and Sanicula have similar properties and uses.

Second Group.—Large Persian or African plants, with milky juice, yielding gum-resins from their stems and roots, usually offensive.

Name.	*Constituents.*
Asafœtida	Resin, gum, sulphureted oil.
Opoponax	Resin, gum, oil.
Sumbul	Resin, bluish oil.
Galbanum	Resin, gum, oil.
Ammoniac	Resin, gum, oil.
Thapsia (European)	Irritating resin and oil.
Etc. (See Asafœtida.)	

Third Group.—Plants containing poisonous, bitter, or nauseous principles, sometimes alkaloids of the coniïne type, not usually very fragrant, sometimes without *vittæ*.

Coniüm (hemlock)	Alkaloids, coniïne, conhydrine.
Cicuta	Cicutoxin, neutral (?) poisonous.
Hydrocotyle	"Vellarin," qualities indefinite.

Besides these, various species of *Œnanthe*, *Phellandrium*, *Sium*, and others have more or less deleterious qualities.

Henry H. Rusby.

UMBILICAL CORD.—A knowledge of the development of the cord is prerequisite for understanding its structure at birth. Consequently its embryology will be described first, then its general condition at term, and finally the finer structure of its component parts.

EMBRYOLOGY.—In young human embryos the layer of cells which later forms the skin does not encircle the body. After covering the dorsal and lateral body walls this layer turns upon itself, and over the back of the embryo it meets and joins the corresponding layer from the opposite side, thus forming a closed transparent sac, the

animals, a peculiarity correlated gratuitously with the great distention of the human amniotic cavity. Its diameter, also variable, averages 12 mm. The "twisting" of the cord, which begins in the second month, is generally due to the spirally arranged vessels within. They may be seen through the semitransparent substance which forms the bulk of the cord, and is called Wharton's jelly. Local thickenings in this tissue produce the so-called "false knots." Other irregularities, purplish in color, are due to intravascular blood clots. An actual twisting may occur, due to the activity of the fœtus. Thus the cord may be wound three times around the neck of the child with fatal results, or around the limbs resulting in intra-uterine amputations. Less serious entanglements are frequent. The cord may be tied in true knots, which rarely if ever interfere with circulation, since they are seldom drawn tight until birth.

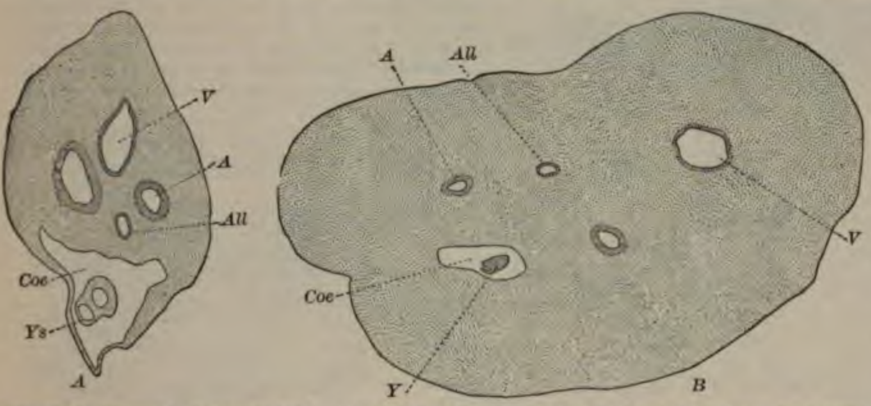

FIG. 4830.—Sections of Umbilical Cord. *A*, Embryo of 21 mm.; *B*, fœtus of sixty-four to sixty-nine days; *Y*, *Ys*, yolk stalk; *Coe*, cœlom. Otherwise the lettering is that of Fig. 4828. (Minot.)

Attachments of the Cord.—The navel, or umbilicus, is the scar which marks the place of separation between the persistent and caducous portions of the cord. The persistent part is lustreless and skin-covered, differing from the rest also in possessing capillaries. Its length in man is from 7 to 9 mm. (Kölliker). The shorter it is, the deeper will be the depression at the navel, which is produced by its contraction (Virchow). In cattle it measures 2 to 4 cm., and a protuberant navel persists for some time.

At the distal end of the cord the umbilical vessels branch and enter the chorionic mesoderm. The outer covering of the cord is continuous with the amnion, which spreads out over these vessels and is in contact with the chorion. Usually the cord meets the chorion at right angles, near the centre of its placental area. Sometimes it arrives by a more acute angle at the placental margin. Occasionally the vessels reach and branch in the non-placental chorion, through which they pass to the placenta. This is the velamentous insertion. Hyrtl found eleven velamentous, nineteen marginal, fifty-four excentric, and sixteen central insertions in one hundred placentas. The velamentous form is probably due to the ovum becoming implanted with its body-stalk turned away from the decidua serotina (Peters). A rare forking of the cord has been termed the insertio furcata. (For Schultze's fold, see *Yolk Sac*).

Covering of the Cord.—The epithelium of the cord has been best described by Minot and Bowen. At two months the ectoderm is a single layer of cells; at three months (Fig. 4832) it is two-layered, the outer being a continuation of the epitrichial layer of the skin; at five and six months the epitrichium is partly cast off, and the deeper layer has become several cells thick, with its outer part cornified. Thus it is intermediate between the many-layered skin and the single-layered amnion. There are, moreover, no lines of demarcation at either end of the cord. The similarity between amniotic and umbilical epithelia is shown by the "amniotic villi" which occur on both. The cord of the cow is beset with these elevations, which in flattened form are found on the amnion. They are merely epithelial proliferations (Fig. 4833) of unknown significance. The cords of domestic animals other than ruminants are smooth. Sometimes near the placental end of human cords, and especially on the adjacent amnion extending from Schultze's fold, pinhead elevations, or larger, flat, white areas may be found. Figs. 4834 and 4835, drawn from sections of the amnion from a normal afterbirth, indicate that these structures are quite like skin. They contain a dermis of dense connective tissue, and an epidermis of germinative, granular, cornified, and epitrichial layers. The covering of the cord, which is intermediate in its structure between skin and amnion, is called skin by Minot, Foulis, McMurrich, and others, and amnion by Kölliker, Hertwig, and Kollmann.

Wharton's Jelly.—The tissue of the cord, except near the blood-vessels, is of a unique sort, known as mucous connective tissue, or Wharton's jelly. Under the epithelium, with which it is inseparably connected, it may be slightly denser. Between the three blood-vessels (Fig. 4836), the tissue is loosest and forms three indistinct columns, the chordæ funiculi. Only in an injected alcoholic specimen have these structures, described more than one hundred and twenty years ago, appeared at all conspicuous. In the meshes of the tissue is a gelatinous substance containing mucin; the meshes themselves are of white fibrous elements, together with a small and

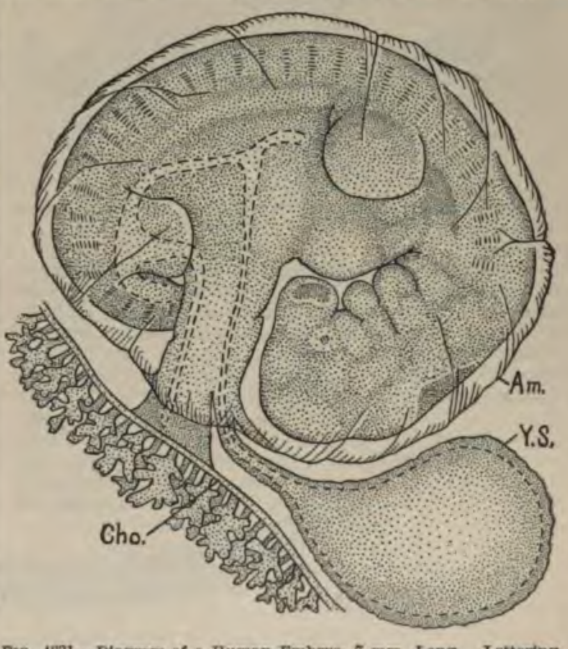

FIG. 4831.—Diagram of a Human Embryo, 7 mm. Long. Lettering as in Fig. 4829. (In part after W. His.)

PUBLISHERS' PRINTING COMPANY
32 AND 34 LAFAYETTE PLACE, NEW YORK

Henneberg's experiments eliminated other hypothetical factors, such as the clotting of the blood and the effect of the increased pulmonary circulation. Lochmann has recently produced general contraction of the vessels, especially of the arteries, by electric stimulation of the living cord. This is of special interest since the many attempts to demonstrate nerves in the cord have failed. Valentin is said to have traced nerve fibres from 8 to 11 cm. from the navel; other investigators have been less successful.

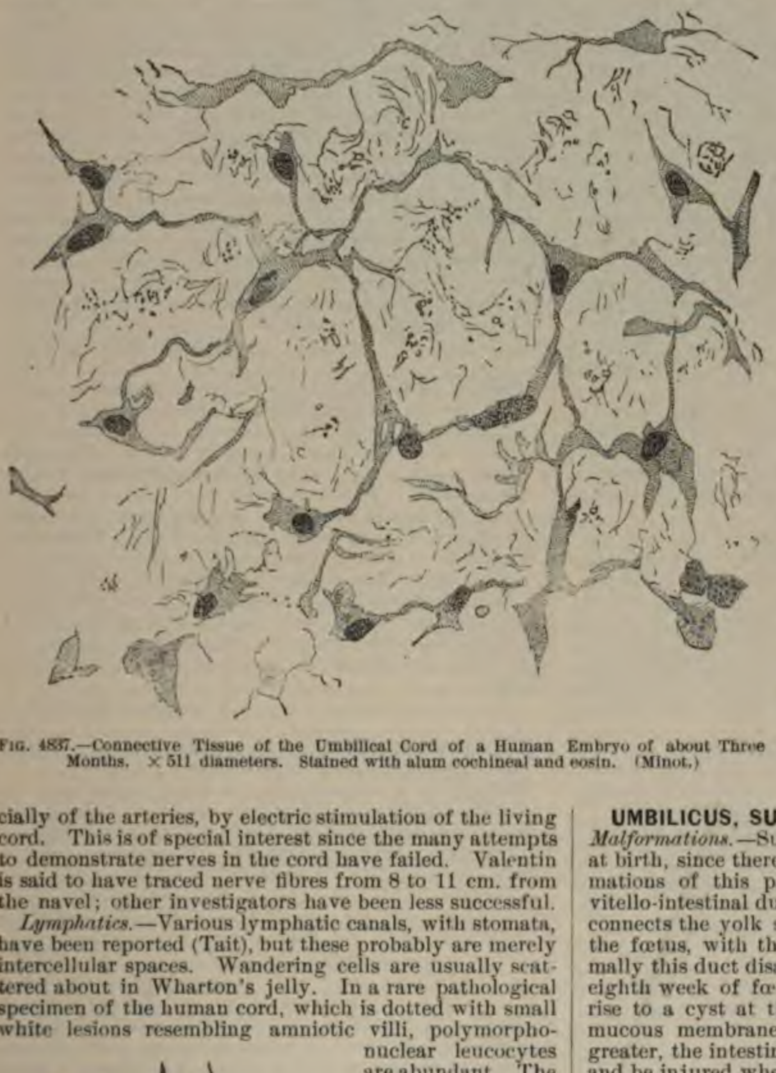

FIG. 4837.—Connective Tissue of the Umbilical Cord of a Human Embryo of about Three Months. × 511 diameters. Stained with alum cochineal and eosin. (Minot.)

Lymphatics.—Various lymphatic canals, with stomata, have been reported (Tait), but these probably are merely intercellular spaces. Wandering cells are usually scattered about in Wharton's jelly. In a rare pathological specimen of the human cord, which is dotted with small white lesions resembling amniotic villi, polymorphonuclear leucocytes are abundant. The acute inflammatory process has not made evident any lymphatic vessels.

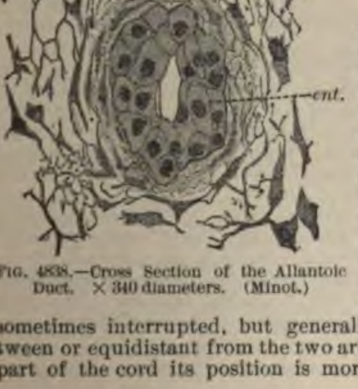

FIG. 4838.—Cross Section of the Allantoic Duct. × 340 diameters. (Minot.)

Allantois.—The allantois, as discovered by Sabine and confirmed by Ahlfeld, is generally to be found as an obliterated canal extending throughout the entire cord at birth. In earlier stages it has a lumen bounded by cuboidal cells (Fig. 4838, *ent.*). Later it is merely a strand of such cells, sometimes interrupted, but generally to be found between or equidistant from the two arteries. In the distal part of the cord its position is more variable (see Fig. 4836, *Y*). It may retain its lumen until birth, when if the intra-abdominal portion is also pervious, a urinary fistula at the umbilicus is produced. For intestinal umbilical fistula, see *Yolk Sac.*

UMBILICUS, SURGICAL AFFECTIONS OF THE.—

Malformations.—Surgical interest in the umbilicus begins at birth, since there may be important congenital malformations of this part of the body. In fœtal life the vitello-intestinal duct passes through the umbilicus and connects the yolk sac, which is outside the abdomen of the fœtus, with the intestine, which is within it. Normally this duct disappears with the yolk sac at about the eighth week of fœtal life, but it may persist and give rise to a cyst at the umbilicus or a fistula lined with mucous membrane; or, if the calibre of the duct is greater, the intestine itself may be prolapsed through it, and be injured when the umbilical cord is tied at birth. Such persistence of fœtal structures will be noticed as an umbilical hernia of the cord at birth; or, if the abnormal condition is less marked, a fistula will be seen when the cord drops off a few days later. Such a fistula may or may not communicate with the lumen of the intestine. If the discharge which comes from the fistula is purely mucous in character, attempts should be made to close the opening by caustics and strapping with adhesive plaster, in order to prevent further prolapse. This treatment may succeed in curing the patient even if the discharge contains a little fæcal matter. If the faulty closure at the umbilicus is more marked, an operation may be necessary to cure the patient, which operation in its essential details is the same as that performed for the purpose of closing an artificial anus—namely, opening of the peritoneal cavity, removal of the fistula, suture of the intestine, suture of the abdominal wall. This is, of course, a serious operation for a young infant.

The edges of the duct may be everted, in which case there will be presented a red, pedunculated tumor which tends to project more and more from the umbilicus. It is covered with mucous membrane which joins the sur-

the appearance of boiling. It deposits a brilliant red sediment, which covers the sides and bottom of its basin and imparts a reddish tinge to the water. The Black Spring also possesses this peculiar boiling characteristic. The Red Spring was analyzed by Messrs. J. M. Safford and J. C. Wharton in 1893, with the following results: One United States gallon contains (solids): Calcium sulphate, gr. 31.16; calcium carbonate, gr. 7.03; magnesium carbonate, gr. 5.75; sodium chloride, gr. 43.87; potassium chloride, gr. 0.44; aluminum sulphate, gr. 0.15; iron carbonate, gr. 0.10; silica, gr. 0.47; organic matter and loss, gr. 2.42. Total, 91.39 grains. Gases: Sulphureted hydrogen and carbonic acid, 9.95 cubic inches. The waters of the Red Spring are highly recommended in renal and bladder affections, especially those arising from the uric acid or lithæmic tendency. They are believed to possess a powerful solvent action on renal calculi and gravel. These waters are also said to be of great value in cases of chronic uterine inflammations, leucorrhœa, etc. The Black Spring water has an excellent reputation in the treatment of rheumatism. The waters of both springs possess tonic and appetizing qualities. A comfortable hotel, with modern conveniences and abundant bathing facilities, was built in 1890. There are also a number of private boarding-houses in the vicinity.

James K. Crook.

UPPER SODA SPRINGS.—Liskyon County, California. Hotel.

These excellent springs are situated on the line of the Shasta scenic route of the Southern Pacific Railroad, at an elevation of 2,363 feet above the sea-level. The location is in Sacramento Canyon, and is picturesquely surrounded by immense forests of pine, fir, spruce, cedar, etc. At the springs is a quiet, spacious, old-fashioned hotel with wide verandas and an air of solid, homelike comfort. The waters are of the alkaline-carbonated class and are very palatable and wholesome. They contain chlorides of sodium and potassium, carbonates and bicarbonates of sodium, magnesium, potassium, iron, calcium, sulphates of sodium and magnesium, and a large quantity of free carbonic-acid gas. The water is aperient, diuretic, tonic, and antacid. It is highly recommended in the treatment of the uric-acid diathesis, gravel, and calculi, and irritative states of bladder and kidneys. The water is also of value in acid dyspepsia and flatulence.

James K. Crook.

URÆMIA. See *Auto-Intoxications*, and *Kidneys, Diseases of.*

URÆMIA, TREATMENT OF.—Regarded from the standpoint of treatment, the term "uræmia" should cover all derangements due primarily to blood poisoning on account of deficient elimination by the kidneys. The term then would include a number of functional disorders causing more or less prolonged invalidism, as well as the more serious conditions to which it is commonly applied. To limit the term to a more definite series of changes or symptoms is not practicable, because of the great variety and diverse nature of the poisons operative in different cases. How entirely dissimilar such poisons may be is illustrated by the fact that the symptoms which follow upon acute obstructive suppression of the urine are very different from those which occur in ordinary uræmia. Death follows in such patients with scarcely one of the clinical features of the latter state. In a case of the kind which I saw in consultation, the patient had his left kidney destroyed by a calculus becoming impacted in its ureter thirteen years before. At the time of my visit he had not passed any urine whatever for eight days; a condition of affairs which warranted the belief that a calculus had become similarly impacted in his right ureter. I stated that if not relieved by operation he would die, as similar cases do, without any symptoms of ordinary uræmia; and so he did, as the operation was refused. He retained his consciousness up to the end, and did not experience convulsions, coma, dyspnœa, vomiting, or intestinal symptoms, and there were no evidences of pulmonary congestion or of œdema in any part of the body. His death was apparently due to asthenia pure and simple.

A careful study of the great variety of symptoms of uræmia itself in different patients suggests the inference that there must be a corresponding variety of distinct poisons present in them, some of which it may be possible to recognize by their own special properties, in the same manner as we would recognize any of our drug poisons by their special properties. We might expect this to be so *a priori*, because modern chemistry has demonstrated that different poisons may arise in the decomposition of even the same tissues; and that the poisons of uræmia originate in the disintegration of the tissues of the body, scarcely admits of a doubt. Thus, two distinct poisons have been isolated from nervous tissue, viz., cholin and neurin, and their presence has been detected in the cerebro-spinal fluid drawn off during life in patients with some form of disease of the nervous system of a degenerative nature. Of these two poisons, neurin is much the more virulent, and it presents properties quite different from those of cholin.

So in uræmia I believe that we have among others one special poison—viz., urea—which is commonly present and which has an important bearing upon the course of renal diseases. The presence of this poison can be distinguished by its own specific effects, and, what is more for our present purpose, it can be combated by appropriate treatment.

In all cases of acute nephritis, from the onset of the first symptoms, a remarkable change occurs in all the arteries of the body, for they shrink in size, and the pulse accordingly rises in tension. The most striking fact about this change is its subsequent persistence, for it continues as long as the nephritis continues, and should that become chronic the high tension becomes likewise established for months or years. This has led many erroneously to attribute the high-tension pulse of chronic renal disease to endarteritis, supposedly caused by the poisoned blood circulating in the vessels. But while it is true that changes in the coats of the blood-vessels, especially when they proceed to the extent of obliterating the lumen of the arterioles, will mechanically cause high-tension pulse, yet this latter symptom appears long before such changes occur, and, as we will show, it is the strain of high tension, rather than the toxic condition of the blood, which causes the endarteritis.

That the high tension is due, not to kidney disease as such, but to the presence in the blood of some special poison, is rendered probable by the opposite condition of low-tension pulse in some patients with marked accompaniments of renal derangement, such as albuminuria and œdema. In these, however, cardio-vascular changes are significantly absent, the arteries being everywhere soft and permeable and the heart unaffected.

In the other class, on the contrary, the pulse is hard and wiry and the artery, though smaller than natural, is yet easily palpable to the touch from being overfull, while in the early stages, before changes have taken place in its coats, it may feel (or be) quite smooth. Ere long the heart gives signs of overwork, from the ischæmia caused by the universal contraction of the arteries, and it becomes hypertrophied. Acute dilatation of the heart, however, may occur at this stage and be associated with very serious symptoms, although not a sign of thickening or of atheromatous change can be detected yet in the arteries accessible to examination.

We have at our command, it so happens, an agent which, when it is experimentally injected into the circulation, produces in the arteries exactly the same condition as that which we have just described. Suprarenal extract, or its active principle, adrenalin, acts as a very powerful and universal vaso-constrictor, and thus greatly raises the general arterial pressure, so that its effects are indistinguishable from those of the supposed blood poison which we find operative in nephritis. If this be a fact it is not necessary to postulate that the daily amount of poison generated must be great to account for the high-tension pulse that persists in kidney disease for months together, because Schaffer and Oliver have shown that nothing is so extraordinary about adrenalin as the minuteness of the dose which will act on the whole vascular system, gr. $\frac{1}{800}$ being sufficient to affect the pulse of a healthy man. If the supposed kidney poison possesses properties at all similar to those of suprarenal extract, its effect would be the same as a continued overdosing with this drug. Under its influence both arteries and arterioles throughout the body would so contract that the heart would labor against a universal obstruction, until, after first enlarging, it might suddenly dilate and fail.

Schaffer, moreover, reports, as one of the striking results of the intravenous injection of suprarenal extract, a most extraordinary shrinkage of the kidney itself, a condition which could not fail seriously to impair its excretion of urea.

It follows as a matter of course that the administration of vaso-dilators is indicated in all such conditions as we have just described, both to relieve the heart from its extra labor caused by arterial obstruction, and to restore the normal conditions in the circulation of the kidneys themselves. For this purpose the nitrites have long been employed, and with good results. The nitrites, however, in every form, even in that of the tetranitrate of erythrol, have the disadvantage of being very evanescent in their action, and the dose often requires to be much increased in order to keep up the effect. In my opinion the ideal vaso-dilator is aconite, and its administration in doses of five drops of the tincture, three or four times a day, is followed in time by the most unmistakable beneficial effect, not alone as regards the general systemic symptoms, but also in respect to the kidneys, which show a marked restoration of functional power. In this case the uncertainty which so commonly characterizes therapeutical inferences, cannot justly be imputed to the action of aconite, for under the steady administration of this remedy the daily excretion of urea increases to from twice to four times the average daily amount excreted before its administration.

I have now the records of observations made on ten patients, four in private and six in hospital practice, in whom the daily excretion of urea was first estimated for from three to six days previous to taking aconite, and then afterward for as long a time as the remedy was administered—*i.e.*, for periods varying from three weeks to nine months. In two of these patients the urea rose from 8 to 32 gm. daily; in one, from 10 to 40 gm. In one case, which I have published, the excretion rose from a daily average of 8 gm., noted for two months, to 32 gm. daily after five drops of the tincture had been given every three hours for one week. The aconite was continued for six months, and then twice diminished to half the dose. The output of urea soon fell to 14 gm., but returned to 30 on resuming the full dose. After six months the aconite was discontinued and the nitrites (tetranitrate of erythrol) were substituted. The urea again fell to 10 gm., when, the aconite being again resumed, the quantity rose to 32 gm.

The same results, so far as the excretion of urea is concerned, followed in the other nine cases. Three of those were hospital patients, and in two of them, after a month's use of aconite, the effect of omitting it altogether for three weeks was carefully noted. With each patient a week passed before the elimination of urea fell off, but then the diminution became decided. The third patient, who came into the hospital with anasarca and albuminuria, severe cerebral symptoms, and extensive cardio-vascular changes, improved so much that he refused to stay long enough for us to observe the effects of withdrawing the remedy.

Next to the improvement in the kidneys, including the disappearance of albumin and casts, the most marked effect of aconite is in relieving the cardiac oppression. In the case above alluded to, acute dilatation of the heart was the first condition which her physician found, and for two months she could not have her head raised, or even be turned in bed, without threatening symptoms of syncope. As soon as the aconite was given, it seemed to act on the heart as a restorative instead of a sedative, doubtless from the relief which the heart experienced from the removal of the general arterial obstruction.

On the other hand, I hold that the administration of such a vaso-dilator will be of the highest service in preventing the development of endarteritis, besides checking the progress of changes in the kidneys themselves; for it is well recognized that atheroma develops in the arteries at the seat of the most long-continued strain, and that is just what high tension is sure to induce.

We cannot expect much from aconite, nor from any functional vaso-dilators for that matter, in conditions in which widespread chronic endarteritis has already caused extensive obliteration of the smaller arteries. In such conditions the pulse tension, as already remarked, is due to permanent closure of a great number of peripheral vessels, and neither aconite nor any similar agent can dilate vessels which have practically ceased to exist. In cases of senile hearts, therefore, aconite should be given with discrimination. Even in them, however, should the pulse be not only of high tension, but also rapid, aconite may be advantageously given till the pulse falls to normal frequency, and then it should be intermitted; for I have seen it do much good in old people who, from their quickened pulse, appeared to have some acute exacerbation of chronic renal trouble.

In puerperal eclampsia we have a remarkable illustration of such a poison being rapidly formed and giving rise to extreme high tension. But, in addition to this high tension, we have the most dangerous addition of another element, viz., the rapid and powerful action of the heart itself. Schaffer's experiments with intravenous injection of suprarenal extract supply a striking parallelism to this condition, for he found that if, after the suprarenal extract had been injected, the vagi were paralyzed with atropine, the heart then acted very violently and forced such an increased amount of blood into the contracted arteries that an enormous rise in blood pressure followed. Under these circumstances the excessive intracranial vascular tension is likely to give rise to a fatal status epilepticus unless the pressure be promptly relieved. It would seem, therefore, that in puerperal eclampsia an analogous paralysis of the vagus occurs, either by overstimulation, by an excessive generation of the vaso-constrictor poison, or else by the conjoint action of this and some other poison resembling atropine. This surmise cannot be considered improbable, if the varied nature of the poisons of uræmia are considered.

Clinically, the best and speediest vaso-dilator which we can use to relieve such a condition is free venesection; but, if that be objected to, then veratrum viride should be given in very large doses, administered according to the effect which it produces on the tension of the pulse, but without reference to any other consideration. Aconite is much too slow for such an emergency, and, besides, aconite does not have the specific effect of veratrum on the great splanchnic blood-vessels. Our object is to quiet the heart and relax the arteries by bleeding the patient, as has been expressed, into her own abdominal veins, which when fully relaxed can hold all the blood of the body.

Precisely the same kind of convulsions as those which take place in puerperal eclampsia occur in acute alcoholism in men, and they have to be treated in the same way, either by full venesection or by doses of twenty drops of the tincture of veratrum viride administered every twenty minutes till the tension of the pulse is counteracted. I have given two drachms of this tincture in four hours and a half in a case of that kind, and as a result of these heroic doses the convulsions ceased and the patient recovered.

It is too commonly the case that practitioners are content in their examinations of the urine to search for only what ought not to be there, such as blood, albumin, casts, pus, sugar, etc. Their examinations, however, should extend also to determining whether the urine contains its normal ingredients in proper proportion and amount. Often the urine may not contain any foreign elements, and the kidneys be free from any organic disease, and yet the patient remain seriously out of health from deficient elimination of urea and other solids. Nothing could be more puzzling than the narration, which patients often make, of symptoms which, particularly as regards nervous manifestations, seem to be inconsistent with any known disease. This feature of itself should lead us to suspect a general toxæmia of some kind, and most likely either of renal or of intestinal origin. Headaches, mental depression, severe neuralgias constantly shifting from one part of the body to the other, all kinds of paræsthesiæ, somnolence alternating with insomnia, and a sense of general prostration, especially in the morning, and also in some instances morning polyuria, are among the many symptoms of which such patients are likely to complain. The diagnosis of the condition is at once made clear when a proper examination of a specimen of the collected urine for twenty-four hours is made, and the output of urea is found to be only one-fifth, one-third, or one-half of what it ought to be for persons of their age or weight. The elimination of urea ought to range, for a woman in good health, between 18 and 20 gm., but it is singular how long some women will live eliminating only 10 gm., or 5 gm., or even only 4 gm., daily for months together. Hysteria is the commonest verdict pronounced upon them, owing to their ever-changing nervous symptoms. But I have had, among men, a number of patients who manifested just such symptoms, both in kind and in number, and in them I have found the urea output to amount to from 11 to 15 gm., when it should range from 22 to 30 gm. Neurasthenia is the favorite term applied to cases of this nature.

In all such patients the pulse tension is low, and there can be little doubt that the underlying disorder, whatever it may be, differs materially, both etiologically and pathologically, from that which is present when the elimination of urea is low but the pulse tension high. In true hysteria I have not found the elimination of urea specially deficient. As to the other solids of the urine the records vary remarkably. Some urines with a low percentage of urea have a great excess of other solids, while in the case of others the total solids may be diminished. The chief factor, therefore, is deficiency of urea. My own view of the etiology of these disorders is that they are of gastro-intestinal origin. In health there is a significant association between the intake of food and the elimination of urea by the kidneys. Within the first hour after a full meal the elimination of urea is from twice to three times what it will be in the fourth hour after the meal. That fact seems to explain why attacks of apoplexy so commonly follow Christmas or Thanksgiving dinners in those who have already damaged kidneys. The serious effects, in kidney diseases, of errors of diet are a further evidence of the close relation of the gastro-intestinal tract to the renal functions. It seems to me, therefore, quite conceivable that certain disordered states in the alimentary canal may exert an inhibitory effect, so to speak, upon the elimination of an adequate amount of urea by the kidneys. At any rate, instead of aconite or vasodilators being of any service, I have found the restoration of the normal output of urea best secured by a persevering and systematic use of intestinal antiseptics. A weekly, or bi-weekly, dose of blue pill is very efficacious. On rising in the morning the patient should take a drachm and a half of sodium sulphate, or of sodium phosphate with ten grains of sodium salicylate, dissolved in a tumbler of water as hot as he can sip. The benzoates are also of much service. Ten grains of either the sodium or the ammonium benzoate may be mentioned as the proper dose. Three such doses, either with or without an equal amount of sodium salicylate, are commonly taken (the benzoate and the salicylate in two separate capsules) in the course of the day—one about an hour after each of the first two meals, and the third just before retiring for the night. Some physicians prescribe, in preference to the above, a mixture of castor oil (♏ xv.) and salol (gr. v.), to be taken half an hour after each meal and again at bedtime. Each dose is enclosed in one of Starr's shellac-covered capsules. Red meats should be avoided, especially at night, and among vegetables asparagus and beets.

The treatment of uræmia occurring in organic derangements of the kidneys is treated fully elsewhere (Vol. V., p. 343), and, therefore, I will only allude to some particular conditions. In acute scarlatinal nephritis, the first danger signal from the kidneys is not the appearance of albumin or of blood corpuscles under the microscope, but a diminution in the quantity of urine excreted and a fall in the specific gravity. When a discovery of this kind is made, treatment should be begun at once. One of the most effective measures that can be employed under these circumstances is the rectal douche, with normal saline solution at 115°-120° F.

Action of the bowels always causes a flow of urine in health, owing to the nervous association between these two adjacent viscera; and this association stands us in excellent stead whenever the kidneys are, from any cause, failing to secrete. I would place more reliance upon this one than upon any other single measure in scarlatinal suppression of urine. At least two gallons of the hot saline solution should be allowed to run in and out at a time, the best instrument for which purpose that I know of being Kemp's rectal irrigator. (See article on *Enteroclysis* in Vol. III.) I have seen also most excellent results from hypodermoclysis in these cases and in the hemorrhagic nephritis of diphtheria. In such cases it is well to inject, beneath the skin of the flank, from two to four ounces of normal saline solution. (See article on *Hypodermoclysis* in Vol. IV.) We need hardly despair of even the most seemingly desperate case of scarlatinal suppression; and if deep coma supervenes, I have found effectual a procedure recommended by Brown-Séquard; it consists in dipping a tablespoon in hot water and holding it in contact with the skin over the kidneys until the surface shows signs of being scalded.

With reference to some points connected with the treatment of chronic interstitial nephritis, I may state that it is not uncommon for a person to be suddenly taken with uræmic convulsions as the first announcement to anybody that he has Bright's disease. Post mortem we find that such persons have long been carrying diseased kidneys with them, with only moderate accompanying symptoms, which they had accredited to biliousness, etc. Others, on the contrary, have long been known to have kidney disease, but they have got along fairly well for many months, or they have even attended to business, and then suddenly serious symptoms have developed and the disease has soon carried them off.

I believe that in the great majority of such patients there has entered into the case a new element, the recognition of which we owe to recent advances in pathology; I refer to a septic invasion of the kidneys by bacteria, of which the commonest form is the colon bacillus. Dr. Flexner has been one of the foremost investigators who have demonstrated the rôle which terminal infections play in the final issue by death of many chronic diseases, particularly diseases of the heart and of the kidneys.

In chronic interstitial nephritis the process seems to be this: A patient with cirrhosed kidneys, who has had polyuria for months, begins to pass much less urine, or perhaps very little. He is then beginning with virtually the same conditions as those which are present in a case of commencing scarlatinal nephritis. Soon afterward he has a convulsion, and becomes comatose, or he has, during the night, an attack of uræmic asthma with œdema of the lungs and pleural effusion, or an attack of vomiting and diarrhœa. Often thereafter the kidneys stop secreting altogether and death follows. At the autopsy the kidneys are found to be acutely inflamed, stuffed with micro-organisms of various kinds, but most frequently with the colon bacillus.

There is nothing so much to be dreaded as an attack of so-called cholera morbus in an elderly person. In such a case we should at once turn our attention to the kidneys, to find out what their condition is. Something also of this kind undoubtedly occurs in those cases which heretofore have been regarded as simply an acute exacerbation of the original chronic malady. I think that I have repeatedly, in patients whose kidneys were in a cirrhosed condition, warded off the worst results after threatening symptoms, such as fever, mental clouding, Cheyne-Stokes breathing, vomiting, and the like, had manifested themselves, by the prompt administration of mercurial cathartics, followed every two or three hours by ten grains of urotropin combined with ten grains of sodium benzoate. In my experience urotropin does not cause untoward symptoms if sodium benzoate is given along with it. Of course, hot saline rectal irrigation also should be used, as in a case of scarlatinal suppression. Against the presence of the colon bacillus in the kidneys urotropin is at least as much of a specific as it is against the bacillus typhosus.

In all cases of chronic interstitial nephritis our prognosis must always be uncertain, because we can never be sure how much working kidney substance these patients may still have. Not uncommonly the most unlooked-for improvement in the action of the kidneys will occur, and then continue until it is suddenly cut short by some error of diet, such as a too hearty meal of meat, particularly if taken at night. With reference to this point we may remark that there is an apparent difference in the activity of proteid metabolism between the day and the night hours. We have a whole series of affections, marked chiefly by nervous disturbances, which are evidently due to various toxæmias, and which are all characterized by being worse in the early morning hours. Many cases of melancholia and of migraine, and all cases of Graves' disease show this peculiarity. In Graves' disease the twenty-eight symptoms, aside from the goitre and exophthalmos, which I have found to be characteristic of this singular malady, are, without exception, worse in the morning. In my notes I have records of no less than eight who could not write or sew in the morning, but could do so in the evening. In all such cases of melancholia, migraine, or Graves' disease, I enjoin entire absence from red meats, especially beef, and most of all at night. Then again the first attacks of gout and of peptic asthma always occur after midnight. I have repeatedly noticed that many patients can take beef at breakfast or at lunch, but if they take it at evening dinner it is sure to cause a very troubled sleep. All these particulars should be borne in mind when we aim to regulate the life of a man who comes to us with a high-tension pulse and rigid arteries.

The chemistry of these night-generated poisons is yet to be worked out, but there can be no doubt that they have much to do with changes which take place in the alimentary canal, changes connected with the nitrogenous elements of food, particularly the red meats; and every person with cirrhosed kidneys should be enjoined, like an asthmatic, not to eat heartily after midday.

For the rest, I may say that the greatest remedy for auto-infection and the best prophylactic against the manifold dangers of chronic interstitial nephritis is life in the open air. Such a case needs a milder climate in winter, just as much as any bronchitic or phthisical patient does. Intestinal antiseptics are of the greatest value; and, as to special medicinal remedies, I have great faith in the employment of gr. $\frac{1}{24}$ of bichloride of mercury, t.i.d. for one week out of three weeks, and of small doses (not more than five grains) of sodium iodide t.i.d., to be taken for prolonged periods.

There can scarcely be a stronger contrast than that which exists between the clinical features of a typical case of chronic interstitial nephritis and those of an equally typical case of chronic parenchymatous nephritis. The first is most commonly a disease of middle or of past middle life, and is associated with the changes of advancing years. Parenchymatous nephritis, on the other hand, attacks the young oftener than the aged, and is not infrequent among children. In kidney cirrhosis albuminuria is usually insignificant in amount, repeatedly is absent, and at no time is of much import as such. In parenchymatous nephritis albuminuria is steadily present and abundant. But, above all, in interstitial nephritis the patient is never waterlogged, unless from consecutive heart disease. In parenchymatous nephritis there is from the beginning a tendency to a general leakage of water into the tissues, so that it often appears first in the face instead of the feet, and the mechanism of this dropsy remains, up to the present time, wholly unexplained. Along with these conditions, anæmia occurs early and is persistent, so that in view of all these differences there can be little doubt that the systemic poisoning in the one disease is quite different in kind from that in the other.

The anatomical changes in the kidneys in these two forms of nephritis are equally contrasting. The capsule of the tough cirrhosed kidney is found to have become almost an integral part of the shrunken organ. It so dips into and adheres to the kidney substance that we have to tear away bits of this if we wish to strip off the membrane. The capsule of the large white kidney is stripped off the soft organ as readily as the rind is from an orange. It is true that these changes are not uniformly restricted to diseased kidneys of either kind, and interstitial changes may be found in parenchymatous nephritis; furthermore, kidneys which are white but not large are not uncommon. But the clinical differences still remain as marked as ever; and, moreover, in the white kidney we find conditions which readily explain why those patients are so difficult to relieve or cure. The glomeruli are pressed upon by masses of the round cells, which fairly stuff Bowman's capsules, and the tubules are choked with every kind of débris.

Now it would seem that if we only had in the kidney the double circulation of the lung, all this ruinous accumulation might be got rid of. We have interstitial pneumonia, if the lung exudates are not removed, just as we have interstitial nephritis also in the kidney if it remains clogged with inflammatory exudates; but interstitial pneumonia is rare, because in the lungs we have the double currents of the pulmonary artery and of the bronchial arteries, and between them the immense exudates of a croupous pneumonia are got rid of, usually before the stuffed air cells are damaged. In the kidneys, on the other hand, we have the one renal artery, which answers to the pulmonary artery in the lungs, and nothing more. To expect that the kidney capsule will allow enough blood-vessels to enter through it to help absorption would be even less warranted than to expect help from the blood-vessels of the pleura to assist in the removal of the inflammatory exudates in the air cells.

We seem, in this condition, to have an obstacle which wears the aspect of a mechanical obstruction quite insuperable to our ordinary medical remedial measures. The attempt to increase the outflow of watery urine by prescribing diuretics for the relief of the dropsy oftener fails than succeeds. We may temporarily succeed by trying one diuretic after another, but the cause of the dropsy remains and the œdema returns just the same as ever. All we can do, then, is to throw upon the skin and bowels the task of working vicariously for the kidneys; but in the majority of instances we make no real headway. Some patients with chronic kidney disease, with dropsy and persistent albuminuria, recover; but whether they do so on account of our therapeutics, or whether they recover spontaneously, we cannot tell.

Such conditions would suggest the advisability of having recourse to surgical measures of relief for the embarrassed renal circulation, and this subject has of late been prominently brought to the attention of the profession by Dr. George M. Edebohls, of New York. In a communication published by him in the New York *Medical Record*, March 28th, 1903, he gives reports of 51 patients, 29 females and 22 males, in whom he had performed decapsulation of the kidneys for chronic nephritis of the interstitial, diffuse, and parenchymatous forms. Of these, 39 cases were more or less benefited, including 19 completely cured, none being considered cured unless they had been for six months free from any signs in the urine of diseased kidneys. For further particulars the reader should consult his paper; but there can be no doubt that this procedure was successful in a sufficient number of patients with serious renal changes to merit its extended trial by other operators.

That the beneficial result followed upon a freer circulation within the kidneys, upon the removal of the constricting capsule, there can be no doubt; but whether an additional factor exists in the development of a new supply of blood-vessels formed in the perirenal tissue after the capsule has been removed, is doubted by Dr. Harold A. Johnson, of San Francisco,[1] who decapsulated the kidneys of ten dogs and examined the kidneys at various dates after the operation. He states that a new capsule is formed about the kidneys without the development of any considerable anastomosis between the renal and the perirenal vessels. The objection to this observation is that the results of such an operation upon healthy kidneys in dogs scarcely prove that a new capsule will be formed in human subjects with kidneys so embarrassed in their circulation that new channels can be taken advantage of whenever possible, as commonly happens in hepatic cirrhosis.

In the management of a case of general renal dropsy, with abundant albuminuria, I may add that I have repeatedly observed that the kidneys start up, as it were, and carry off the water when milk and a fluid diet are given up, and solid food, including meat, given instead, with a restriction of liquids. The effects of such a change in regimen, however, should be watched carefully.

As to diaphoresis, the subcutaneous infiltration makes the skin tense and glossy, and thus closes the sweat ducts whose opening on the surface is at an angle. A thorough oiling of the skin, therefore, before using our diaphoretic measures, makes the action of the sweat glands much more effective. *William H. Thomson.*

URAL; URALIUM.—This drug is also known as *chloral-urethane*, and, as its name implies, it is a compound of urethane and chloral. It occurs as a white crystalline body, readily soluble in alcohol, but almost insoluble in water. It is decomposed by hot water.

Ural was introduced by Dr. Poppi, of Bologna, in 1889, as a better hypnotic for neurotic patients and the insane than are most of the drugs employed for this purpose. He considered it to be more active than urethane and more safe than chloral, and better borne by the stomach. In the hands of others it has not furnished such favorable results, and has not secured any position as an hypnotic remedy. *Beaumont Small.*

URANIUM ACETATE AND NITRATE, $UO_2C_2H_3O_2$-$2H_2O$ and $UO_2(HNO_3)_2.6H_2O$, are yellow crystalline salts which are soluble in water, and háve been employed to some extent in diabetes in dose of 0.01–0.02 gm. (gr. $\frac{1}{6}$–$\frac{1}{3}$). It is claimed that they stimulate the sugar-consuming cells of the body. The acetate has also been used as a catarrh snuff or in solution as a nasal douche. They are powerful drugs, and there is very little clinical evidence in favor of their employment at all.

W. A. Bastedo.

URESIN is a double citrate of lithium and urotropine, which, according to Kudintscheff and Soanki, has the power of diminishing the excretion of uric acid and of dissolving gravel. The dose is 1 gm. (gr. xv.).

W. A. Bastedo.

URETERS, PATHOLOGY OF.—MALFORMATIONS OF THE URETERS.—The ureters take their embryonic origin from the lower part of the Wolffian duct. Malformations of the ureters are, on the whole, not very rare. If the kidney of one side is absent the ureter of the same side is generally absent also. Sometimes, however, in this case the ureter may exist, and then usually as a small duct. Absence of one kidney and ureter has been observed without any other malformation of the urogenital tract but kryptorchismus. Usually, however, in such cases other malformations are present, and uterus unicornis, absence of the vas deferens and a seminal vesicle, or a malformation of one side of the prostate, have been found.

Both kidneys and both ureters may be missing; in one case of this kind the fœtus lived ten minutes after birth. In cases in which the kidney was but incompletely developed, the ureter also showed incomplete development. In one such case the ureter did not reach the bladder; in another it had an abnormally small lumen.

A partial duplication of the ureter is not rare, especially in its upper part. Double ureters usually unite before they enter the bladder. A perfect duplication of the ureters is rare; in such cases the points of entrance into the bladder are generally near each other. They may, however, end as much as 1.5 cm. removed from each other. Double ureter is sometimes combined with a horseshoe kidney; in such a case three or even four ureters may apparently originate from one kidney. Sometimes two ureters end in two separate parts of one kidney on the same side. In this case the ventral ureter connects with the lower and ventral kidney, the dorsal ureter with the dorsal kidney, situated nearer the diaphragm. The first ureter enters the bladder at a higher level than the second ureter. This arrangement is similar to the one found in a doubling of the Wolffian duct. In the case of doubling of the ureter the pelvis of the kidney may also be double, or may be single; the latter occurrence is, however, much less frequent. Double ureters may be found on both sides or on one side only.

Of clinical importance are congenital valvular projections of the mucous membrane of the ureter, which are sometimes met with. These may be found in all parts of its course, especially, however, at the place of its entrance into the bladder and pelvis. If the concavity of such projections is directed toward the kidney they may obstruct the flow of urine and cause hydronephrosis. Such valves may become fixed by external adhesions. Congenital torsion of the ureter may have a similar significance.

Besides a valvular obstruction a congenital stenosis or atresia has been found, especially in the lower part of the ureter. It may be followed by a great dilatation of the upper part of the ureter and by a forward bulging of its lower part either outside or inside the bladder. In the latter case such a diverticulum may cover the internal meatus of the urethra. Such diverticula of the ureter have, however, also been found in cases in which the ureter was patent.

The ureters may enter the pelvis of the kidney in its centre instead of at its lowest point. Under these conditions the collection of urine in the lower part of the pelvis may entirely occlude the opening of the ureter. A similar result may be produced if the insertion of the ureter into the pelvis is an oblique one. A projecting part of the ureter may become pressed against the opposite side of the wall of the ureter by the collection of urine. Instead of running straight down to the bladder the ureter may be bent in its further course so that it forms an angle.

The ureter may enter the bladder higher up than is normal, or it may end in the urethra (colliculus seminalis), in the vesiculæ seminales (in the male), or below the external meatus of the urethra and in the uterus or vagina (female). A double ureter may have one normal and one abnormal ending.

INFLAMMATION OF THE URETERS.—Inflammation of the ureters rarely starts in the ureters themselves. This may, however, be the case if a calculus becomes impacted in a ureter, or if during labor the ureters become compressed and injured. The mechanical lesion may be followed by a secondary infection with micro-organisms. Usually inflammation of the ureters is secondary to inflammatory changes in the kidney and pelvis of the kidney to cystitis, or to inflammation of the ovaries or Fallopian tubes, or of the connective tissue included in the fold of the ligamentum latum. In the latter case the infection is carried to the ureters through the lymphatics; in the two former cases the propagation of the infection may take place either through the urine or through a continuous growth of the micro-organisms along the mucous membrane. On the whole, the ureters are not very favorable to inflammatory changes. Cystitis may exist for many years without the affection extending to the mucous membrane of the ureters. Inflammation may be found after a primary cystitis only in the pelvis of the kidney, the ureters remaining unaffected. These facts seem to indicate that the propagation of the infection from the bladder upward takes place principally through urine carrying micro-organisms and regurgitating into the ureters. Such a regurgitation can easily take place if, through an obstacle to the outflow of urine in the urethra for instance, first a dilatation of the ureters takes place. In this case the openings of the ureters into the bladder soon become enlarged as well. Experiments have shown, however, that even without a previous dilatation of the ureters, if the bladder is slowly distended through injection of a solution of methylene blue, the injected fluid in a certain number of cases may pass upward into the ureters.

---

[1] Annals of Surgery, April, 1903.

Propagation of the inflammation of the kidney to the ureters may take place in cases in which the pelvis of the kidney is infected, as, for instance, in cases of stones in the pelvis or of pyelonephritis following abscesses in the kidney.

Anatomically, the mucous membrane is red (hyperæmia), œdematous, infiltrated by leucocytes, while its epithelial cells are thrown off in increased numbers. The infiltration with leucocytes may go so far that a purulent inflammation is produced. In severe cases in which decomposition of the stagnating urine takes place, we may find a diphtheritic inflammation of the mucosa. [illegible] membranes are formed, consisting of a fibrinous ex[illegible] and the necrotic superficial parts of the mucous membrane.

In severe chronic inflammations the mucous [illegible] may hypertrophy and form villous projections; [illegible] cases a simple thickening takes place through [illegible] tion of the connective tissue. The inflamma[illegible] times proceeds from the ureter to the connective [illegible] surrounding it, the latter becoming greatly th[illegible] consequence.

In certain cases of chronic inflammation [illegible] *granulosa, nodularis, polyposa*) we find small [illegible] lary nodules in variable number disseminated [illegible] cous membrane of the ureters. They consist [illegible] tion of small round cells similar to or identi[illegible] lymphocytes. It has been maintained that [illegible] them is normally present in the ureter and [illegible] membrane. This is, however, not the case [illegible] both children and also in healthy adults [illegible] tirely absent, although it may be found in [illegible] in other general and local inflammation [illegible] If these nodules, however, are present in [illegible] they probably point to a chronic inflam[illegible] mucous membrane around the [illegible] ally red and œdematous. The nodules [illegible] observed in typhoid fever and in diseases [illegible] and of the heart. A similar anatomical [illegible] mation has been described in the compres[illegible]

Ureteritis [illegible] An inflamm[illegible] [illegible]

A condition without much clinical significance [illegible] pathological interest is the *ureteritis cystica*. [illegible] dition the ureter is covered with superficial cysts [illegible] are especially frequent in the upper half of the ureter, near the pelvis of the kidney; they are usually of the size of a pinhead and sometimes they are twice as large; they contain a material like mucus. Not rarely they are distributed in small groups in the mucous membrane, which may occasionally form polypoid processes containing these cysts. They are often found combined with inflammatory conditions of the ureters. They take their origin from the "Brunnschen Epithelnester," formed by an ingrowth of the ureteral epithelium into the connective tissue. These epithelial nests may branch and form secondary processes; at the surface they may become occluded by connective tissue, and the cells in their centre may become dissolved. In this way cysts are formed. The degenerating epithelial cells, together with certain products of the blood, may give rise to structures which probably incorrectly have been believed to be micro-organisms and the cause of the cyst formation. The structures, described by different authors as micro-organisms, are not identical, and they have also been interpreted in a different way by different investigators [illegible] sporidia, coccidia). Similar structures seem to be present in the colloid cysts of the thyroid.

Tuberculosis of the Ureters.—A primary tuberculosis of the ureters is not known. Tuberculosis of the [illegible] ity, or into the intestines; or if the retention of the stone occurs at the lower end of the ureter, the stone may produce an artificial passage into the bladder.

The injury caused by a stone may be complicated by the settling of micro-organisms at such places; then pyelonephritis and pyonephrosis may follow, or near its wall at the place of injury an abscess, lodging the stone, may arise at the side of the ureter. If the ureter is entirely occluded by a stone, its lumen below the obstruction may become considerably shrunken.

In tropical and subtropical countries distomum hæmatobium and its eggs may live in the wall of the ureters, and may cause papillary outgrowths of the mucous membrane. Another parasite to be found, though rarely, in the ureters, is eustrongylus gigas. In cases of hemorrhages from the ureter or kidney, or of chyluria, coagula of blood or lymph may fill its lumen.

OBSTRUCTION OF THE URETERS.—The causes of obstruction to the flow of urine in the ureters may be the following: Calculus in the ureter, stricture in the ureter through inflammation of its mucous membrane, or through inflammation of the surrounding connective tissues. Compression of the ureter through exudates in the para- or perimetrium, or through enlarged lymph glands or a tumor. Obstruction caused by a projecting tumor, by tuberculous products, or by a coagulum of blood or lymph, by parasites, or by compression of the ureter through an abnormally situated branch of the renal artery. The formation of abnormal folds, or of a valve caused by the obliquity of the ureter's insertion into the renal pelvis, or a twist of the ureter on its long axis, may also obstruct the flow.

Inflammatory changes in the mucous membrane leading to a stricture may be caused by the injury of a calculus, or by an inflammation with formation of diphtheritic membranes. Stricture may follow an ascending inflammation, originally caused by the gonococcus; whether, however, the changes in the ureters are also caused by the gonococcus or are produced by a secondary infection with other organisms, is not certain.

Obstruction to the flow of the urine in the ureters may be caused by changes in the bladder or in the urethra. If the bladder cannot contract sufficiently, obstruction in the ureters may follow. The urine collecting behind the obstacle causes a dilatation of the ureters. The ureter may not only become dilated, but also tortuous. If the condition is a chronic one, the wall of the ureters becomes thickened; this thickening is produced by hypertrophy of the muscular coat. Inflammatory changes also are frequently present in the ureteral wall, contributing to the thickening. The result of a chronic obstruction is hydronephrosis and destruction of the kidney. If, as is often the case, micro-organisms are present at the point of lesion, or are added secondarily, a pyonephrosis follows. If an artificial stenosis of the ureter is produced in animals, hydronephrosis does not necessarily follow. Atrophy of the kidney may be the only result, and if a hydronephrosis does follow, the fluid may contain urine (uronephrosis).

In the case of a congenital obstruction to the flow of urine, hydronephrosis does not necessarily follow; simple atrophy of the kidney of the affected side may be the only result.

TUMORS OF THE URETERS.—Primary tumors of the uterus, rectum, bladder, and kidney may secondarily affect the ureters. Carcinoma of the uterus frequently penetrates the wall of the ureters, causing hydronephrosis. In several cases one ureter was in its whole circumference included in a fibroma of the uterus, probably to be explained by secondary concrescence of originally separated fibromatous nodules.

Primary tumors of the ureters and the pelvis of the kidney are rare. Benign papillary tumors and carcinoma have been found most frequently; myoma striocellulare, sarcoma, and endothelioma are very rare. The ordinary papillomata consist of a fibrous centre covered by one or two rows of epithelial cells. Tumors showing a transition from typical benign papillomata to carcinomata of a papillomatous structure have been found. Typical papillomatous carcinomata also have been described; these are rarer than the benign papillomata.

The fact is of importance that in several well-authenticated cases the epithelium of a papilloma which had existed for some time as a benign tumor, later on began to infiltrate the deeper tissues, thus becoming a carcinoma. Besides the papillomatous variety of carcinoma, the ordinary non-papillomatous carcinoma has been found in the ureters and in the pelvis of the kidney. It may have the character of an alveolar carcinoma with cuboidal cells, or it may be of the cylindrical-celled or of the squamous-celled variety. Transformations of the epithelium of the ureter into the stratified squamous type have also been observed without the presence of a tumor (leucoplasia).

It is of interest to note that quite a number of benign papillomata, or indeed of carcinomata, may be present at the same time, and that tumor nodules may even extend the entire length of the ureter, reaching the bladder. The favorite sites for the isolated as well as for the multiple tumors are the pelvis of the kidney and the vesicular end of the ureters. This suggests a certain analogy to the favorite seat of œsophageal neoplasms.

The multiplicity of malignant tumors may be caused by implantation of cells carried away by the urine and kept back at places where a greater resistance to their passage is offered, or to metastatic growth along the lymph channels. Whether the multiple occurrence of the benign papillomata is to be explained in a similar way, is still doubtful. In several instances the origin of the neoplasms has been connected with the presence of a stone in the ureter. No convincing case, however, has been reported so far. A problem is thus presented similar to that in connection with the gall bladder.

The tumors of the ureters may cause hydro-, hæmato-, and pyonephrosis. Carcinoma of the ureters may spread to the kidney, bladder, seminal vesicles, lymph glands, and peritoneum, and may cause metastases in the liver pleural cavity, and lung. *Leo Loeb.*

URETERS, SURGERY OF THE.—The ureter is a flattened, whitish tube which connects the pelvis of the kidney with the bladder. It begins at the level of the twelfth rib, about 4 cm. (1.6 in.) from the median line. It crosses the pelvic brim one-third of the distance, that is, about 3 cm. (1.2 in.) from the median line, to the anterior superior iliac spine. It can be palpated just above the brim of the pelvis. In the pelvis it lies just in front of the common iliac artery and then curves sharply forward to pierce the base of the bladder (Fig. 4839). In the abdomen it lies upon the psoas magnus muscle. Either the right or the left ureter can be exposed without opening the peritoneum, through an oblique incision parallel with and a little above Poupart's ligament. The ascending or descending colon is freed and pushed toward the median line, exposing the ureter.

The length of the ureter is from 25 to 30 cm. (10 to 12 in.). The function of the ureter is simply to transmit urine which collects in the pelvis of the kidney. This is done by a slow peristaltic action. The portion of the ureter close to the bladder can be palpated in man through the rectum, while in woman the lower end of the ureter can be palpated to a distance of 5–8 cm. (2–3 in.) through the vagina. If there is a stone in any portion of the ureter the lower end is said to be extremely sensitive.

Traumatisms.—Injury to the ureter is not common. It may be opened by stab or gunshot wounds, or torn by the passage of a wheel across the abdomen. If it is torn clear across, little or no blood will enter the bladder, so that the urine passed from the bladder may be entirely clear. If it is partially torn, some urine from the injured side may reach the bladder. In either case there will be a retroperitoneal extravasation of urine, with more or less obstruction in the corresponding kidney. Such a condition was formerly treated by repeated aspirations. At the present time the proper procedure is to expose the ureter, to suture or tampon the wound, or to resect and suture the ureter if the injury is more severe. In any case drainage should be employed. If the ureter is injured beyond hope of repair, or if there is reflex anuria threatening the life of the patient, nephrectomy should be performed.

The ureter is frequently injured in pelvic operations, being cut or seized in a clamp or ligature. This is especially the case in operations for carcinoma of the uterus, while the tube is less often injured in operations for carcinoma of the rectum, because the regional lymph glands in the latter disease are not so near the ureters. The patient may die from ureteral infection, or from obstruction to the urinary flow, or he may recover with a urinary fistula. Long-continued pressure during childbirth may cause necrosis of the wall of the ureter and a fistulous communication between it and the uterus or vagina. Many plastic operations have been devised for curing such a fistula. They consist either in the re-establishment of the wall of the ureter, or in its implantation into the bladder higher up. Details of this operation are given in text-books on gynecology. Many operators make it a practice at the close of a difficult pelvic operation to examine the ureters so as to make sure they have not been injured. It is also a good practice in many cases to insert a ureteral probe before operation to serve as a guide to prevent injury of the ureter.

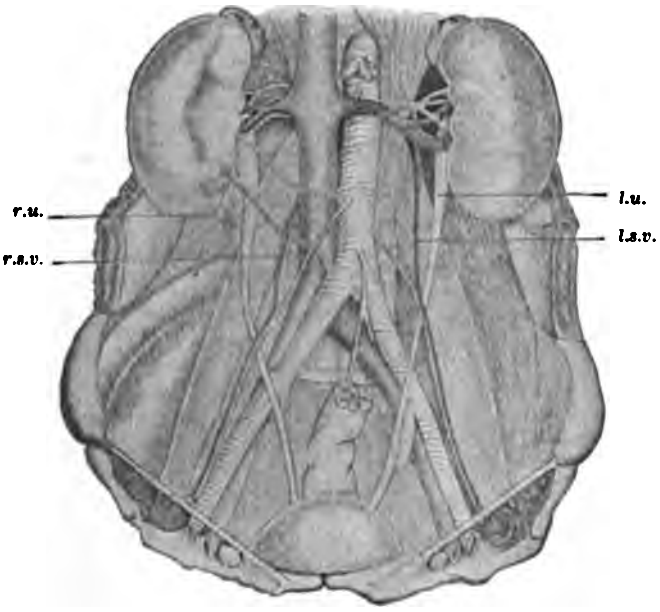

FIG. 4839.—Relations of Ureters. *r.u.*, Right ureter; *l.u.*, left ureter; *r.s.v.*, right spermatic vein; *l.s.v.*, left spermatic vein.

Inflammations.—Ureteritis rarely occurs as an independent disease; it forms a part of the general inflammation of the urinary tract. Gonorrhœal inflammation of the ureter may give rise to the formation of ureteral valves and strictures. Tuberculosis changes the whole ureter into a stiff, inelastic tube. In acute inflammation the ureter is very tender, and in chronic inflammation it is thickened. Both of these conditions may be recognized by abdominal palpation in not too stout patients, and also by examination through the rectum or the vagina. Any obstruction in the ureter is of the greatest importance, since it may lead to hydro- or pyonephrosis.

There is a disease known as chronic polypoid ureteritis, in which the mucous membrane of the ureter is thickly studded with cysts.

If a renal calculus becomes blocked in its passage through the ureter a suppurative periureteritis may be produced. The pus which forms around the ureter will soon destroy its wall, giving rise to extravasation of urine.

Obstruction.—The lumen of the ureter may be blocked by a foreign body, such as a calculus, or a blood clot, or an existing inflammation, or the effects of a previous one, or by pressure of a tumor or a focus of inflammation outside of the ureter. The best treatment is of course to remove the cause if possible.

TREATMENT.—An inflammatory condition may be treated by irrigation. Strictures of the lower end of the ureter may be dilated by metal catheters, varying in diameter from 2 to 5 mm. (0.1 to 0.2 in.).

If a ureter is ruptured by traumatism or accidentally cut across during an operation and its ends are freshened and sutured, the continuity of its lumen will in most cases be restored. If the condition is such that owing to damage of a portion of the ureter or a stricture a resection is necessary, suture at once becomes more difficult. Schopf first sutured the ureter in 1886, inserting stitches which did not puncture the mucous membrane. Bovée suggested the idea of cutting the ends of the ureter obliquely so that the resulting scar should not be a circular one. D'Antoma invaginated the central end of the ureter into the peripheral one, which he split up to facilitate the operation, and then closed by suture. Van Hook inserted the central end into a lateral split in the peripheral end (Fig. 4840). The peripheral end is ligated above the lateral slit. All of the methods of suture described have been successfully employed. The methods of implantation, as shown by experiments upon animals, give the greatest safety against leakage. Unfortunately these methods may be impracticable on account of the loss of a portion of the ureter. This tube has a certain elasticity, so that direct suture may be possible, even when the loss amounts to as much as 8 cm. (3.2 in.). The nutrition of the ureter is kept up by two small arteries which spring from the renal artery and accompany the ureter almost to the bladder; hence in isolating the ureter for the purpose of suture, it should not be peeled bare of its surrounding connective tissue. When the operation is finished, the ureter should be covered with peritoneum or other living tissue and not surrounded with gauze.

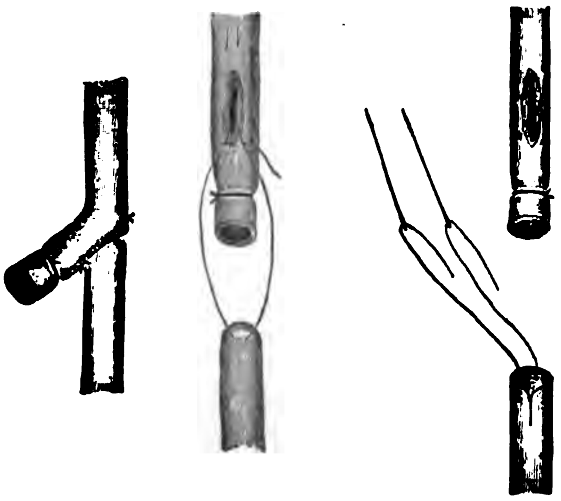

FIG. 4840 Illustrates Different Methods of Reuniting the Cut Ends of the Ureter after a Portion of the Tube has been Resected. (Van Hook's lateral uretero-ureteral anastomosis.)

If the defect in the ureter is situated at its upper end, it may be possible to suture the peripheral portion of the ureter into the pelvis of the kidney. If the defect is in the lower portion of the ureter, the central end may be implanted in the upper part of the bladder. Such an implantation, if possible, should be made extraperitoneally. In some cases the sutures employed have been drawn out through the urethra. Witzel and others have implanted the ureter obliquely in the vesical wall so as to prevent the back flow of urine. In most of these cases a catheter has been left in the bladder for a few days.

The ureters have several times been implanted in the rectum or sigmoid flexure, but the success of this operation is a limited one, as most of the patients have died from peritonitis or pyelonephritis or hydronephrosis.

Edward Milton Foote.

URETHANE.—By the simple title *urethane* is understood, in medicine, the body *ethylic urethane* (ethylic carbamate) $NH_2.COOC_2H_5$. This compound occurs in colorless tabular crystals, soluble in water, alcohol, and ether. It has no odor and but a mild ethereal taste, producing a sensation of coolness in the tongue. Urethane operates upon the animal system as a quite pure, though not overpowerful hypnotic, without effect upon the peripheral sensory apparatus, and without untoward effects of any kind. It is used in medicine for procuring sleep, and is found fairly efficient in the more tractable conditions of insomnia. Doses of 1 gm. (gr. xv.) commonly suffice, but the drug may be required in two or three times this quantity, and such large doses have been perfectly well borne. The remedy has also been administered by hypodermatic injection. From the uncertainty of its operation, urethane has not established itself as a valuable medicine and is not official in the United States Pharmacopœia. It may be prescribed in simple aqueous solution.

Edward Curtis.

URETHRA, INJURIES AND DISEASES OF THE.—Anatomy.—The urethra under normal conditions is a closed canal, averaging about eight inches in length. It is to be divided, both anatomically and clinically, into two chief parts, the anterior and the posterior urethra.

The anterior urethra is that portion which extends from the meatus to the anterior layer of the triangular ligament. This portion is on the average about six inches in length, and is itself divided into three portions, which have somewhat different clinical characteristics. The first portion extends from the meatus backward for about one-half an inch. It is somewhat wider in its central portion than at either of its extremities, and is therefore known as the fossa navicularis. The constriction at its posterior extremity is occasionally of some importance, as the point of an instrument may become arrested and its further advance prevented until a proper direction is given.

The next, or median portion, extends from the fossa navicularis backward for about three and one-half inches. It is without constriction, and may be regarded as representing the calibre of the urethra, and should in health permit the introduction of a No. 26 F. sound without stretching.

The portion of the urethra lying behind this median portion and in front of the triangular ligament is known as the bulbus urethræ, or bulb. It is a more distensible and roomy portion of the urethra, and under pathological conditions or in old people may be dilated so that a pocket occurs just in front of the triangular ligament. This portion of the urethra is important because, owing to its distensibility, the floor is here readily pushed downward by an instrument advancing along the urethra until it lies below the level of the opening in the triangular ligament, and the instrument is then arrested because its point comes sharply against the ligament, and false passages are here of common occurrence. It is also to be remembered that in inflammatory conditions of the urethra the disease is apt to remain longer in this region, possibly owing to the fact that it is the most dependent portion of the fixed urethra and infectious materials gravitate into it.

The deep urethra, or that lying between the anterior layer of the triangular ligament and the urethral orifice of the bladder, is from one and three-quarters to two inches in length on the average. It is divided into two portions: that lying between the anterior and posterior layers of the triangular ligament, or the membranous portion, and that lying behind the posterior layer of the triangular ligament and surrounded by the prostate or the prostatic urethra. The membranous portion, as its name betokens, is easily distensible, and prone to injury both from instruments and from external violence.

The prostatic urethra, or that portion lying within the prostate, is interesting chiefly as containing the orifices of the ejaculatory ducts and of the glands of the prostate. It is divided at the centre of the floor by a median elevation known as the verumontanum. This contains a furrow in its anterior portion into which open the ejaculatory ducts, and it is known as the sinus pocularis. It is believed to be the homologue of the uterine cavity in the female. On either side of the verumontanum lie the prostatic sinuses, so called, into which open the ducts of the prostatic follicles.

While the anterior urethra may be artificially considered as a straight canal, it is not so under normal conditions. The posterior, or bulbous portion, is more or less fixed in the perineal tissues, having in the erect position an almost antero-posterior direction, though rising somewhat in its anterior portion. With this the penile portion makes a sharp angle, owing to the pendulous position of the anterior urethra, and the angle so formed is commonly known as a penoscrotal angle. It is important as being commonly the seat of sensitive granulations following inflammatory diseases of the urethra, and of so-called spasmodic stricture and strictures of large calibre.

Glands of the Urethra.—The anterior urethra is plentifully provided with small glands situated in the submucous layer and opening into the urethra by ducts running forward. These are known as the glands of Littré, and are of prime importance in inflammatory conditions of the urethra.

Cowper's glands lie between the layers of the triangular ligament on either side of the membranous urethra, and open by ducts of considerable length into the bulbous portion of the urethra.

The prostatic follicles or glands, above referred to, lie among the muscular fibres of the prostate gland.

INJURIES OF THE URETHRA.

The pendulous portion of the urethra is, owing to its great mobility, little liable to injury, though it may, of course, be injured by cuts, stabs, or crushing accidents involving the whole pubic region.

The bulbous urethra is the most liable to accident, and next to that the membranous urethra.

Rupture of the Urethra.—*Etiology.*—Injury to the urethra occurs most frequently by falls upon the perineum astride some hard object, as a beam, fence, or chair. Under these circumstances the urethra is forced against the pubic ramus upon either side, the force of the blow rarely being exactly median. The injuries taking place in this way may vary from very slight and trifling lacerations to complete transverse division of the urethra.

It may be mentioned here that another not uncommon form of injury to the urethra is from the careless use of stiff instruments, which tend to leave the urethra in the region of the bulb, especially where inflammatory processes have damaged the mucous membrane. The injury in these cases may vary from slight punctured wounds to complete transverse division, as in one case, seen by the writer, in which violent efforts to pass a silver catheter upon an old man with prostatic obstruction resulted in rupture of the bulbous urethra, with the formation of a large blood clot closely simulating conditions found in traumatic rupture of the urethra. It may in general be said that the amount of injury, particularly that due to violence, is greater than either the signs or symptoms would indicate, and for this reason a false sense of security may lead to the neglect of patients, with considerable damage to the bulbous or membranous urethra.

Pathology (*Clinical*).—When any considerable rent has occurred in the urethra, the train of symptoms following is due to the extremely irritating qualities of the urine which infiltrates the tissues. The rapidity with which spreading gangrene may take place from infiltrations of this character is hardly equalled by any process seen elsewhere in the body. The direction in which the infiltration will spread depends upon the anatomical arrangement of the fasciæ in this region, and is so characteristic as to require careful consideration. When rupture takes place in the bulbous portion of the urethra, infection will spread to the tissues of the scrotum and then upward through the space between the pubic spine and the insertion of the fascia into the symphysis. It will not tend to go downward on to the thigh, owing to the adhesion of the superficial fascia in the region of Poupart's ligament. Having once gained access to the front of the abdomen through the space above mentioned, it may spread upward to almost any extent. In the later stages the spread may be more atypical, owing to the breaking down of the natural barriers. If the rupture take place in the membranous portion the extravasation will follow the layers of the pelvic fascia, spreading between the fascia and the wall of the pelvis, and possibly reaching the thigh through the space on the inner side of the femoral vessels. If rupture occur in the prostatic urethra the infection will extend into the connective tissue in the pelvis between the fascia and the peritoneum, and pelvic abscess may result. Rupture of the prostatic urethra, except when due to instruments or sharp spicules of bone, in fracture of the pelvis, is almost unknown.

The most characteristic pathological phenomenon of traumatic rupture of the urethra is the formation of a blood clot. This will generally be found in the perineal region between the scrotum and the anus, and will vary from a very small quantity to an amount sufficient to cause a bulging tumor as large as an orange. At first this blood is unmixed with urine, but as the bladder becomes distended leakage will take place, and the size of the tumor may be considerably increased by additions from this source.

Rupture occurs most commonly upon the floor of the urethra, and in the more extensive cases the urethra may be completely divided, with the exception of a small strip of mucous membrane on the upper wall.

The elasticity of the tissues forming the urethra is great, and the tendency of the ends to retract is marked, but not excessive except where complete division of the urethra has occurred, when the retraction may separate the divided ends of the urethra for a considerable distance, the intervening space being filled with blood, urine, and tissue detritus.

Symptoms.—Pain is not a characteristic symptom of rupture of the urethra, and extensive damage may exist without causing severe pain except on micturition. The contact of urine with the raw surfaces is always extremely painful, but with this exception pain may be striking by its absence.

Hemorrhage.—A small amount of bleeding from the meatus is quite characteristic of damage to the urethra. This is usually seen in the form of a few drops of blood, which appear shortly after the injury, and a little intermittent oozing is likely to continue for some time if treatment is not instituted. Hemorrhages of considerable amount are extremely rare, though instances have been occasionally reported.

Retention of Urine.—This symptom is quite characteristic of rupture of the urethra. Generally the patient will be unable to empty his bladder at all, though in the milder degrees the attempt may be successful at first, and later fail on account of swelling which occurs about the injured part. This symptom, taken in connection with the slight bleeding from the meatus and the history of injury, is almost pathognomonic of rupture of the urethra.

Tenesmus.—Where the damage is sufficient to cause retention, tenesmus will always follow after a longer or shorter time. As the bladder distends, leakage takes place into the injured area, and the pain results in violent bladder tenesmus, which is likely to cause an increase of the bleeding from the meatus. This symptom, while constant, is not of great importance, as it will occur only in the presence of other symptoms sufficient in themselves to warrant the diagnosis.

Shock.—In rupture of the urethra uncomplicated by fracture of the pelvis or extensive damage to other tissues, shock is not a prominent symptom, though it may readily occur when the blow causing damage to the urethra has at the same time struck one or the other testicle with sufficient violence to cause the rather characteristic symptoms of shock from this cause. When rupture of the urethra is a complication of extensive crushing injuries involving the pelvis, shock may be a prominent symptom; but in these cases it is a symptom of injury to other tissues rather than to the urethra.

Fever.—The occurrence of fever after rupture of the urethra is not an immediate symptom. It comes only when infection of the blood clot has taken place, and is, therefore, too late a symptom to be of diagnostic value.

Treatment.—When, from the occurrence of any of the above symptoms, rupture of the urethra is suspected, an attempt should be made to enter the bladder with a soft instrument. This may occasionally be successful, but will on the whole do more to confirm the diagnosis than to prove itself of value in the treatment. The instrument will generally leave the urethra at the point of rupture and impinge upon some of the irregularities which the injury has caused. If a stiffer instrument is to be tried, the attempt must be made with the greatest care, the attendant bearing in mind the fact that he will probably fail, and that it is his duty to do no further injury to an already damaged urethra. In general it may be said that, should a soft instrument fail to find its way into the bladder, no further instrumentation should be undertaken until all preparations have been made for any operation which may be necessary to insure success, for to attempt to enter the urethra with a stiff instrument without being prepared to take the consequences should failure result, and resort immediately to a cutting operation, is little short of meddlesome surgery.

If the means for radical operation be not at hand, overdistention of the bladder may be prevented by aspiration above the pubes. This is not to be regarded as a curative measure, and will not prevent the leakage of urine into the damaged tissues, but it may contribute to the comfort of the patient during necessary delay.

The operation of election is perineal section, with evacuation of the blood clot, and if possible union of the divided ends of the urethra. There is a growing tendency among surgeons to do this operation, even in cases in which, under ether, an instrument can be made to pass. This comes from the conviction that the amount of scar tissue following the injury will be less when treated by the open method, and from the very general experience of the intractability of urethral strictures resulting from this accident.

The first step in the operation should be the attempt to pass a full-sized sound. This will probably fail, but in case of success it may be used as a guide to perineal section. If it fails it may still be used as a guide to the point of rupture. The patient should then be placed in the lithotomy position, and a median incision made in the perineum. When the blood clot has been evacuated and the bleeding, which is generally most marked from the posterior end, controlled, search should be made for the ends of the urethra. The anterior end can generally be found without difficulty, as the instrument in the urethra is a direct guide to its position; but the discovery of the posterior portion may be a matter of difficulty, or even impossibility.

We cannot here go at length into the methods of search. If, after a considerable search, the posterior fragment cannot be found, recourse should be had to retrograde catheterization. For this purpose the bladder is opened above the pubes, as described in the section on suprapubic cystotomy. The catheter is then passed from the bladder into the wound, and the posterior fragment of the urethra can generally be located. This having been done, the further procedure is the same in either event.

It is generally thought wise to attempt to unite the divided ends of the urethra and thereby diminish the amount of scar tissue. This is best done with catgut sutures, which may or may not include the mucous membrane. When the wound has been largely closed two courses are at our disposal: either a large soft-rubber catheter may be passed into the bladder and tied in place, or it may be passed down to the point of rupture and the bladder drained with a perineal tube. In either case no further closure of the wound with sutures is indicated, and a light packing of gauze should be left in position. The rest of the treatment is so similar to that after perineal section for stricture that its further discussion will be unnecessary here.

Rupture of the pendulous portion of the urethra will be accompanied by extravasation into the tissues of the penis, with rapid swelling, œdema, and tissue necrosis, unless relieved. Incision should be prompt and free, the wound in the urethra sutured or not, according to its extent, the external wound packed with gauze and the bladder drained with a catheter.

Foreign Bodies in the Urethra.—Foreign bodies in the urethra are of two classes: those introduced from without, either by the patient or by the doctor, and those coming down from above, as, for instance, stones which, having passed the ureter, have become impacted in the urethra and obstruct the passage of urine.

Of the foreign bodies introduced from without there are an immense variety, of which detailed account cannot be given here, and their introduction by the patient is generally due to some mental perversion. Occasionally pieces of instruments or catheters may break off and be left in the urethra. In these cases their presence is at once known and the proper measures can be taken.

Foreign bodies left in the anterior urethra can occasionally be forced out by pressure on the urethra, but such an occurrence is unusual. They may frequently be removed by the introduction of a full-sized endoscope in a good light, the body being seized with proper alligator forceps. In order to prevent it from slipping back along the urethra, which it has a marked tendency to do, the fingers of the left hand should compress the urethra behind it and prevent such slipping. In case removal by the endoscope is impossible, an external urethrotomy over the body is always proper, and the only necessary precaution is to make sure that the body is firmly held in position before the incision is made.

Foreign bodies in the deep urethra can rarely be reached by means of the endoscope. By far the most common of these bodies are urethral calculi which are too large to pass the urethra. In these cases they cannot infrequently be pushed back into the bladder by the use of a full-sized sound, and where this can be done without undue violence it will serve to relieve the retention which always exists. Once they have been pushed back into the bladder, they may be removed by the measures appropriate to stone in the bladder. When, in rare instances, they cannot be pushed back as above described, a small perineal incision or boutonnière can be made, and, with the forefinger of the left hand in the rectum, the foreign body can be grasped with dressing forceps and removed.

INFLAMMATORY DISEASES OF THE URETHRA.

Inflammatory conditions affecting the urethra may be classified under four general headings. These are: 1. Gonorrhœal. 2. Simple. 3. Syphilitic. 4. Chancroidal.

Gonorrhœal Inflammation.—The space at our command will not permit us to digress into the interesting discussion of the relation of the gonococcus of Neisser to this disease. Suffice it to say that gonorrhœal processes are always due to the above-mentioned organism, and that when doubt of its presence exists the classification cannot be made with certainty. The occurrence of other organisms closely resembling the gonococcus in staining properties and morphological characteristics is now beyond question, and in doubtful cases the question can only be decided by cultures.

Pathology.—The prime characteristic of this organism, as revealed in the varying severity of the inflammations which it causes, is its affinity for mucous membranes. While the gonococci are capable of producing inflammatory processes elsewhere, these inflammations are atypical and do not show the same virulent characteristics as are observed in the urethra. Another extremely important characteristic is the liking of the gonococcus for the deeper layers of the mucous membrane and for the glandular structures lying in the submucous layer. Upon this characteristic depends the extremely unsatisfactory results of treatment, as the gonococcus, once fairly established in the deeper layers, can be reached with difficulty, if at all, and may slumber for months, or even years, in some of these obscure hiding places.

Symptoms.—Acute infection. Where an acute, fresh infection or original infection has occurred, a well-marked period of incubation will always be found, and the absence of such a period should give rise to serious doubt as to the diagnosis. Infections with other organisms of a transient, unimportant character, and so-called "flare-ups" of previous infections, will show little or no period of incubation, but a fresh infection, uninfluenced by previous conditions, will always show a well-marked period of incubation, varying from four to seven days.

The first symptom is as a rule a slight itching or smarting of the urethra accompanied by a moderate mucoid discharge. In ordinary cases this rapidly increases during the following day or two, and the patient has severe burning on urination with a profuse yellow or greenish purulent discharge. In many cases about this time a certain amount of swelling and œdema appears. This is first noticeable around the meatus, and is evidenced by a slight pouting of the urethra. This is followed by œdema of the penis—sometimes extreme,—probably due to lymphatic obstruction. The lymphatics, especially upon the dorsum, are often to be seen as well-defined red marks, extending up to the region of the pubes. The glands in the groin at this time are frequently somewhat enlarged and tender. As a rule they do not go on to suppuration, and are in this way to be distinguished from the suppurating glands most commonly seen with chancroidal ulcerations. They are generally more marked upon one side than upon the other, and subside without local treatment.

In the absence of treatment the discharge and inflammatory symptoms continue to increase for from ten days to two weeks. The subsidence without treatment is a slow process, and probably in uncomplicated cases lasts for from six to eight weeks, at which time a certain proportion of untreated cases may be spontaneously cured.

The occurrence of any complications, however, may immensely protract the course of the disease, and there are some cases which have earned for themselves with some justice the title of "incurable."

Posterior Infections.—The disease starts in the anterior urethra, generally in the region of the fossa navicularis, and tends to extend slowly backward by continuity. In many cases it ultimately involves the greater part of the anterior urethra. In a considerable proportion of cases there is extension to the posterior urethra. This extension is frequently due to continuity of the process, but may undoubtedly be favored by the incautious use of instruments, or by injections, and has long been held up as an argument against the use of local treatment during the acute stages. Infection of the posterior urethra opens the way to a great variety of complications which do not belong strictly to the urethra itself; that is to say, prostatitis, seminal vesiculitis, epididymitis, orchitis, and Cowperitis. These do not fall within the scope of this article, and for their discussion the reader is referred to the sections on these conditions.

The distinction between a posterior urethritis and a prostatitis is hardly to be made, and it is probable that comparatively few cases of posterior infection occur without some involvement of the prostate. The symptoms of a posterior infection are quite different from those of an uncomplicated anterior urethritis, and it is frequently possible to decide that the infection has passed the triangular ligament. Thus, frequency of micturition is an almost unfailing symptom, and may vary from a very moderate increase to an almost persistent tenesmus. Pain is likely to be a prominent symptom, and the amount of pus coming with the latter portion of the urine will be found to be increased. Not infrequently the amount of discharge from the anterior urethra decreases at this time, and this has been held as an almost pathognomonic sign of posterior infection; but while it very generally occurs, it cannot be regarded as distinctive, and the reasons for its occurrence have not been satisfactorily explained.

Treatment of Acute Anterior Urethritis.—For many years the effort has been made by surgeons to abort this disease, and from our knowledge of the infectious agent this is theoretically possible. Practically, however, we rarely see these cases at a sufficiently early date, as symptoms sufficient to attract the patient's notice do not as a rule occur until the micro-organism has reached the deeper layers of the mucous membrane and has become relatively inaccessible. Where we have an opportunity to treat a patient, known to have been exposed, before the occurrence of symptoms, we are rarely in a position to postulate that infection would certainly have taken place, and claims of this kind are not therefore entitled to weight. Nevertheless, certain cases may be, if not actually aborted, at least cut short, and it is entirely permissible to attempt to abort cases seen within twenty-four hours of the appearance of symptoms.

The methods most generally employed are the use of antiseptic injections, or irrigations of the anterior urethra, considerably stronger than would properly be used in more developed cases or for any considerable length of time. Solutions of nitrate of silver (one to three or four grains to the ounce), of argonin and protargol (from two to five per cent.), and argyrol (from five to ten per cent.) are among the best. In order to be successful the treatment must be carried out mostly by the surgeon himself.

A fair sample of these methods is the following: A patient seen with a moderate muco-purulent discharge containing gonococci is given an injection in the anterior urethra of a solution of nitrate of silver, two grains to the ounce. This will produce a considerable burning, which will subside in from one-half to two hours. If seen in the morning the patient may be instructed to return later in the day, when an injection of the same solution, about one-half strength, may be given. He may then be given a solution of one of the silver salts of comparatively mild strength—as, for instance, a one-per-cent. solution of protargol—and told to use it himself as an interior injection, twice before the next visit on the following morning. A stronger solution of one of the silver salts, as, for instance, a three-per-cent. solution of protargol, may then be given by the surgeon, while the patient uses his own solution at noon and the stronger injection is given again at night. In the more favorable cases the discharge may be promptly checked and the gonococci will rapidly disappear, and by the end of a week the case may be in the subacute stage and run a comparatively short course.

Most cases, however, will not be proper subjects for this abortive treatment. Treatment is both general and local, and the opinion is gaining ground that both forms of treatment are of value for patients who really want to get well. This remark may seem unnecessary, but there are a considerable number of patients, more especially those seen in hospital practice, who will not give sufficiently regular attention to their disease to make its elaborate treatment worth while. These patients are, therefore, best given general treatment and not subjected to local measures until the acute stage has so far subsided as to make treatment at very short intervals unnecessary.

General Treatment.—This includes hygienic measures and diet. It is important to advise scrupulous regard for the general health and avoidance of dissipation or excess in any direction. Alcohol must be absolutely interdicted, and we have frequently seen ginger ale do harm. Highly seasoned irritating foods, fatty, fried, or strongly acid foods are also objectionable. Smoking, except to excess, is not objectionable. The drinking of large quantities of liquids—water, or perhaps better, milk—is valuable as a diuretic, and in this connection the use of alkaline diuretics, as the acetate or citrate of potash, is useful. Careful instructions in regard to the infectious nature of the discharge and the importance of personal cleanliness should never be omitted.

Of the drugs known to have a beneficial effect upon the mucous membranes of the urinary tract the following are the chief: balsam of copaiba, oleoresin of cubebs, sandal-wood oil, salol, and urotropin.

The balsams undoubtedly have some effect upon the mucous membranes to which they are conveyed by their solution in the urine.

Copaiba is perhaps best suited to the poorer class of patients, to whom expense is important. It is likely to disagree with the stomach and not infrequently produces erythematous rashes, which promptly disappear upon withdrawal of the drug.

Cubebs is much in the same class with copaiba. It is slightly less nauseating, and in our experience somewhat less efficient.

Sandal-wood oil is the most effective, but most expensive of this group. In order to act properly it must be pure, and on account of its expense it is frequently adulterated. When given in capsules it does not often upset the stomach, and its most common unpleasant effect is pain in the lumbar region. This may be combated by the use of moderate doses of salol, but in some cases it will force the abandonment of the drug.

Salol is regarded as a urinary antiseptic, and is excreted in the urine as salicylic acid and carbolic acid. Urotropin comes much under the same heading, and acts by virtue of the formalin which it liberates. We have personally not seen good results from the use of these drugs in acute urethritis, and do not regard them as likely to appeal to the mucous membranes in the same manner as do the balsams.

Patients who cannot or will not come frequently to see the surgeon may be treated as above described, with advice and balsams, and they will probably get well somewhat more quickly than if left untreated.

Local Treatment.—This consists in the application of antiseptic and astringent solutions to the anterior urethra. It may be done by injection or by irrigation. Injections are given with a small blunt-pointed syringe, holding from one to two drachms, by means of which the anterior urethra is distended without the use of force sufficient to drive the solution into the posterior urethra. Irrigations are carried out with a soft-rubber catheter (which is advanced slowly along the urethra, washing it out continually as the catheter advances) or with a blunt nozzle, through which a considerable stream is injected into the urethra, at first with sufficient force to close the cut-off muscle. After the anterior urethra has thus been irrigated the solution may be allowed to flow back into the bladder, and is then passed, thus thoroughly washing both the anterior and the posterior urethra (Fig. 4841).

The distinctive characteristics of these two methods are that the method of injection uses small quantities and depends upon antiseptic and penetrating properties, while the method of irrigation uses solutions less active and depends upon the quantity used, in part at least, for its mechanical effect.

The solutions used for injection are chiefly the silver salts. These, with the exception of nitrate of silver, are all comparatively modern products and are to some extent still in the experimental stage. Their claims to usefulness depend upon the fact that they are organic salts of silver and are not precipitated, as are the inorganic. They thus have greater power to penetrate to the deeper layers of the mucous membrane, and theoretically, at least, are more likely to reach the organisms beneath. There are several of them at present which have each their ardent advocates, and we cannot undertake to discuss their relative efficiency. Argonin and protargol may be used in strengths varying from one-half to four per cent. The citrate of silver should be used saturated, which is about one to four thousand, and the newest candidate for favor, argyrol, may be used in from one to ten-per-cent. solutions. They are all less irritating than the nitrate of silver, and the evidence goes to show that their claims to attention are substantial.

Where injections are to be used they should be given at least once a day by the surgeon himself, and during the acute stage the patient should use a less powerful solution twice or three times more in the twenty-four hours. The number of injections may be decreased as the inflammation subsides. All solutions used in this way should be held in the urethra for from five to ten minutes, as in this way their efficiency is much increased.

The solutions most commonly used for irrigation are permanganate of potassium of strengths of from 1 to 3,000, to 1 to 6,000; corrosive sublimate, 1 to 10,000 to 1 to 50,000; and nitrate of silver, 1 to 4,000 to 1 to 8,000. Irrigation should always be carried out by the surgeon himself, and there can be no doubt that when carelessly used it is capable of doing great harm. We do not believe that it is a procedure which can safely be left to the patient, and think that its greatest field of usefulness is in connection with injections, the irrigation being given by the surgeon and the injection used by the patient. Since these irrigations depend for their efficiency in part upon the quantity used, this should always be considerable, and most authorities agree in advising the use of from one to three pints. If the solution prove irritating to the anterior urethra it should be diluted before it is allowed to flow back into the bladder. The method in which a catheter is employed and the urethra cautiously irrigated inch by inch, from the meatus to the bulb, care being taken to see that a free back flow is kept up, commends itself to us as being less liable to be followed by complications, and we are inclined to think that for practitioners who are not specialists this method is likely to be most generally useful.

Treatment of Acute Posterior Urethritis.—The occurrence of this form of inflammation has already been noted. When this is confined to the urethra itself the process may occasionally be headed off by the use of instillations of nitrate-of-silver (from one to five grains to the ounce), of which solution five to ten drops should be used. As a rule, however, these cases do best when not treated locally during the acute stage. For a further discussion of this the reader is referred to the pages in the article on *Prostate, The*, in Vol. VI.

CHRONIC URETHRITIS.—This name is given to the cases which, with or without treatment, continue for an undue length of time. As a rule the only symptom is a very moderate discharge, most noticeable in the morning, and the more or less constant presence of shreds in the urine. It generally is not a source of annoyance to the patient, except from the knowledge that he is not cured. It is far more to be dreaded as a source of infection than the more acute conditions, as the very mild symptoms lull the patient to a false sense of security or are overlooked through ignorance of the damage which they may cause. The treatment belongs really in the province of the specialist, and obstinate cases are likely to be a source of considerable annoyance to the general practitioner.

Continuance of the inflammation is frequently due to infection of the prostate or seminal vesicles, or to a stricture, and for a discussion of these causes the reader is referred to other sections of the present article. Another not uncommon cause is the so-called granular patches, or granulations, in the urethra. These are small areas, most commonly found in the bulb or at the peno-scrotal angle, where the infection has persisted in the deeper layers with more or less destruction of mucous membrane. These patches can best be treated with the endoscope. An instrument should be selected as large as the urethra will accommodate without causing undue pain. This should be passed to the region of the bulb and the obturator withdrawn. Then, with a good illumination, the surgeon should follow the whole course of the pendulous urethra, drying his field from time to time with an applicator, and accurately localize any granular patches which exist. These can generally be distinguished by the different texture of the tissues and by the loss of the normal lustre. It must, however, be admitted that these granulations are more frequently found by those who are expert in the use of the endoscope than by those who use it only occasionally. The granulations should be touched with nitrate of silver, from fifteen to thirty grains to the ounce, and generally after one or two applications marked improvement will be seen.

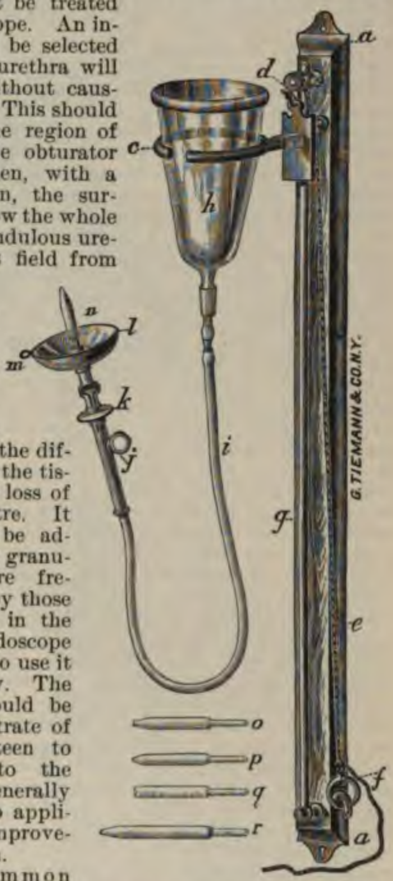

FIG. 4841.—Valentine Apparatus for Irrigating the Urethra and Bladder. The support for the apparatus is attached to the wall or to the woodwork of the room in such a manner that the bottom of the irrigator (*h*) is nine feet from the floor. The patient sits on a chair eighteen inches high. All irrigations are performed from this elevation; differences in the force of the stream are procured by drawing back or pushing forward the flange (*k*). *a*, *a*, board with brass rod (*g*); *c*, collar holding irrigator; *d*, pulley to raise irrigator for use or to lower it for cleaning and filling, but not for producing variations of force of stream; *e*, cord for drawing up irrigator; *f*, ring at end of hoisting cord; *g*, brass rod, serving as track for metal block which supports collar; *i*, soft-rubber tube six and one-half feet long; *j*, ring for fourth finger; *l*, shield for directing flow from urethra into basin on patient's lap; *m*, small ring for suspending stopcock when not in use; *n*, nozzle in place; *o*, pointed nozzle for normal meatus; *p*, dome-shaped nozzle for large meatus; *q*, flattened nozzle for small meatus; *r*, nozzle for irrigating female urethra and bladder.

Another common cause of a slight amount of discharge is to be found in the persistence of infection in the glands of the urethra. These can hardly be reached by local applications, and are best treated by stretching the urethra moderately with sounds or with a Kollman dilator. This should not be done more than once in five to seven days, and the urethra should be carefully irrigated with some mild antiseptic solution after instrumentation. The patient should also be given either one of the balsams or the oil of sandal-wood, which act extremely well in these chronic or subacute cases. The use of astringent washes, as permanganate of potassium, sulphate or sulpho-carbolate of zinc, and the like, is also useful, as the discharge is in part due to hypersecretion of a slightly injected mucous membrane, which will yield nicely to the use of astringents, either by injection or by irrigation.

Other Forms of Urethritis.—There still remain to be considered three other forms of urethritis, which are important chiefly because they are occasionally confounded with gonorrhœal urethritis. Such mistakes can hardly occur except where a diagnosis is to be made between the later stages of an acute urethritis and the earlier stages of these other varieties. An inflammation of the urethra coming on after a definite period of incubation, accompanied by a profuse purulent discharge and showing the presence of intracellular diplococci, can hardly be mistaken. It is not to be denied that there are other diplococci in the urethral discharges, and that they may occasionally stand in an etiological relation, but these are very rarely capable of producing a profuse discharge, with other symptoms of acute infection. When we have to deal with a so-called "gleety" discharge, showing the presence of diplococci, the diagnosis cannot be so easily made, and it is also true that even the use of Gram's stain is not sufficient to distinguish between these organisms, and cultural methods alone are to be regarded as absolute. When, therefore, the importance of an accurate diagnosis is extreme, no staining or morphological distinctions are to be regarded as absolute. The most important question which the practitioner is called upon to decide is the distinction between a fresh infection and the lighting up of an old gonorrhœal inflammation. As is well known, this tendency to recur is very marked, even after the lapse of months or years. A "flare-up," so called, may generally be distinguished by its rapid onset, showing little or no period of incubation, its comparatively mild course, and its tendency to subside under mild treatment. Gonococci will generally be present in considerable numbers at first, but they rapidly disappear. These cases are to be distinguished from the cases of so-called "simple urethritis," which are due to infections of the urethra with other organisms. It is now beyond question that other organisms are capable of exciting urethritis, but they act rather as a local irritant and differ markedly from a gonorrhœal infection. They show little or no period of incubation, the discharge as a rule is muco-purulent, and they subside in a few days, with or without treatment. If the discharge be examined under the microscope a variety of cocci and bacilli may be found, and possibly intracellular organisms. The infection is frequently not pure, and mixed cultures are generally to be obtained. It is of the first importance that these cases should not be confused with a true gonorrhœal infection, as serious consequences might follow such a mistake.

Treatment.—These cases do well under mild astringent or antiseptic irrigations, and are to be treated locally from the very start. As a rule they subside in the course of a week or ten days.

Chancroidal Urethritis.—The possibility of a chancroidal ulceration extending into the urethra as far as the fossa navicularis must be remembered. As a rule the diagnosis is accompanied by no difficulties, and the evidence of an ulcerative process generally extending out on to the glans will render the diagnosis easy. The treatment is that of chancroidal ulcers elsewhere.

Syphilitic Urethritis.—Intra-urethral chancres are not uncommon. Their presence is accompanied by a moderate purulent or muco-purulent discharge, which might be mistaken for an atypical case of gonorrhœa. Such errors may be avoided by palpation of the anterior urethra, which will show the presence of an indurated area, generally in the first inch and a half of the urethra. These are to be distinguished from peri-urethral abscesses, or so-called folliculitis, by their hardness, and by the absence of tenderness; often by their position at or near the meatus, and by the appearance of a roseola. The treatment is that of syphilis elsewhere.

STRICTURE OF THE URETHRA.

Strictures of the urethra may be congenital or acquired, but the vast majority of strictures with which the practitioner has to deal come under the latter heading.

Congenital Strictures.—Congenital strictures of the urethra are rare. They are generally at the meatus and may be of extremely small calibre.

The *etiology* is obscure. Cases of stricture further back than the meatus have been reported as congenital.

The most generally accepted theory in regard to the causation of hypospadias and epispadias is that they are due to intra-uterine stricture with rupture and sloughing. If this theory be accepted it will clear up the etiology of congenital stricture.

The *treatment* is that of stricture in the adult.

Acquired Stricture.—*Spasmodic Stricture.*—Under this heading we must consider the so-called spasmodic strictures, which, though not strictures in the narrowest sense of the word, are yet frequently productive of the symptoms of stricture. They are due to spasm of the muscular fibres in the urethra, producing more or less obstruction. By far the most common cause of spasm is a sensitive area due to inflammation, which may be sufficiently localized to be described as ulcer. This, when approached by an instrument, resents the interference, causing contraction of the muscular fibres and a consequent obstruction to the passage of the instrument. It may in this way give rise to signs closely resembling organic stricture, and is, to be distinguished largely by the history, which will as a rule show an entire absence of symptoms except when the urethra is examined with an instrument.

There are also cases of spasmodic stricture apparently of purely nervous origin. These occur in neurotic individuals, and are most pronounced when their nervous symptoms are prominent. The diagnosis is to be made only upon the history, an entire absence of inflammatory disease, and the demonstration of the absence of local areas of congestion. It is probable that, if put to this test, the number of spasmodic strictures of nervous origin will not be found large. Spasmodic stricture disappears under full surgical anæsthesia.

Organic Stricture.—The two prime causes of organic stricture are trauma and gonorrhœal urethritis.

Traumatic stricture has already been discussed under rupture of the urethra and will not be further mentioned here.

While it is not to be denied that urethritis of other than gonorrhœal origin is at times sufficiently severe to be capable of producing true organic stricture, cases in which such has actually occurred are extremely rare.

Pathology.—The trouble begins with the loss of a small portion of the mucous membrane, which results in the failure of the tissues to protect the deeper parts, and as a result they become infiltrated with urine. This sets up an inflammatory exudate in the submucous layer, with the deposit of fibrous tissue. It is stated upon good authority that the fibrous tissue here formed differs from scar tissue in other regions by showing a greater tendency to contract. This may be real or due to the fact that in many cases infiltration has taken place about the whole circumference of the urethra, and that a very moderate amount of contraction at any one part will produce a very decided contraction of the whole. It is also to be remembered that the process of formation is an extremely slow one, and, therefore, that the scar is laid down layer upon layer in the endeavor to protect the deeper parts from the extremely irritating urine which infiltrates it. In this way a concentric scar is formed, and we need not suppose any exceptional qualities in the fibrous tissue in order to show an extremely persistent tendency to contract.

Changes in Other Organs.

Changes in the Urethra.—The changes in the urethra itself due to stricture and yet not immediately at the point of stricture, are due to the fact that the urethra behind the point of narrowing is not completely emptied. The condition begins by the retention of a drop of urine behind the stricture—leading to irritation and frequently a slight discharge, which is often referred to as a "gleet."

This is nothing more than the attempt on the part of the mucous membrane to protect itself against the irritating properties of the urine. As the process goes on and the narrowing becomes more complete, there is dilatation of the urethra at this point, which may become extreme. With this dilatation goes a decrease in vitality of the tissues, with consequent maceration and perforation of the mucous membrane, leading to a small abscess, which may go on to the formation of a fistulous opening behind the stricture and in extreme cases to extravasation of urine. The abscesses and fistulæ thus formed may be multiple, and the cause of multiple fistula formation is not necessarily the presence of multiple strictures. Multiple fistulæ may and frequently do exist with but one stricture. This is due to the fact that, as the fistula becomes chronic, much fibrous tissue is deposited along its walls, which then contract and the fistula no longer serves to drain the cavity from which it started. The infection then extends in another direction, with the formation of a new fistula, and the process may go on until several are formed, giving rise to the condition known as "a watering-pot perineum."

Extravasation of urine is due to a rupture of the urethra behind a stricture, and differs in no way from that which occurs from traumatic rupture of the urethra.

Changes in the Bladder, Ureters, and Kidneys.—With the increasing obstruction in the urethra comes a hypertrophy of the bladder, with not infrequent sacculation, and unless this hypertrophy absolutely keeps pace with the obstruction there comes a time when the bladder is not completely emptied, and there is residual urine and a condition favoring cystitis. The number of cases in which some residual urine is to be found is probably much larger than is generally supposed, and is stated by some writers as high as sixty per cent. With the occurrence of residual urine of any amount there comes a back pressure upon the ureters and pelves of the kidneys, resulting in dilatation and thereby favoring infection not only of the ureter and pelvis, but also of the secreting portions of the kidney. In this way arise the conditions known as pyelonephritis, or "surgical kidney," rendering any surgical operation risky.

Varieties of Stricture.—It is customary to describe the anatomical characteristics of a stricture as one of three varieties.

A stricture which is extremely narrow and resembles a band constricting the urethra is spoken of as linear.

A wider band, which constricts a moderate amount of the urethra in a symmetric manner, is spoken of as an annular stricture.

A stricture of greater length, which has narrowed the urethra unequally in its different parts and has, therefore, pushed the portion of the canal which remains patulous first to one side and then to the other, is spoken of as tortuous.

These varieties are not of great importance in the treatment of stricture, for in some cases all three varieties may be present in one patient, and it is difficult, without the use of complicated apparatus, to decide exactly as to the particular class to which a given case belongs.

Strictures are also divided, according to their diameter, into strictures of large and strictures of small calibre. This is a distinction which, in the light of our present knowledge, might properly be abandoned. The term of "large calibre" was introduced by Otis and his followers, who regarded any narrowing of the canal below that calibre, established by an arbitrary scale, as evidence of stricture. To-day it is generally admitted that many so-called strictures of large calibre should properly have been regarded as physiological narrowings of the canal, and, as the term carries with it no important distinction, it should properly be abandoned. For practical purposes, only the strictures which were termed by Otis "strictures of small calibre" are to be regarded as organic strictures at all. It is always proper in describing a stricture to speak of it as a large or a small stricture, but when these expressions are used they are not intended to refer to the term "stricture of large calibre," which has come to carry with it an especial meaning, and is not to-day believed to be in accordance with the facts.

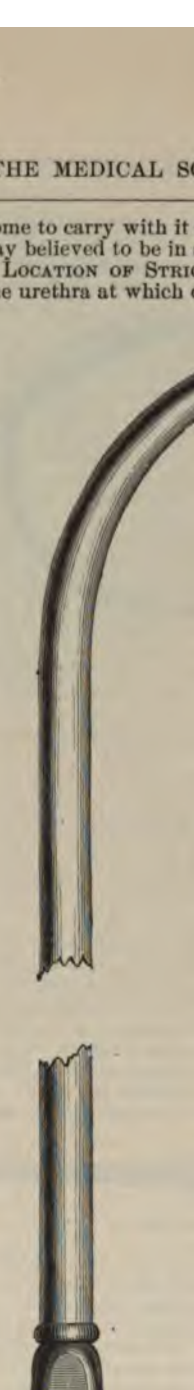

Fig. 4842.—Curved Steel Sound.

Location of Strictures.—There are three points in the urethra at which organic stricture is most commonly to be found. First, the region of the bulb. Second, the region of the peno-scrotal angle. Third, a point at the posterior limits of the fossa navicularis.

True stricture of the membranous urethra is rare except in cases of rupture of the urethra.

Stricture of the prostatic urethra is probably unknown.

Symptoms of Stricture.—Organic stricture of the urethra may exist without symptoms; in fact, in the early stages most strictures do not attract the patient's attention.

A gleety discharge with the constant presence of shreds in the urine is a very constant symptom of stricture.

Slight burning or irritation and slight frequency of urination are commonly observed, but they are by no means constant.

Dribbling at the end of the act of urination is common, and due to the inability of the urethra to contract regularly and empty itself.

Irregularities in the shape of the stream of urine are popularly supposed to be important, but as they are largely due to the shape of the meatus they need not be given much importance.

Difficulty in starting the stream is a more common symptom and, though likely to be due to other causes, should always attract attention.

Frequency of urination in marked degree and of constant character is a late symptom, due to changes in the bladder resulting in the accumulation of residual urine.

Retention of urine is a comparatively late symptom, but may occur with strictures of moderately large calibre, especially after careless instrumentation, exposure to cold, or excesses in alcohol. In these cases it is due to an acute congestion of the mucous membrane, which is usually temporary.

Diagnosis.—The diagnosis of stricture is to be made only by a careful local examination of the urethra, such examination having been suggested by almost any one of the above-mentioned symptoms. It is wise to carry out such an examination in a routine way, and the following routine is suggested, not because of exceptional value, but because it has been found valuable in practice:

Examination should be begun with a sound as large as the meatus will comfortably admit. If this is arrested a smaller size may be tried, but stiff instruments smaller than 18 or 20 F. cannot be regarded as safe. The presence of stricture having been ascertained with the sound, examination may then be made with the bougie à boule (Fig. 4843). The larger sizes of this instrument are likely to give confusing results, as it is difficult to distinguish physiological from pathological narrowings. With these instruments it is possible to locate the position of the stricture and its size, if it will admit them at all. They are not of much value in sizes smaller than No. 10 F., as the points become engaged in small pockets in the urethra. If sizes smaller than this are required, flexible bougies, either of the English webbing or the French make, are most valuable. With them the presence of organic stricture can be definitely ascertained by the peculiar gripping sensation felt as they are being withdrawn. This sensation is sufficiently peculiar to be distinctive if once felt. If soft bougies cannot be passed, resort must be had to the filiform bougies. These are extremely liable to be caught in the orifices of the ducts and glands of the urethra, and their use is a matter of some difficulty and belongs to the province of the specialist.

TREATMENT.—The treatment of stricture of the urethra may be briefly considered under three general headings:

1. Gradual dilatation.
2. Continuous dilatation.
3. Urethrotomy, internal or external.

Gradual dilatation is the treatment of election in all cases above No. 10 of the French scale. In many of the more chronic cases it will fail and must be replaced by some more radical method, but an attempt at cure by this means is never out of place except in cases in which retention has either occurred or is threatened, or in which nothing but a filiform bougie or the small sizes of bougies can be passed.

For strictures of a calibre 18 to 20 of the French scale the conical steel sound is the best instrument. This should be passed gently through the stricture, no force being used and no attempt being made to increase the sizes more rapidly than is compatible with comfort. The object to be attained is to dilate the stricture so gradually as not to cause bleeding except in most moderate amounts.

For strictures below 18 F. the soft gum elastic bougies are safer, as the smaller sizes of steel sounds are deadly weapons except in the hands of the very expert.

Gradual Dilatation.—The possibility of dilating a stricture by the passage of instruments of increasing size depends upon the stirring up of a mild grade of inflammation in the stricture, thus promoting absorption and softening the scar. For this reason instruments should be passed at such intervals as give the best results in individual cases. The interval will vary from three to six or seven days, and the attendant should be guided by the facility with which the sizes can be increased. The average interval will be about once in five days. After dilatation has been carried up to 28 or 30 F. the interval should be extended as rapidly as possible without the occurrence of recontraction. In this way it may soon be increased from weeks to months, and a condition attained when the patient can either pass an instrument for himself, or visit his surgeon once or twice a year to see that the calibre has been maintained.

Any instrumentation should be followed by a thorough washing of the urethra, to remove as far as possible dangers of infection.

This form of treatment will fail in cases of old stricture with much scar-tissue formation, particularly those which bleed very readily, and in which each gain in size is accompanied by corresponding damage to the mucous membrane. If, after a moderate trial of one or two months, no notable gain has been attained, it is better to resort to some more radical form of treatment than waste further time in what is likely to prove a hopeless task.

There are also a certain number of what are known as "resilient strictures," which, though they can be dilated up to or above 20 F., cannot be kept at this figure except by constant treatment, and show a very marked tendency to recontract. Under these circumstances, after a fair trial of gradual dilatation, resort should be had to cutting operations.

Continuous Dilatation.—The term "continuous dilatation" is applied to a method occasionally applicable to strictures of small calibre, through which only the smallest instruments can be passed. It may be tried on any passable stricture before resorting to cutting operations, but is likely to prove successful only in a small number of cases. A filiform bougie may be passed through the stricture and fastened in place. After the lapse of twenty-four to forty-eight hours it will be found that a larger instrument can be inserted. These small solid instruments in the urethra do not interfere with the passage of urine. By gradually increasing the size every few days, with the patient, of course, under constant observation, it may be possible to obtain a calibre sufficiently large to warrant the employment of gradual dilatation. It is to be remembered, however, that this treatment is applicable only to a small class of cases under constant observation, and requires considerable skill and an intimate knowledge of the treatment of stricture in order to be successful.

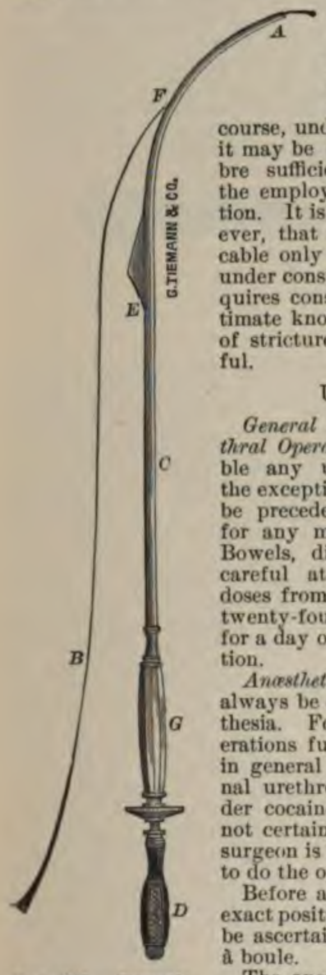

FIG. 4846. — Teevan's Modification of Maisonneuve's Urethrotome.

URETHROTOMY.

General Preparation for All Urethral Operations.—Whenever possible any urethral operation, with the exception of meatotomy, should be preceded by a preparation as for any major surgical operation. Bowels, diet, etc., should receive careful attention. Urotropin in doses from ten to fifteen grains in twenty-four hours should be given for a day or two previous to operation.

Anæsthetics. — Meatotomy may always be done with cocaine anæsthesia. For all other urethral operations full surgical anæsthesia is in general to be preferred. Internal urethrotomy may be done under cocaine, but the anæsthesia is not certain to be complete and the surgeon is likely to feel hurried and to do the operation less thoroughly.

Before any cutting operation the exact position of the stricture should be ascertained by means of bougie à boule.

The operations upon the urethra coming under the head of urethrotomy may be divided into two general groups:

INTERNAL URETHROTOMY AND EXTERNAL URETHROTOMY. — *Internal Urethrotomy.* — This procedure becomes the operation of election under the following general conditions:

1st. Stricture of the meatus. All narrowings of the meatus sufficient to be pathological are best treated by cutting operations, as dilatation in this region is likely to be both painful and unsuccessful.

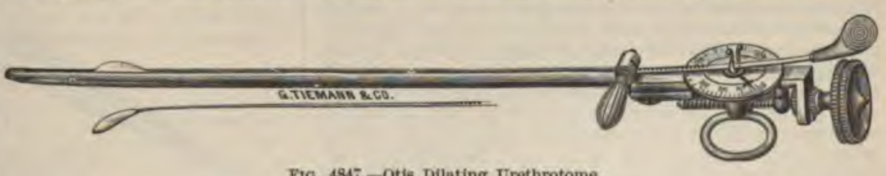

FIG. 4847.—Otis Dilating Urethrotome.

2d. In strictures anterior to the bulb, large enough to admit the necessary instruments, under the following conditions:

(*a*) When gradual dilatation, tried for a sufficient length of time, has failed to give good results.

(*b*) In case of so-called "irritable strictures," namely, those followed by increased discharge, increase of spasm, urethral fever, etc.; also in the so-called "resilient strictures."

(*c*) The presence of urinary fistulæ and other suppurative peri-urethral complications not requiring perineal section.

(*d*) To admit the passage of instruments prior to operations within the bladder, as in litholapaxy or before operation on an enlarged prostate, to permit urethral drainage.

There are two general types of internal urethrotomy:

1st. The operation cutting from before backward. For this the Maisonneuve and modifications of this instrument (Fig. 4846) serve as a type. Briefly described, the operation is as follows:

A filiform bougie is passed through the stricture and the instrument is then attached to this as a guide. The shaft is passed down to the anterior face of the stricture and the knife is then pushed forward until all stricture tissue has been divided. The knife is then withdrawn into its sheath, the instrument removed, and a bulbous bougie or sound passed to ascertain that all the scar tissue has been divided. The objection to operations of this type are that it is difficult to divide the whole thickness of the stricture, and consequently the cutting has to be repeated.

2d. Operation cutting from behind forward.

In this country the instrument invented by Otis, and Wyeth's modification of the same, are much more generally used. These do their cutting from behind forward.

The Otis urethrotome is passed until the cutting blade is half an inch behind the posterior face of the stricture. The instrument is then screwed open until the stricture is put upon the stretch, when the knife is withdrawn so as thoroughly to divide the scar tissue. The instrument is then further screwed open in order to insure full dilatation at the point of incision. A full-sized sound should then be passed in order to ascertain whether or not the calibre of the urethra is normal. This operation is applicable to any part of the urethra anterior to the bulb.

In the portion of the urethra between the bulb and the posterior limits of the fossa navicularis all cutting should be done on the roof in the median line. Strictures in the fossa and at the meatus should be cut upon the floor. Strictures behind the limits above mentioned should not be treated by internal urethrotomy except when combined with external, on account of the danger of wounding large vessels and giving rise to primary or secondary hemorrhage. In all operations within the urethra, except at the meatus or of very minor degrees, it is wise to tie in a catheter for the first day or two. This serves the double purpose of preventing hemorrhage and avoiding a possibility of infiltration of urine.

Meatotomy.—Operations within an inch of the meatus may be done with a blunt-pointed straight bistoury, and, as above mentioned, all cutting should be upon the floor. If preferred, the Otis instrument may be used in the reversed position.

External Urethrotomy.—External urethrotomy becomes the operation of election for the great majority of all strictures at or posterior to the bulb, which require anything more than gradual dilatation. It will be seen, therefore, that the operations anterior to the bulb are amenable to internal, those posterior, to external urethrotomy. This operation is particularly adapted to tight strictures of the bulbous portion, with or without urinary fistulæ; to traumatic stricture; and to all so-called impassable strictures. The type of operation in external urethrotomy will vary with the possibility of passing a guide through the stricture. It has become customary to speak of all operations done with a guide as simply "external urethrotomy." When no guide can be introduced the term "external urethrotomy without a guide," or perineal section, is generally adopted.

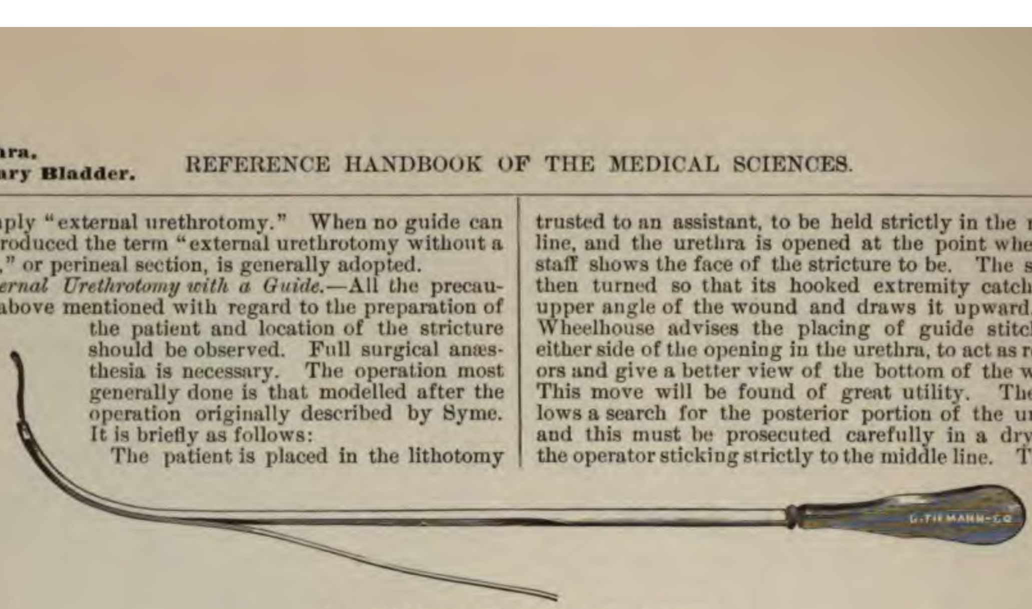

FIG. 4848.—Gouley Tunnelled, Grooved Guide.

External Urethrotomy with a Guide.—All the precautions above mentioned with regard to the preparation of the patient and location of the stricture should be observed. Full surgical anæsthesia is necessary. The operation most generally done is that modelled after the operation originally described by Syme. It is briefly as follows:

The patient is placed in the lithotomy position. A grooved guide is passed, care being taken to ascertain that it has entered the bladder, and is held strictly in the middle line. The knife is then introduced in the middle line of the perineum, about half or three-quarters of an inch in front of the anus or behind the stricture. With the blade of the knife turned upward, it is pushed rapidly forward until it strikes the groove of the guide, when the cut is continued upward, completely dividing all stricture tissue from behind forward. The guide is then withdrawn and a full-sized sound passed to make sure that the stricture is completely divided. This is withdrawn and a catheter is tied in place in order to drain the bladder and form a smooth surface around which the wound may heal. In regard to the length of time during which this catheter should remain in place much difference of opinion exists. Many of the best authorities advise that it should be removed after two or three days, long before the wound is healed and while urinary leakage will still occur freely. It has seemed wiser to me to leave the catheter in place for a week or ten days, or even two weeks, until the wound is nearly closed. It may be necessary to remove the first catheter and replace it by another, but I believe that smooth healing without complication is more likely to be obtained by the adoption of this course than when the catheter is removed in a few days and the urinary fistula allowed to close as best it can.

FIG. 4849.—Wheelhouse Staff.

External Urethrotomy without a Guide.—Perineal Section.—This operation is among the most difficult and tedious of the operations of surgery. It should never be undertaken except by a surgeon who is prepared for a major operation. The best light, the best assistance, and the best surroundings should always be secured. Before deciding to do the operation without a guide a painstaking attempt should be made to pass a filiform bougie through the stricture, for, if this can be done, the operation is converted instantly from one of great difficulty to one of perfect simplicity. Attempts to pass an instrument having failed, two courses are open, one by far the best: to open the urethra in front of the stricture and attempt to find the opening in the stricture (Wheelhouse operation), or the knife may be boldly plunged into the apex of the prostate behind the stricture and the urethra opened at this point (Cock's operation).

Wheelhouse Operation.—For this operation a special straight grooved staff terminating in a hook, invented by Mr. Wheelhouse, is frequently used (Fig. 4849).

With the patient in the lithotomy position, this staff, with its groove upon the floor of the urethra, should be passed down to the face of the stricture. It is then intrusted to an assistant, to be held strictly in the middle line, and the urethra is opened at the point where the staff shows the face of the stricture to be. The staff is then turned so that its hooked extremity catches the upper angle of the wound and draws it upward. Mr. Wheelhouse advises the placing of guide stitches in either side of the opening in the urethra, to act as retractors and give a better view of the bottom of the wound. This move will be found of great utility. Then follows a search for the posterior portion of the urethra, and this must be prosecuted carefully in a dry field, the operator sticking strictly to the middle line. The orifice will frequently be found nearer the roof than the floor and every likely pocket should be searched with a probe until the right one be found. If the bladder be distended with urine, pressure with the hand above the pubes may force a few drops of urine out at the opening, thus giving the key to the situation. Time, patience, and a good light are the prime requisites to success, but in the most skilful hands hours may be consumed in the search. In case of failure, after prolonged search, the bladder may be opened above the pubes and an instrument passed through the urethra from behind forward, or Cock's operation may be done. I am inclined to believe that suprapubic cystotomy and retrograde catheterization is an operation which has been too much dreaded, and that it may frequently be done without running a risk so great as that taken by a prolonged and fruitless search for the urethra. When the orifice has been found, a probe-pointed gorget or grooved director should be passed to the bladder and the stricture divided along the floor or dilated with a proper dilator. After this a full-sized steel sound should be passed to the bladder, it being made to turn the corner at the urethral opening with the assistance of the gorget. This having been done, the bladder should be washed out and a catheter tied in place to secure permanent drainage. Some authorities advise the drainage of the bladder with a perineal tube brought out at the perineal wound and left in position for a few days. I believe that, except in cases complicated with abscess formation or enlarged prostate, an in-lying catheter will secure sufficiently good drainage and promote a more rapid healing of the wound.

Cock's Operation.—This operation may be dismissed with the comment that to plunge a knife blindly into the tissues in order to open a urethra, the position of which is uncertain, is not to-day a sound surgical procedure.

MISCELLANEOUS METHODS OF OPERATION.—*Divulsion.*—The operation of divulsion, though still practised by some of the best genito-urinary surgeons, hardly comes up to the standard of modern accuracy. It is impossible to tell in exactly what direction the splitting force will be exerted, and the rent may occur in an undesirable place. It seems to have no obvious advantages over a carefully practised internal urethrotomy, and is capable of giving bad results through the formation of excessive scar tissue.

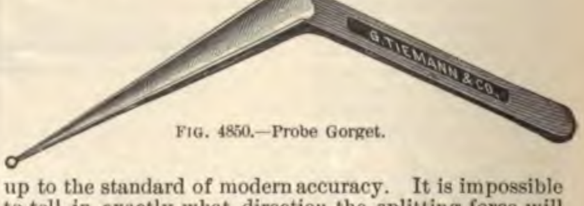

FIG. 4850.—Probe Gorget.

Excision.—A considerable number of surgeons have practised the operation of excising well-localized strictures through a perineal opening. These have been treated by an attempt to bring the ends of the urethra together, by grafting, and by plastic operations. In some of the best cases, however, the ends of the urethra have been left separated and allowed to granulate up over an in-lying catheter. The operation appears to have given excellent results in properly selected cases.

Electrolysis.—The application of electricity to the absorption of strictures has been enthusiastically advocated from time to time. Its advocates have, however, generally been enthusiasts whose results have not been verified by general experience, and it may be confidently asserted that electricity cannot be expected to cure organic stricture of the urethra.

PROGNOSIS OF OPERATIVE TREATMENT OF STRICTURE.—Internal urethrotomy is frequently referred to as a trivial operation, devoid of danger. This statement, however, cannot be allowed to stand in the face of statistics, and a practitioner advising the operation must reckon with a mortality in the vicinity of two per cent., when all cases are taken into consideration. While this is not a large mortality, it is sufficiently important to emphasize the necessity of doing the operation only when it is distinctly indicated.

Uncomplicated cases of external urethrotomy should not have a mortality higher than that of internal urethrotomy. The possibility of complications is, however, considerable, as the strictures of the deep urethra, to which this operation is applicable, are more likely to have affected the other urinary organs, thereby increasing the risk of any surgical operation.

Perineal section is an operation of considerable mortality, which cannot be accurately stated, but is probably in the vicinity of fifteen per cent. This is due to the fact that the cases are much less favorable for operation on account of the frequency of pyelitis and pyelonephritis, and the mortality is not directly due to the operation itself, but to conditions antedating the operation. It must, however, be considered as a distinctly dangerous operation, but the mortality should never deter a properly qualified surgeon, as the conditions which call for it are certain either to prove fatal or to leave the patient in a condition less favorable for operation.

RESULTS OF TREATMENT.—The ultimate results in the treatment of stricture of the urethra may be considered from two points of view:

1st. As affected by the position of the stricture, and

2d. By the method of treatment.

Position of the Stricture.—In general it may be said that the outlook for radical cure decreases with the distance the stricture is situated from the meatus. Stricture at or near the meatus, if treated by a proper cutting operation, is practically alway sentirely relieved. Strictures of the pendulous urethra can generally be radically cured. Strictures of the bulbous and membranous urethra generally require the more or less continuous use of instruments in order to maintain a full calibre.

Method of Treatment.—Gradual dilatation will radically cure a certain number of cases of stricture of the anterior urethra. The exact proportion cannot be accurately stated, but in the majority of cases the full calibre of the urethra is maintained only by the occasional passage of instruments.

Internal urethrotomy is more likely to produce radical cure in properly selected cases of stricture of the anterior urethra. The percentage of cures cannot with certainty be stated at over fifty per cent., and in extensive or narrow strictures it is not notably more successful than gradual dilatation.

External Urethrotomy and Perineal Section.—Strictures of the deep urethra requiring external urethrotomy or perineal section are rarely, if ever, radically cured by operation. A certain amount of recontraction is to be expected, and permanent cure should never be promised to the patient, though it may occasionally result. The old saying, "Once a stricture always a stricture," is nowhere more applicable than to the deep urethra.

Complications of Stricture of the Urethra.—The most serious complication requiring surgical treatment is abscess formation and infiltration of urine. The direction which the septic processes will take has been already described under the section on rupture of the urethra. Where the rupture takes place owing to an organic stricture of the urethra, the process is likely to be more insidious in its onset, but none the less disastrous in its consequences. Extreme destruction of tissue in the region of the bulbous and membranous urethra and in the loose tissue of the scrotum occasionally takes place. The treatment should consist in free incision and drainage of all accessible infected areas, together with relief of the stricture.

Hemorrhage.—Hemorrhage in operations for stricture of the urethra, either internal or external, is rarely serious. When occurring in internal urethrotomy it can be efficiently controlled by the passage of a full-sized catheter to the bladder, followed by pressure along the urethra against the catheter. This can sometimes be exerted by a T-bandage, pressing the parts snugly against the pubes, or by winding a narrow bandage or strip of adhesive plaster about the penis.

Hemorrhage following external urethrotomy can be controlled by pressure or by packing the wound. Care should be taken to ascertain that leakage is not going on backward into the bladder, as evidenced by the occurrence of clots in the urine coming through the catheter, or by failure of the catheter to drain. Should the hemorrhage taking place in this direction be alarming, it may be controlled by the distention of the deep urethra with a perineal tube, combined with packing the wound. These hemorrhages may be primary or secondary, and are rarely of serious note.

Septicæmia.—It is extremely rare to-day that serious general infection follows operations upon the urethra except where rupture of the urethra or abscess formation has already occurred. Much of the improvement is probably due to the use of urinary antiseptics, of which urotropin is at present the most valuable. However, in isolated cases extremely virulent streptococcus infections occur, which are as a rule rapidly fatal. Treatment should be addressed to supporting the patient's condition, and will probably have little effect upon the result. *Hugh Cabot.*

URICIDIN is a granular salt containing the sulphate, chloride and citrate of sodium, the citrate of lithium, and other salts. It is made by adding 20 parts of sulphuric acid and 4 parts of hydrochloric acid to sufficient clarified lemon juice to represent 50 parts of citric acid. This is then nearly neutralized with sodium bicarbonate, 1 part of lithium carbonate is added, and it is evaporated down and granulated. It is employed in teaspoonful doses in gout and rheumatism. *W. A. Bastedo.*

URINARY BLADDER, EXTIRPATION OF.—HISTORY.—The first operation for removal of the bladder was made by Bardenheuer, in 1887, in the male. The first operation in the female was made by Pawlik, in 1888. Since that time more than a hundred cases have been operated upon. In this country the operation has been done by many different surgeons, both in the male and in the female. In the female, Martin, of Chicago, was the first to operate, his first operation being in 1892. The bladder was removed with a uterine fibroid. He has also operated on several other cases. Mann,* of Buffalo, has operated on three cases, the first one in 1900. C. C. Frederick, of Buffalo, E. Reynolds, of Boston, and A. Lapthorn Smith, of Montreal, have each operated once. The operations upon the male for exstrophy have been quite numerous.

INDICATIONS.—The indications for the performance of this operation are: first, incurable disease of the bladder, such as cancer and tuberculosis; second, exstrophy; third, incurable disease of surrounding organs which has begun to involve the bladder, such as cancer of the uterus in the female.

---

* Trans. Amer. Gyn. Soc., 1901.

MANAGEMENT OF THE URETERS.—In the male the method generally proposed has been the grafting of the ureters into the bowel. In 100 cases collected by Bovée the ureter was grafted into the bowel separately 31 times; by the Maydl and Pozza method, 44 times; into the urethra, 13 times; into the vagina, 8 times; and into the skin, 4 times. This is the most important question connected with the operation, and must be clearly understood. As the conditions in the male and the female vary very much, different methods may be used in the two sexes. I will, therefore, first consider the methods in the male.

The first plan used by Bardenheuer was to insert the cut ends of the ureters directly into the rectum. Experimentation upon the lower animals, by Peterson and others, shows conclusively that this is an exceedingly dangerous method, as in almost every case, within a comparatively short time, infection travelled from the bowel to the kidney, and the animal died of this complication. The same thing has been noted in man, and the method is now considered so dangerous as to be practically given up.

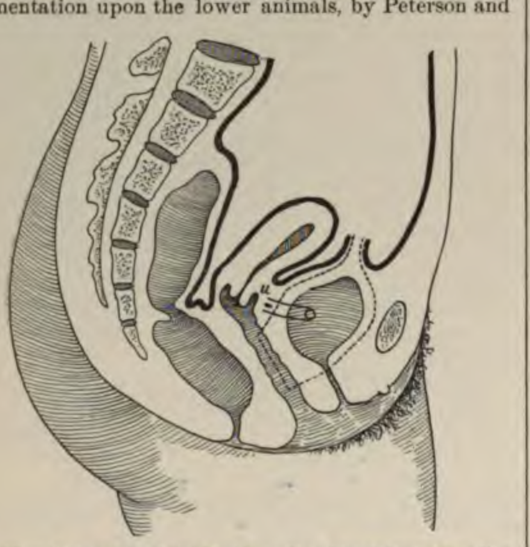

FIG. 4851.—Extirpation of the Bladder. The dotted line shows line of incision. The ureter (*u*) is roughly shown entering the bladder.

Maydl proposed the removal of the trigone of the bladder with the ureters, and the transplantation of this piece of the mucous membrane of the bladder directly into the intestine. The results of this have been very much better, as the natural valvular action at the end of the ureters seems to prevent the ingress of infecting germs; so that many cases in which this has been performed have been permanently successful. This can only be done in cases in which the trigone is healthy, so that in exstrophy of the bladder it is the only recognized method. In the case of malignant disease and of tuberculous disease, which are most apt to affect the posterior wall of the bladder, it may be impossible to dissect out the trigone; in which case it will be necessary to put the cut ends of the ureters into the intestine. But, as this is almost certainly fatal, it would seem to rule out operations for removal of the bladder for these indications in the male in a large proportion of cases.

In the female we have the choice of two methods, both of which have been proved to be successful. We may either open the ureters into the vagina by a previous operation, as was done by Pawlik, or we may leave the cut ends of the ureters opening into the vagina after the removal of the bladder—methods which really amount to the same; or we may perform the operation of Maydl, or, better still, its modification by Pozza.

Pozza's operation differs from Maydl's in that more of the mucous membrane of the bladder is removed, and the trigone is not retained in one piece, but is divided by making a longitudinal median incision before separation. The results of both the Maydl and Pozza operations have been most satisfactory. Out of forty-four cases only two died of infection.

The grafting of the ureter to the skin has been done ten times, but the results are not encouraging. Sonnenberg implanted the exposed ureter of an ectopic bladder into the urethra of the glans penis. In all, more than twelve cases have been done by this method. It leaves dribbling of urine, but this is more easily taken care of than is grafting to the skin.

In the female, when the bladder is removed, by removing at the same time a portion of the anterior wall of the bladder the cut ends of the ureters may be left entirely alone; and, when cicatrization has taken place, they will be found to empty into the vagina. This gives an opportunity of making a receptacle for the urine out of the vagina by simply closing the vaginal entrance. As the urethra must also necessarily be cut in removing the bladder, it also will open into the vagina, and the patient will be able to empty the vagina through the urethra, either by the catheter or by voluntary effort, as was done in Pawlik's case. If the vagina is maintained in an aseptic condition during healing, ascending infection will be prevented. After complete healing of all the parts the danger of infection will be very greatly diminished.

In exstrophy of the bladder, in the female, the Maydl or the Pozza operation may be done on the vagina, thus obviating the necessity of opening the abdomen.

The Mauclaire-Gersuny operation consists in implanting the ureters into the rectum, which is cut off from the bowel above after an artificial anus has been made. Gersuny modified the original operation by bringing the bowel exit into the sphincter ani, thus doing away with the artificial anus and maintaining a separate receptacle for the urine.

TECHNIQUE.—*Exstrophy in Men.*—The trigone is first dissected out with the ureters. The abdomen is then opened and the trigone carried into the rectum through an incision and sewed in place. After this the bladder is removed and the opening closed. The incision may be made curved, with its concavity downward from one inguinal canal to the other; a vertical incision may be made which can be enlarged by a transverse incision crossing the lower end of the vertical one.

In women the Pozza operation will be necessary, in order to get around the uterus. If it is desired to transplant the ureters into the vagina, a transverse incision may be made down to the peritoneum. After the trigone has been dissected out, the vagina can be pushed up by an assistant and opened and the trigone inserted. It will be necessary to dissect off the mucous membrane of the vagina on the anterior wall beforehand, so as to make a raw surface to which the trigone can adhere. The closure of the vagina can be left to a later date.

Cancer or Tuberculosis in the Male.—Although the indication may seem to be urgent, so far the technique of the operation is not complete enough to warrant its performance unless the parts around the bladder are healthy. This can be satisfactorily ascertained only after the bladder is opened. Suprapubic cystotomy must first be performed, and the bladder carefully examined. If the trigone be healthy, the abdomen must then be opened by a free longitudinal incision, the bladder thoroughly disinfected and laid open, and the trigone may then be dissected out (the patient being in the Trendelenburg position), with the ureters, and put into the rectum; after which the bladder may be easily removed, mostly by blunt dissection.

Cancer or Tuberculosis in the Female.—Owing to the fact that the ureters may be left undisturbed in the female, the operation is much easier than in the male. After the bladder has been carefully washed out, a median abdominal incision is made, and the patient put in the Trendelenburg position, self-retaining retractors being introduced. The peritoneal covering is then incised over the bladder from side to side. The bladder is afterward loosened with the finger down to the attachments of the base, so that it is held only by the urethra, ureters, and attachments to the anterior wall. These are then cut with strong scissors, so as to remove a portion of the anterior wall of the vagina as big as a fifty-cent piece. Any bleeding vessels are tied and the peritoneum closed over the seat of the bladder with catgut suture. If the patient be in good condition, and no previous infection of the bladder exists, the vaginal entrance may then be closed by a plastic operation.

AFTER-TREATMENT.—In order to keep the urine aseptic, and thus prevent ascending infection of the ureters, in all these operations it is well to give the patient large doses of benzoate of ammonium, beginning a few days before the operation. In women the vagina must be kept well cleansed out and drained. If the vagina be closed at the time of the operation, a self-retaining catheter should be passed through the urethra and left, the vagina being washed out through the catheter at least twice a day.

RESULTS.—Bovée has collected 100 operations. Of these the operation was done 21 times for malignant disease, 3 times for tuberculosis, once for epispadias, once for fibroid of the uterus, and 5 times for conditions not noted.

In exstrophy Maydl's operation was done 38 times, with 8 deaths; Pozza's operation, 4 times—no deaths; anastomosis of the ureters into the rectum, 10 times, with 3 deaths; and separate anastomosis into sigmoid, twice, both patients dying. Sonnenberg's operation was done 13 times—no deaths.

For malignant disease 21 operations were done, with 11 deaths.

In 7 the ureters were grafted into the vagina, with 1 death from collapse, and 1 from peritonitis on the ninth day.

For tuberculosis, 3 cases, with 2 deaths, are reported.

Altogether there were 26 deaths in 100 cases. Sixty-nine operations for exstrophy gave 19 per cent. mortality, and 31 operations for other conditions gave 42 per cent. mortality. *Matthew D. Mann.*

URINARY SEDATIVES.—The conditions which require the use of urinary sedatives may be dependent upon some state of the urine itself or upon something entirely independent of it.

1. Certain drugs may cause intense irritability of the whole urinary tract—as, for example, cantharides and turpentine. A very acid urine or one containing crystals of uric acid or of calcic oxalate may give rise to symptoms of irritation. Again, a decomposing urine may produce similar effects. An alkaline urine, especially when associated with phosphaturia, may also give rise to discomfort.

2. We may begin at the kidney and find an occasional exciting factor outside of the urine itself, even as far down as the meatus. Pyelitis is a frequent cause, as are cystitis and vesical calculus. In women a uterus which is anteverted pushes into the bladder, while a retroverted uterus may pull upon that same viscus. Pelvic tumor, either prostatic in men or of the various kinds to which women are liable, may diminish the size of the bladder by direct pressure, or by traction, to such an extent that the desire to empty it is very frequent. Tumors of the bladder have a similar effect at times, though in these cases the sense of a foreign body in the bladder seems very often to furnish the stimulus. Stricture of the urethra seldom gives signs of urinary irritability until, in the process of contraction, it has reached such a small calibre that there is back pressure in the bladder. Finally, an adherent and tight foreskin is a well-known cause of occasional nocturnal, or even diurnal, incontinence, in children. We have thus very briefly suggested the more frequent causes of urinary irritability, as we can only hope for relief in a given case by carefully studying out the exciting factor. No good can be gained and much harm may be done by trying to cure all cases with any one remedy.

3. To the two classes of irritability mentioned we must add a third, in which we can find no tangible stimulus, and have to fall back upon a purely nervous origin for the affection.

Many remedies which have in the past been considered valuable in these cases have in recent years fallen into disuse; some deservedly as of little value, others through having been supplanted by more powerful drugs, acting in the same manner and more convenient to use.

As regards the cases which are due to some condition of the urine itself, an excessively acid urine can be rendered less irritating either by increasing the ingestion of liquids, and so diluting it, or by giving one of the alkalies. The citrate or acetate of potassium is most useful in these cases. Few patients will drink enough water unless given specific directions. Each of the salts named, when given in fairly large doses, has the effect of producing thirst and thereby making it easier for the patient to take enough water, while at the same time it renders the urine alkaline. Care should be taken not to make the urine too alkaline, lest we get a deposit of phosphates. If we are confronted by an excessively alkaline condition of the urine, it can be corrected by giving a drug that will change the reaction. The mineral acids are of little or no value for this purpose. Benzoic acid is useful. Given as benzoate of sodium, by the mouth, it is excreted in the urine as benzoic acid, which, besides the effect of rendering the excretion acid, also exerts an antiseptic effect. Ten grains given in a glass of water three times a day is usually enough. Urotropin makes the urine acid, and causes rapid disappearance of the phosphates in cases in which they are deposited in alkaline, neutral, or slightly acid urine. Five grains, given well diluted twice a day, is an ordinary dose. It is particularly valuable in the cases in which the urine is alkaline from decomposition, as it is broken up in its passage through the body, and the formalin which is set free is eliminated by the kidneys. In these cases the dose may have to be considerably increased. The bactericidal action of this remedy is marked. Boric acid in sufficient doses will render the urine acid, but it is less well borne by the stomach than are the remedies mentioned. Salol will give an acid urine, and is often of value, especially in cystitis.

In cases in which the irritability is due to crystals of uric acid or of oxalate of lime, measures looking to the elimination of the source of the crystals are needed. The usual antirheumatic remedies will remove the excess of uric acid. At times there is much difficulty in preventing the formation of oxalate-of-lime crystals. In the obstinate cases, in which other methods fail, one or two drops of strong nitro-muriatic acid, taken after meals in a full glass of water, will relieve the difficulty.

A careful regulation of the diet is of great importance in these cases. The amount of meat should be restricted when the uric acid is in excess. It should be borne in mind that fruit at times, and rhubarb often, cause an excess of calcic oxalate in the urine. Hæmaturia has been known to follow after eating rhubarb, so great was the irritation caused by the calcic oxalate crystals.

In case the discomfort comes from the use of certain drugs, as cantharides or turpentine, the omission of the medicine would at once suggest itself.

Alcohol is always contraindicated in any inflammation of the genito-urinary tract, and we often see the first serious symptoms, in a prostatic or stricture case, follow the ingestion of even a moderate amount of alcohol. A source of irritation which is often not considered is ginger ale. This is especially harmful in gonorrhœa, and I have seen a severe exacerbation follow its use. Under the same conditions highly spiced foods, such as curries, Welsh rarebit, etc., should be carefully avoided.

Pyelitis, whether of tuberculous or of some other origin, must needs be treated by drugs; some medicine must be used which is eliminated by the kidneys. Of these, probably all owe their value almost entirely to their antiseptic action. The remedies promising most are urotropin, buchu, uva ursi, pareira brava, and chimaphila. Urotropin is best given in doses of five grains three times a day. The dose of the fluid extract of each of the other drugs mentioned is a teaspoonful, well diluted, three or four times a day. These all have a slight antiseptic action, as shown by the diminished tendency to decomposition when the urine is left standing. This is particularly true of urotropin, but in very large doses it may cause some frequency of urination by rendering the urine too acid. Uva ursi has some diuretic action, as has also chimaphila. Buchu does not increase the amount of urine appreciably. In the very chronic form the stigmata of Zea Mays will be found a more effective remedy, as they stimulate the renal epithelium directly. A teaspoonful of the fluid extract may be given every four hours. In rare cases, in which something stimulating is required, small doses of turpentine may be of value. If the pyelitis be associated with renal calculus, a surgical operation, with removal of the stones and temporary drainage of the kidney, offers the best hope of permanent relief. By correcting the reaction of the urine we may prevent any increase in the size of the stones, but the chance of causing them to dissolve is remote. Hyoscyamus, phenacetin, belladonna, and opium in its various preparations, afford temporary relief. Sweet spirits of nitre at times helps and may relieve the vesical tenesmus, which is often associated with this disease. In tuberculous cases there is little hope of permanent relief except through nephrectomy or through the breaking down and complete disappearance of the organ, in consequence of which it will cease altogether to secrete any urine. In these cases the pain is often referred to parts of the urinary tract which are situated lower down and which are not involved in the disease.

In the cases due to diminution of the size of the bladder from extraneous causes the removal of those causes at once suggests itself. In prostatic hypertrophy the flow from an overdistended bladder may easily be mistaken for abnormal frequency of urination. This possibility should be investigated before seeking for a further cause. Overdistention may also occur in connection with a stricture of small calibre. Drawing off the residual urine under the strictest aseptic precautions one or more times daily may entirely relieve the symptoms. The administration of five grains of urotropin three times a day diminishes the danger of cystitis. In cystitis an antiseptic which will be eliminated in the urine is indicated. In many cases washing out the bladder once or twice a day with an antiseptic solution, such as a four-per-cent. solution of boric acid, is necessary. When stronger antiseptic washes are needed, one of permanganate of potassium or of citrate of silver will be found serviceable. Nitrate of silver is more stimulating and should seldom be used in solutions of more than one grain to the ounce. Pareira brava is said to be useful in chronic catarrh of the bladder. It checks bleeding in these cases and diminishes the muco-purulent secretion. Cubebs, copaiba, and sandal-wood, though more effective in irritation of the urethra, exert their influence through the medium of the urine and are of use in bladder affections. This is especially so of the oil of sandal-wood. All of these drugs resemble each other closely. It should be borne in mind that while they are being taken the urine is somewhat irritating. When they are given in large doses, they give rise to a constant desire to urinate, and the pain and difficulty in doing so are great. In some cases, in which the bladder and urethra are much inflamed, the pain may be so great as to lead to complete retention. The ordinary dose of each of these drugs is ten minims three times a day. They are best given in capsules, as the taste is disagreeable. Even in doses of ten minims twice a day the oil of sandal-wood at times gives so much backache that it has to be discontinued.

For the relief of the pain and frequency of urination associated with the presence of a calculus in the bladder, operation alone is of any avail. Morphine or belladonna or a combination of the two may afford great temporary relief.

At times we are forced to abandon our search for a tangible cause and fall back upon a neurosis as an explanation of the trouble. Here we may expect relief from the use of nervous sedatives, such as one of the bromides or hyoscyamus. Treatment of the condition through the urine proves as a rule unsuccessful, and washing out the bladder often only aggravates the patient's suffering. In the tenesmus of tuberculosis washing the bladder is generally worse than useless, especially if we have to pass a catheter for this purpose.

In the cases in which we need urinary sedatives, when the cause lies in the urethra itself, copaiba, sandal-wood oil, and cubebs give great relief. In the intense burning which accompanies micturition and which does not yield to internal medication or local treatment, the injection into the urethra of a two-per-cent. solution of cocaine alleviates the distress temporarily. In men, urination with the penis submerged in water as hot as can be borne, often gives relief.

Finally, in those cases of incontinence in children in which the trouble does not yield to belladonna in full doses, and appears to be caused by an irritable bladder, circumcision at times effects a cure.

Franklin G. Balch.

URINE.—Physical Properties. Quantity.—The amount of urine voided is dependent (1) on the state of the renal epithelium; (2) on the rapidity of the blood flow through the kidneys. It is independent of the blood pressure.

A normal healthy adult of the average weight of 75 kgm. passes from 1,500 to 2,000 c.c. of urine in twenty-four hours. Infants pass absolutely less, but, in proportion to their body weight, relatively more urine; this is largely due to the liquid diet. Abundant ingestion of fluids increases diuresis (*urina potus*); sweating (violent exercise, hot weather) decreases it. Less urine is normally passed at night than during the day; in chronic nephritis this ratio may be reversed.

Pathology.—Destructive renal lesions or local circulatory disturbances, in order to influence the flow of urine, must be bilateral; unilateral interference with diuresis is compensated by the healthy organ.

(*a*) *Polyuria.* The more chronic the nephritis the greater the tendency to polyuria (contracted kidney, amyloid). This is chiefly due to the contraction of the renal tissues and the resulting acceleration of the blood flow. During convalescence from acute nephritis; in heart and lung disease as soon as the circulatory disturbances begin to be compensated; in diabetes mellitus, and insipidus; after psychic shocks, and in various neuroses (*urina spastica*); after the exhibition of certain drugs (see *Diuretics*), and after the ingestion of certain articles of food (tea, coffee, alcohol, etc.)—the flow of urine is increased.

(*b*) *Oliguria.* In acute nephritis, in acute exacerbations of chronic nephritis, and in heart and lung diseases leading to stasis the flow of urine is decreased.

(*c*) *Anuria.* In uræmia (occasionally), in diseases causing great loss of fluids through other emunctories than the kidneys (acute gastritis and intestinal catarrh, with profuse vomiting and diarrhœa, cholera, dysentery), in rapidly progressive forms of anæmia, and in hysteria, the urine may be altogether suppressed.

Determination.—The urine should preferably be collected from morning to morning before eating; the bladder should be emptied before the collection is begun; the patients should urinate before going to stool, as, particularly in old women, much urine may be lost during the act of defecation. The total quantity may be measured or determined by weighing; the weight multiplied by the specific gravity yielding the volume. For clinical purposes the former method is best; for exact determinations the latter is to be preferred.

The Specific Gravity.—The specific gravity of the urine is, as a rule, high when little urine is voided and low when the flow of urine is abundant. The same factors, therefore, that determine physiological fluctuations in the amount of urine also determine corresponding fluctuations in its specific gravity. As the normal total quantity varies from 1,500 to 2,000 c.c., so the normal specific gravity varies correspondingly from 1.025 to 1.015.

The specific gravity of the urine is an index of the excretion of urinary solids. If the latter were all heavier than water, the last two figures of the specific gravity (expressed in four figures) would directly indicate the quantity by weight of urinary solids contained in one litre of urine. As some of the excreta are, however, heavier than water, or of the same specific gravity, their weight is greater than indicated by these two figures. It has been found empirically that the last two figures of the specific gravity multiplied by 2.2337 give the weight in grains of the solids in one litre of the urine. [Example: Specific gravity = 1.018; 18 multiplied by 2.2337 = 40.2066 grains of solids in one litre of urine.] This calculation, while not absolutely accurate, is useful for comparative studies.

Pathology.—In severe *febrile diseases* the specific gravity is usually low without a corresponding increase of urine as soon as the patient's vitality begins to flag and general metabolism is reduced.

In *acute and subacute nephritis* the specific gravity is usually high, the water excretion correspondingly reduced. In the healing stage of acute nephritis the flow often increases, whereas the specific gravity remains low; this indicates that the kidneys are regaining their power to excrete water, but not as yet to eliminate solids. In acute exacerbations of *chronic nephritis* and in the terminal stages of destructive inflammation and degeneration of the kidneys the specific gravity is reduced; when it occurs suddenly, this is a bad prognostic omen, and often indicates threatening uræmia. In contracted kidney the specific gravity is low and the flow abundant. In diabetes mellitus the flow is great and the specific gravity very high, whereas in diabetes insipidus the flow is also great, but the specific gravity very low.

Determination.—The specific gravity may be determined (*a*) by weighing with a hydrostatic balance, (*b*) with a pyknometer, and (*c*) with an aerometer. The first method is useful only in very exact work, and requires a complicated balance; it will not be described here. The second and third methods are useful for clinical work. In ordinary comparative studies the aerometer is quite sufficient.

The *pyknometer* is a flask with a long neck that is drawn out in one place (see Fig. 4852); at the narrowest point is a mark; the flask is closed with a ground-glass stopper. The flask is first filled with distilled water to the mark and weighed; it is then filled with the filtered urine to the mark and weighed again. The weight of the urine divided by the weight of the water gives the specific gravity. It is very important that the temperature of the water and that of the urine should be exactly alike when the pyknometer is filled and when it is weighed. For other forms of pyknometers than the one shown in Fig. 4852, see text-books.

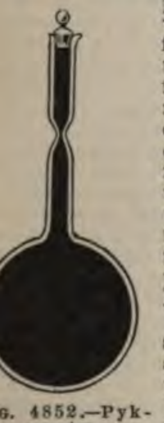

FIG. 4852.—Pyknometer.

The *aerometer* (urometer). This instrument consists of a glass cylinder and a float (see Fig. 4853). The latter should be graduated from 1.000 to 1.040. It is better to have two floats, the one reading from 1.000 to 1.020 and the other from 1.020 to 1.040. The urine is poured into the cylinder, the float introduced into the urine, and the specific gravity read off directly from the aerometer scale. Here, too, the temperature is important; it should be about 17.5° C., for the aerometers are graduated at this temperature. If the urine is warmer than 17.5° C., one-third of a urometer degree should be added for each degree of temperature; if the urine is colder than 17.5° C., the reading should be corrected by subtraction—one-third urometer degree for each degree of temperature. [Example: Urine 20.5° C., specific gravity 1.017. Corrected, $1.017 + 3 \times \frac{1}{3} = 1.018$.] A temperature scale is found on many urometers.

REACTION.—Normal urine is never neutral to litmus; it is either acid, amphoteric, or alkaline. The acidity is never due to the presence of free acid, but to the excess of acid salts (monobasic phosphates and urates) over alkaline salts (dibasic phosphates and urates). When the two are mixed in certain definite proportions the reaction becomes amphoteric. The urine becomes alkaline after eating (HCl—secretion) and after the ingestion of certain salts of vegetable origin (citrates, tartrates, etc.), as the latter are excreted as carbonates. Old urine is usually alkaline as the micrococcus ureæ generates ammonium carbonate.

Pathologically the acidity of the urine is always increased in febrile processes, for here increased katabolism of proteid with liberation of sulphuric and phosphoric acids from proteid-sulphur and proteid-phosphorus occurs. In leukæmia, scurvy, and diabetes the urine is also in general acid.

Increased alkalinity is a valuable sign only if the above-named physiological factors can all be excluded. It is important to determine whether the urinary alkalinity is due to the liberation of ammonia or to the presence in solution of fixed alkali. Free ammonia signifies fermentation of the urine and points to cystitis. Fixed alkali appearing in excess in fresh urine may be due to the withdrawal of acid from the body (vomiting and frequent lavage), to the admixture of alkaline secretions from the urinary passages, or to the rapid absorption of exudates and transudates.

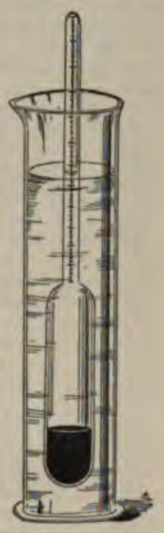

FIG. 4853.—Aerometer.

Determination.—For clinical purposes the litmus test is sufficient: blue litmus paper turning red in acid urine, and red litmus paper turning blue in alkaline urine. If the blue color remains after the paper dries, the alkalinity is due to fixed alkali; if it vanishes, to free ammonia.

Optical Properties.—(*a*) *Color.* The color of the urine is dependent on its concentration, its reaction, and the pigments it contains. Normal urine may be from pale yellow to reddish-brown. The greater the concentration the darker the color. Acid urine becomes more pale when it is alkalinized, and alkaline urine darker when it is acidified.

Certain pathologic pigments change the color of the urine. Bile pigment colors it green or brown, blood pigment red to brown red, urobilin dark brown, and melanin brown to black. Certain aromatic decomposition products that are found in the body (indican, phenols) cause the urine to turn dark on standing. Certain fruits (cherries, raspberries, etc.) and certain medicaments impart a characteristic color to the urine (see carbolic acid, coal-tar preparations, resorcin, naphthol, salol, chrysarobin, rheum, senna, santonin, etc.).

(*b*) *Fluorescence.* Pale yellow normal urine shows a bluish, yellowish-red urine, a greenish or yellow fluorescence. Urine containing albumin shows more fluorescence than normal urine, and ammoniacal urine more than urine that is not decomposed.

(*c*) *Behavior toward Polarized Light.* Normal urine is almost always slightly lævorotary; it is never dextrorotary, and hardly ever optically inactive. The presence of certain abnormal constituents (dextrose, levulose, glycuronic acid, etc.) produces typical polarimetric phenomena that will be described below.

(*d*) *The Spectrum.* Normal urine shows no absorption bands, but the coefficient of light extinction varies in different regions of the spectrum. In pathologic urines hæmatoporphyrin, uroerythrin, and urobilin produce typical spectra (see below).

ODOR.—Fresh normal urine has a characteristic odor that is not disagreeable. The disagreeable, so-called, urinous odor is due to the presence of bacterial decomposition products (probably ammonia and phenols). Occasionally the urine emits an odor of H_2S (hydrothionuria). Certain substances impart a characteristic odor to the urine when taken by mouth (valerian, garlic, copaiba, cubebs, saffron, turpentine [violets], etc.). The peculiar odor of the urine after eating asparagus is due to methyl-mercaptan.

TRANSPARENCY.—Normal acid urine is clear, for the normal acid and neutral salts of the urine are all readily soluble in water. Normal acid urine becomes cloudy if more quadriurate is excreted than can be dissolved in the urinary water. Normal alkaline urine is always cloudy, for the alkaline salts of the urine (*i.e.*, normal phosphates and carbonates and diphosphates of the alkaline earths) are essentially insoluble in water or in the mixture of neutral and acid salts in solution in the urine. The proteid constituents of clear urine are not in true solution, but in colloidal solution; hence the tendency of the urine to filter with decreasing rapidity. The scanty epithelia, the mucin bodies, and the crystals in suspension in normal urine form a fine cloud (nubecula) on standing.

FREEZING POINT (CRYOSCOPY).—The freezing point of the urine may be considered an index of the osmo-regulating function of the kidneys. The attempt has been made to utilize freezing-point determinations ("cryoscopy") in the diagnosis of renal diseases. The results obtained so far by different investigators are, however, ambiguous, even contradictory, so that this method is for the present of subordinate importance. This field is nevertheless promising, and as soon as the technique shall be simplified and perfected cryoscopy may become a valuable laboratory adjuvant to diagnosis. For a review of the complete literature to date see H. Strauss: *Zeitschr. f. klin. Med.*, 1902, vol. xlvii., pp. 337 to 407.

ELECTRIC CONDUCTIVITY.—The resistance offered by the urine to the passage of an electric current has been utilized in order to determine the quantity of mineral salts present in the urine. There is without doubt a connection between the total ash of the urine and its conductivity. Only those urinary constituents can be estimated by determining the electrical conductivity that are electrolytes, and it might be imagined that the large number of non-electrolytes that may be present in normal and pathological urines would interfere with this determination. It has been shown, however, that such bodies as urea, uric acid, even sugar and albumin in the quantities ordinarily present in pathologic urine, exercise only a very small effect in lowering the conductivity of the urine. The conductivity of the urine is essentially, therefore, a function of the total mineral content, and the determination has a significance similar to that of the determination of the specific gravity. It is, however, more accurate. This method, when simplified as to technique, will prove a valuable aid in the determination of the eliminatory power of the kidneys for inorganic constituents. In combination with similar determinations with the blood serum it promises to throw much light on the pathology of renal insufficiency and of a variety of metabolic disorders.

CHEMICAL EXAMINATION.

ORGANIC CONSTITUENTS.

THE ALBUMINS.—*Albuminuria.—Physiological Albuminuria.* Every urine contains traces of albumin that are derived from cellular elements. This albumin is nucleo-albumin and differs from the albumins of the serum; the quantities normally present in the urine are so small that they cannot be detected by ordinary tests; the substance must first be isolated from large quantities. Every albuminuria of an *hæmatogenic* type must be considered pathological, and the conception of a *physiological* excretion of serum-albumin that some authors advocate should be discarded. All that the term physiological albuminuria implies is that a small quantity of blood albumin may occasionally be excreted in apparently healthy subjects; that this albuminuria may be transitory, and that it may lead to no serious consequences. A biologic phenomenon, however, because it is innocent, need not, therefore, be physiological. Transitory albuminuria in otherwise healthy persons (muscular exercise, cold bathing, pregnancy, and psychic shock) must always be attributed to circulatory disturbances in the kidneys or to slight nutritional impairment of the glomerular or tubular epithelia. Subjects with such albuminurias should always be considered predisposed to proper renal disease.

Pathological Albuminuria. Fluids containing albumin (pus, blood, lymph, cystic fluid, and sperma) may enter the urine below the kidneys (*albuminuria spuria extra-renalis; pseudo-albuminuria*), or soluble albumin may enter the urine within the kidneys from the blood (*albuminuria vera-renalis*). The two forms can usually be differentiated without difficulty. In *A. extra-renalis* the centrifuged and filtered urine contains only a small percentage of albumin as compared to the number of cellular elements in the sediment. If the latter consists of pure pus, the albumin percentage in the filtrate compared with the number of cellular elements in 1 $mm.^3$ of the sediment should be as 1:50,000. If it exceeds this proportion, then the albuminuria should not be considered due to the admixture of pus alone. In affections of the kidneys that produce only a slight degree of true albuminuria (contracted kidney) the combination of extra-renal albuminuria (*e.g.*, cystitis) and renal albuminuria may be difficult to recognize. Here the study of the cellular sediment, on the one hand, of general clinical symptoms (heart, arteries, and retina), and of certain peculiarities of the urine (quantity and specific gravity) on the other, must determine the diagnosis.

In *A. renalis* the excretion of albumin may be due to (1) inflammatory and degenerative lesions of the renal tissues; (2) circulatory disturbances in the kidneys; (3) certain febrile diseases (bacterial toxins and lowered blood pressure); (4) anæmia and cachexia (hæmatogenous albuminuria). Finally, there are certain forms of cyclic and intermittent albuminuria of unknown etiology occurring in healthy subjects or in sufferers from very chronic types of nephritis.

In acute nephritis the percentage of albumin is high (as high as five per cent., although usually not above one per cent.). In certain chronic forms of nephritis the percentage may be equally high. As a rule, however, the more chronic the nephritis the smaller the percentage of albumin. In very chronic forms there may even be no albumin at all.

In true albuminuria the urine may contain the following albumins alone or in combination: (1) Serum-albumin (serin); (2) serum globulin (paraglobulin); (3) mucin (nucleo-albumin); (4) albumose; (5) peptone; (6) fibrin (fibrinogen?); (7) hæmoglobin (methæmoglobin); (8) "Bence-Jones albumin"; (9) histon and nucleo-histon.

Serum Albumin and Globulin.—These two albumins almost invariably occur together in pathological urine. The proportion of the two, the so-called "albumin quotient" (serum-globulin), varies greatly in different cases. It may, moreover, differ not only from the quotient of normal serum, but also of the serum of the nephritic patient. The tests for serum-albumin and globulin may be described together.

Tests. Only those four tests are given here that are of value clinically and that render it possible to differentiate these albumins from albumoses, nucleo-albumins, etc. For the numerous other albumin reactions I refer to text-books of physiological chemistry.

1. The Nitric Acid Test.—A small quantity of cold filtered urine is poured into a test tube and a few cubic centimetres of concentrated nitric acid allowed to slowly

flow down the sides of the vessel. If albumin is present, an opaque zone forms at the plane of contact; if the amount of albumin is small, the ring may not form for one or two minutes.

Urates, certain balsams, and resins may form a similar ring; the albumin ring, however, begins at the plane of contact and extends upward, whereas the urate ring is more apt to begin above the plane of contact and gradually extend down to the acid. The urate ring, moreover, does not appear if the urine is well diluted. It also disappears on heating. The ring produced by balsams and resins is soluble in ether, and may be made to disappear by heating the liquid with this solvent. Nucleo-albumin and albumoses also form a ring with nitric acid. The test should always be repeated with diluted urine; if the ring becomes thicker in the diluted urine, the presence of nucleo-albumin is rendered probable. The albumose ring disappears on heating and reappears on cooling, the liquid meanwhile turning bright yellow; if the liquid becomes only partially clear on heating, albumin and albumoses may be present together. Urea, if present in large quantities, may crystallize out in this test as urea-nitrate and form a white zone above the acid. The crystalline character of this precipitate usually reveals its origin. If the urine contains much pigment or indoxyl multicolored rings may appear below the albumin ring.

2. The Boiling Test.—The urine is slightly acidulated with acetic acid and boiled. A flocculent precipitate may be due to the presence of albumin or of earthy phosphates. One or two drops of nitric acid for every cubic centimetre of the urine are now added; if the precipitate dissolves, it consisted of phosphates; if it does not dissolve, or if it becomes more intense, it consisted of albumin. Care must be taken to add just enough nitric acid, for, if too little is added, only a portion of the basic phosphates is converted into acid phosphates and the albumin in combination with a base (albuminate) remains in solution; if too much nitric acid is added, albumin-nitrate forms, and this, too, remains dissolved. The danger of dissolving the albumin in an excess of acid is decreased if acetic acid is used instead, and if the urine, prior to boiling, is mixed with one-sixth volume of saturated sodium chloride solution.

Bence-Jones albumin also coagulates on heating in acid urine, but at a low temperature (50° C.), and on boiling this coagulate disappears. Albumoses and nucleo-albumins (mucins) are not precipitated by this test.

3. The Potassium Ferrocyanide Test.—This is the most delicate one of the ordinary clinical tests. The urine is rendered strongly acid with acetic acid and a ten-per-cent. solution of potassium ferrocyanide, added drop by drop. If albumin is present even in traces, a cloudiness appears at once; if large quantities are present, a flocculent precipitate appears. In this test the urine should first be filtered until it is clear; if owing to the presence of microbes the urine cannot be cleared, a specimen of the urine should always be compared with the specimen treated with the reagent in order to determine whether the cloudiness has become more pronounced in the latter. It is well to dilute the urine for this test.

Albumoses are also thrown down, but they dissolve on boiling the liquid and reappear on cooling. If the urine contains much mucin or urate, precipitates form when the acetic acid is added; but they can both be made to disappear if the urine is warmed.

4. The Biuret Reaction.—The urine is treated with potassium hydrate solution and a ten-per-cent. copper sulphate solution added drop by drop. In the presence of albumin alone the liquid turns pure violet; in the presence of albumoses or peptones it turns rose; if albumin and albumoses or peptone are present together, the urine assumes tints intermediary between violet and rose. If small quantities of albumins are present, care must be exercised not to add too much copper solution, as otherwise the violet or rose tint is obscured by the blue of the reagent.

Special Test for Globulin.—The excretion of globulin is of subordinate clinical interest; only a few cases are on record in which it appeared alone in the urine; occasionally, however, it may be desirable to examine the urine for its presence. The following method is practical:

The urine is mixed with an equal volume of saturated ammonium- or magnesium-sulphate solution; this precipitates the globulins and albumoses, but leaves the serum-albumin in solution (the latter being precipitated only if the urine is saturated with the above salts). The precipitate is dissolved in one-per-cent. soda solution and the liquid acidified with acetic acid. Albumoses remain in solution while globulins are precipitated, and this precipitate, moreover, is insoluble in sodium chloride solution.

Quantitative Estimation of Coagulable Albumin.—For accurate determinations a measured quantity of the urine should be acidified and boiled, the coagulate collected in a weighed filter, washed with water, alcohol, ether, dried to a constant weight, and weighed. A nitrogen determination is then made with a portion of this residue (Kjeldahl method, see below), and the value obtained multiplied by 6.25 (albumin contains 16 per cent of N; if therefore we find X nitrogen, this corresponds to $\frac{100}{16} = 6.25$ times X of albumin). The figure obtained by this multiplication indicates in grams the amount of albumin present in the quantity of residue used for the determination. From this the amount present in the total urine can be calculated.

For ordinary clinical purposes of comparison the method of Esbach is sufficiently accurate. The method is based on the precipitation of albumin by picric acid. The apparatus used is called Esbach's albuminometer (Fig. 4854) The tube is filled with urine to *U* and with reagent to *R*. The two liquids are thoroughly mixed by inverting the tube several times. The apparatus is then allowed to stand for twenty-four hours at room temperature and the height of the column of precipitate determined. The figures ½ to 7 on the apparatus below *U* indicate the amount of albumin in grams per litre of urine; if, therefore, *e.g.*, the height of the column of coagulate corresponds to 3, the urine contains 3 gm. of albumin to the litre (1,000 c.c.), or 0.3 per cent. Esbach's reagent is 10 gm. of picric acid and 20 gm. of citric acid dissolved in 1 litre of water. In this test the reaction of the urine should be acid, its specific gravity not above 1.010, and it should not contain more than 0.4 per cent. of albumin; otherwise the determination is not accurate. It will be necessary, therefore, as a rule, to dilute and acidify the urine prior to making the determination. Occasionally the precipitate of albumin will not settle; then this method cannot be employed; nor can it be employed if the urine contains quinine or antipyrin.

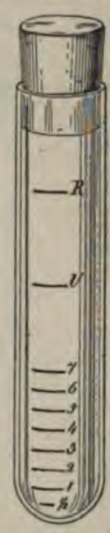

FIG. 4854.—Esbach's Albuminometer.

Nucleo-Albumin (Mucins).—The mucin of the older writers has been shown to consist of albumin in combination with one of these acids that are usually present in the urine, viz., nucleinic acid, chondroitin-sulphuric acid, and taurocholic acid. On the addition of acetic acid to the urine these compounds are precipitated as nucleo-albumin, chondro-albumin, and albumin taurocholate. These bodies alone or combined form "mucin," and it is quite clear that the character of this substance must vary according to the relative quantities of these acids present in the urine. The taurocholate is often absent from normal urine, but it is present in abundance in icteric urine. Chondro-albumin is a glycoproteid and can be split into proteid and carbohydrate, while nucleo-albumin is a "phosphorous proteid" and can be split into proteid and nuclein.

Mucins are always present in traces in normal urine. They are excreted in excess in desquamative catarrh of the urinary passages, in infectious forms of nephritis (diphtheria and scarlatina), in toxic nephritis (tar, pyrogallol, corrosive sublimate, arsenic), in typhoid fever, in croupous pneumonia (disappearing within twenty-four to forty-eight hours after the crisis), after chloroform anæsthesia, and, particularly, in icterus.

Tests. Clouding of the diluted urine with acetic acid speaks for the presence of mucin bodies; if the mixture is shaken with chloroform or ether, a cloudy ring of mucin forms at the plane of contact after the liquids have been allowed to separate. Mucins give the nitric acid test (see above), but the ring of coagulate first forms 0.5 to 1 cm. above the acid and later extends down to it. If the urine is sufficiently diluted, the urate ring, that behaves similarly, is not formed. In order fully to identify the substance it must be isolated from large quantities of the urine (see text-books of physiological chemistry).

Albumoses and Peptone.—It is doubtful whether peptone (in the sense of Kühne) ever appears in the urine. Recent investigations have shown the peptones of the older writers to be albumoses (hemialbumose, deuteroalbumose [peptone in the sense of Brücke], propeptone, histon, etc.). All these bodies appear in the urine when the intracellular disassimilation of the proteids is perverted as the result either of bacterial invasion (suppuration, tuberculosis), or of intoxication with certain inorganic poisons (phosphorus), or of certain metabolic disorders of unknown pathogenesis (osteomalacia). Pyogenic "peptonuria" is clinically important, for the diagnosis of "pus somewhere" may frequently be strengthened by the appearance of albumoses in the urine; the differentiation is also occasionally possible, with the aid of this sign, between purulent and tuberculous or simple serous exudates (meningitis, pleuritis, etc.).

Tests. In order to get rid of the common albumins the urine is treated with an equal volume of saturated salt solution, acidified with acetic acid and boiled. The solution is filtered hot; coagulated albumins remain behind while albumoses go into the filtrate from which they separate on cooling. The filtrate should give the biuret reaction (see above), and the precipitate formed on cooling should redissolve on boiling.

The differentiation of the different albumoses that may be present in the urine is possible, but the chemical manipulations incident to this separation are so complicated that a description of these methods lies beyond the scope of this article. (For an excellent exposé of the subject see Neubauer u. Vogel, "Harnanalyse," 1898, pp. 466 to 484.)

Fibrin (*Fibrinogen*).—These bodies occasionally appear in the urine in chyluria and in hæmaturia, also in croupous inflammation of the urinary passages (tuberculosis, diphtheria). Fibrinogen only appears in profuse hæmaturia, and its presence may be suspected from the formation of coagula in the urine; the latter may form either within the urinary passages or not until the urine is voided.

Test. The coagula are filtered off, repeatedly washed with a five- to ten-per-cent. solution of NaCl dissolved in a boiling one-per-cent. soda solution, or in a 0.5-per-cent HCl solution (the coagulate must not dissolve in *cold* soda or HCl solution!), and the liquid submitted to the ordinary tests for albumin. If the coagula consisted of fibrin, these tests will be positive.

Hæmoglobin (*Methæmoglobin*)—*Hæmaturia, Hæmoglobinuria.* In *hæmaturia* the blood enters the urine somewhere in the urinary passages; it may be the result of acute inflammatory affections, neoplasms, or trauma of the kidneys, ureters, bladder, or urethra.

In *hæmoglobinuria* blood pigment that is already in solution in the renal blood passes through the renal epithelia into the urine; hæmoglobinuria may be the result of poisoning (potassium chlorate, mushrooms, sulphuretted hydrogen, arseniated hydrogen, pyrogallic acid, etc.); it may also follow the transfusion of blood from one species to another; it may follow severe cutaneous burns and certain infectious diseases. Finally, there is an independent form of paroxysmal hæmoglobinuria of unknown etiology.

In hæmoglobinuria the filtered urine is always red, whereas in hæmaturia, provided the urine is fresh, the filtrate may be colorless. Other substances than blood pigment may, however, impart a red color to the urine so that recourse must be had to one of the following tests in order to establish the presence of hæmoglobin in the urine. (For the detection of blood corpuscles in the sediment see below.)

Tests. 1. Boiling.—In the presence of blood pigment a brown coagulate forms that usually floats on the surface of the liquid and that can be decolorized by shaking the urine with sulphuric acid-alcohol.

2. Heller's Test.—This test is based on the formation of hæmochromogen from hæmoglobin by the action of caustic alkali. Five drops of a ten-per-cent. sodium hydrate solution are added to half a test tube of urine. The mixture is boiled and allowed to stand. The earthy phosphates and carbonates in the precipitate will be found colored brown, brown-red, or blood-red (hæmochromogen spectrum). In alkaline urine the test may fail because the phosphates are already precipitated; to such urine an equal volume of normal acid urine may be added in order to obtain the reaction.

3. Almén's Test.—To 10 c.c. of urine is added a mixture of 5 c.c. of *old* oil of turpentine, and 5 c.c. of tincture of guaiac. If blood pigment is present, a white ring will form that gradually turns blue. The test may be modified by adding 5 c.c. of ether and shaking the mixture; the ether dissolves the pigment and forms a blue layer on top of the urine.

4. Teichmann's Test.—The precipitate obtained in tests 1 or 2, or, better still, the precipitate obtained by the addition to the urine of tannin solution, is filtered off, washed with water and allowed to dry in the air. A small portion is placed on a slide with a crystal of sodium chloride and a drop of glacial acetic acid, covered with a cover slip and heated to boiling for about one minute, the evaporating fluid being constantly replaced by glacial acetic acid, drop by drop. As soon as the fluid turns brown, it is allowed to cool slowly. Under the microscope *hæmin* crystals (Teichmann's crystals, Fig. 4855) of characteristic form and arrangement will be seen.

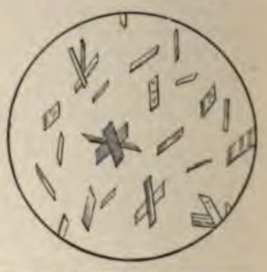

FIG. 4855.—Teichmann's Crystals.

5. Spectroscopic Test.—The diluted urine on direct spectroscopic examination gives the spectrum either of oxyhæmoglobin or of methæmoglobin, provided the urine is acid. On addition of ammonium sulphide the spectrum of gas-free, reduced hæmoglobin appears. After treating the urine with caustic alkali (see Test 2) the spectrum of hæmochromogen appears.

"*Bence-Jones Albumin.*"—This body occurs in the urine in association with multiple myomata of the bones. Nothing is known of its origin. It may be formed in the intestinal tract by some perverted process of disassimilation. This albumin is usually considered an albumose, but it differs from all other known digestive albumoses. It, moreover, resembles true albumin inasmuch as it coagulates on heating to 100° C. (Magnus-Levy), and yields primary and secondary albumoses on peptic digestion. No hetero group can, however, be demonstrated among the digestive products. The body has been found crystallized in the urine.

Test. If urine gives a marked albumose reaction (see above), the presence of Bence-Jones albumin may be suspected, for only in "Bence-Jones albumosuria" do we find such large quantities of "albumose." Such urine should be treated with an equal volume of saturated ammonium-sulphate solution—in this way the body is salted out. It can be further identified by submitting it to peptic digestion and determining the absence of hetero-albumose and the presence of proto-albumose in the mixture of digestive products.

Histon and Nucleo-Histon.—These two albumins are derived from the cell nuclei; they occasionally appear in the urine in affections accompanied by great destruction of leucocytes.

Test. The urine is freed from albumin by boiling, cooled, and precipitated with four volumes of alcohol (95 per cent.). The precipitate is dissolved in hot water and the solution allowed to cool. In order to get rid of uric acid it is acidified with HCl and allowed to stand for four hours; the uric-acid crystals are filtered off and the filtrate precipitated with ammonia; the precipitate is then washed with water containing a little ammonia and redissolved in diluted acetic acid. This solution, if histon is present, should coagulate on boiling and give the biuret reaction.

NITROGENOUS CONSTITUENTS OTHER THAN ALBUMINS.—From eighty-three to ninety-three per cent. of the urinary nitrogen is secreted as urea; the remaining seven to seventeen per cent. of nitrogen appears in the urine in the form of diamins, amido acids, urea, purin bodies (uric acid and its congeners), nucleinic acid, creatin and creatinin, oxaluric acid, allantoin, preformed ammonia, etc.

The Total Nitrogen and Nitrogenous Equilibrium.—We speak of nitrogenous equilibrium when the output of nitrogen corresponds to the intake. The level of nitrogenous equilibrium varies in different persons and in one and the same individual at different times. It is dependent on the health of the subject, the mode of life, the composition of the food, etc. The following rules govern the level of nitrogenous equilibrium: If an individual is fed on a constant diet sufficiently abundant to maintain full nutrition, then the urinary N-excretion becomes constant at the expiration of from two to four days. The organism, however, has a tendency to accommodate the N-output to the N-intake; and the N-output of one period of twenty-four hours is dependent on the N-intake of the preceding period of twenty-four hours. If the N-intake is altered, the latter factor chiefly determines the N-output in the beginning; after the expiration of a number of days, however, the determining influence of the former factor predominates. If, therefore, the N-intake fluctuates from day to day, the sum of the N-output during a prolonged period of time will equal the sum of the N-intake during this time; but for individual periods of twenty-four hours during this time great differences in the N-output will become apparent. It is clear, therefore, that any calculation in regard to the relation between N-intake and N-output that is based on an observation extending only over a period of twenty-four hours is altogether devoid of value.

A healthy adult can maintain N-equilibrium on 0.6 gm. of albumin per kilogram body weight pro die—or with more. As soon as less N is ingested, N-equilibrium can no longer be maintained, for the organism then begins to disassimilate its proper tissues in order to cover the deficit. The *upper* boundary of N-disassimilation has so far not been determined.

Determination of Total Urinary Nitrogen.—Considerable N is eliminated in the fæces; this N is in part derived from the gastro-intestinal secretions, in part from desquamating epithelia, and in part from ingesta that are not absorbed. This amount of N must be included in the calculation, and must be determined in metabolic studies. N-equilibrium is only established when Food-N *minus* Fæces-N *equals* Urine-N.

The urine should be gathered from morning (before breakfast) to the following morning, not from night to night. The N found in such urine correctly indicates the total N excreted in twenty-four hours: (*a*) if the last nitrogenous food is ingested at least eight or ten hours prior to the collection of the last urine (hence the advantage of collecting from morning to morning); (*b*) if no great fluctuations are permitted in the amount of water ingested during the period of observation as against previous periods; for abundant water-drinking washes out an abnormal amount of nitrogenous material, whereas restriction of fluids exercises the reverse effect and favors the retention of nitrogenous material.

The Kjeldahl Method for Determining the Urinary N.—This method is simpler than all other methods for determining nitrogen; it is more rapid and does not require so much skill and experience on the part of the operator. The method is based on the following principle: The nitrogenous substances of the urine on boiling with concentrated sulphuric acid are destroyed and all the nitrogen that is not in direct combination with oxygen is converted into ammonia, and hence is present in the solution as ammonium sulphate. If the acid solution is now treated with hot soda lye, the ammonia is liberated; it is distilled into a measured quantity of normal acid and the excess of acid titrated back.

According to the concentration of the urine 5 c.c. or 10 c.c. of urine are poured into a so-called Kjeldahl flask (*i.e.*, a flask of hard glass with a round bottom and a long neck, holding from 200 to 300 c.c.); to this are added 20 c.c. of concentrated H_2SO_4, and a small quantity (about one-third gram) of the yellow oxide of mercury. The mixture is boiled until the solution becomes quite colorless, care being taken not to heat too rapidly in order to prevent the escape of vapors. On cooling, the contents of the Kjeldahl flask is transferred to a Kjeldahl retort by repeated rinsing with a little distilled water. The Kjeldahl retort is a large round-bottomed flask holding about 500 c.c. To the liquid in this retort are added 40 c.c., of a solution of sodium sulphide (40 gm. to 1,000 c.c. of water), 160 c.c. of sodium hydrate solution (270 gm. to 1.000 c.c. of water), and a small quantity of talcum. The sulphide is necessary in order to decompose the amido-compounds of mercury that form and that would not give up all their nitrogen if sodium hydrate alone were used. The talcum is added in order to render ebullition more gentle and to prevent bumping. As soon as all the solutions have been poured into the retort it is immediately connected with a condenser and the distillation begun. The vapors of ammonia and the water are collected in a flask containing 40 c.c. of a one-fourth normal H_2SO_4; the distillation is continued until about two-thirds of the fluid have gone over; the condenser is then rinsed with water and the washings added to the distillate. The acid is now retitrated with a one-fourth normal sodium hydrate solution, using rosolic acid as an indicator. The difference indicates the amount of acid neutralized by the ammonia. As 1 c.c. of the one-fourth normal solution represents 0.0035 gm. of N, this figure must be multiplied by the number of cubic centimetres of urine (5 or 10) used for the analysis in order to determine the amount of N contained in this quantity of urine. The N in the twenty-four hours' urine can easily be calculated from this. There are numerous modifications of the Kjeldahl method, but the above plan has been found quite satisfactory and altogether reliable in the hands of the author. (For these modifications and for certain refinements of the methods I refer to Huppert: "Analyse des Harns," 1898, pp. 801 to 807).

Diamins.—The diamins (putrescin and cadaverin) are of rare occurrence in the urine of man and are of subordinate clinical importance.

Amido Acids.—Of this group of nitrogenous urine bodies *carbamic acid* is occasionally found in normal urine, but it has no clinical significance. It is too rare, moreover, to merit discussion in this condensed article. Other members of this group—viz., cystin, leucin, and tyrosin—frequently appear in the urine in crystallized form; they will hence be discussed in detail under the heading of urinary sediments (see below).

Urea.—The excretion of urea is dependent on two factors, viz.: (1) the ingestion of nitrogenous food (chiefly albumins); (2) the catabolism of the organized albumin of the body. As the latter factor is a minor source of urea, and as it is, moreover, fairly constant, the excretion of urea may be said to be largely dependent on the ingestion of proteid pabulum. In interpreting the plus or minus of urea excretion both factors must nevertheless be included in the calculation, for it is clear that a diseased person who is consuming an abnormal quantity of the organized albumin of his proper tissues, and at the same time is eating a normal amount of proteid food, will excrete more urea than a healthy individual who is destroying a normal amount of body tissues and is eating the same amount of food. Or, again, a healthy, underfed subject will excrete less urea than an underfed, diseased subject, for the latter contributes more to the urinary nitrogen from his own tissues.

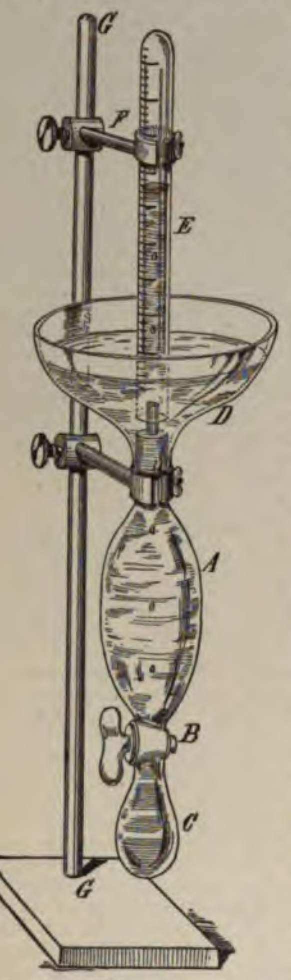

FIG. 4856.—Hüfner's Apparatus.

Normal urine contains as much as four per cent. of urea. The average quantity excreted in twenty-four hours by a healthy adult on a mixed diet is 33 gm. Fluctuations in the urea excretions from 20 to 45 gm. may nevertheless still be within physiological limits; a person performing hard physical labor will excrete more than 33 gm.; a person leading a sedentary life less. On a diet containing little N or after fasting the urea excretion may fall to 15 to 20 gm. Women excrete from 20 to 32 gm. a day. On a diet rich in N as much as 100 gm. may be excreted. The excretion of urea is always increased in febrile diseases, and in diabetes mellitus. It is always decreased in affections of the liver and kidney parenchyma, and in all chronic disorders that are accompanied by malnutrition.

Tests. Qualitative tests for urea are of no clinical importance. Quantitative estimations of the urea excretion, on the other hand, are of great clinical interest as an index of a variety of functional and organic perversions that have been indicated above.

Estimation of the Urea from the Specific Gravity of the Urine.—As urea is the chief solid constituent of the urine, the urea content can be approximately estimated from the specific gravity. Empirically it has been determined that urine of a specific gravity of 1.014 contains about one per cent. of urea; of 1.014 to 1.020, about one and a half per cent.; of 1.020 to 1.024, about two to two and a half per cent.; of 1.028, about three per cent. of urea. In febrile and cachectic states, in which the urinary chlorides are reduced, this estimation must be corrected. For the chlorides in these diseases are excreted in such small amounts that they exercise no appreciable influence on the urinary specific gravity. Consequently, a given specific gravity indicates *more* urea than is given in the above figures.

Of the accurate methods for determining urea the method of Hüfner is the most convenient for clinical work, the method of Mörner and Sjöquist the most accurate for scientific work. These two methods alone will therefore be described. The titration method of Liebig-Pflüger, the method of Folin, etc., are all very good, but they do not surpass in convenience nor in accuracy the two methods mentioned and to be presently described.

The Hypobromite Method of Hüfner (Knop).—This method is based on the fact that sodium hypobromite in alkaline solution decomposes urea into nitrogen, carbon dioxide and water, according to the following formula:

$$\underset{\text{Urea.}}{CO(NH_2)_2} + \underset{\text{Sodium hypobromite.}}{3NaOBr} = 3NaBr + CO_2 + 2H_2O + 2N$$

The CO_2 that develops is absorbed by the soda lye while the N passes through the lye and is measured; from the volume of N liberated the amount of urea can be calculated. This method is inaccurate in two respects: (1) the amount of N liberated is never quite as large as the theoretical amount; (2) hypobromite of soda also liberates N from other nitrogenous constituents of the urine than urea. Notwithstanding these two sources of error, the method is sufficiently accurate to merit general employment.

Hüfner's Apparatus (Fig. 4856) consists of three parts, viz.: (1) a cylindrical vessel, *A*, connected by a glass cock, *B*, with a smaller cylindrical receptacle, *C*; (2) a dish, *D*, that is connected with the upper end of *A* by a rubber cork (as shown in the figure), so that the open upper extremity of *A* protrudes into *D*; (3) an eudiometer tube, *E*, that should be from 30 to 40 cm. long, 2 cm. wide, and should be graduated for 0.2 cm. The eudiometer tube can be held in an inverted position over the upper end of *A* by a clamp, *F*, attached to a stand, *G*.

The Hypobromite Solution.—Seventy cubic centimetres of thirty-per-cent. sodium hydrate solution are diluted with 180 cc. of distilled water; the solution is then mixed with 5 c.c. of bromine. The bromine dissolves in the lye, and sodium bromide and sodium hypobromite are formed according to the formula:

$$3NaOH + Br_2 = NaBr + NaBrO + H_2O$$

The hypobromite solution should be kept in a cool, dark place in a tightly stoppered bottle, and should be made fresh every few days, as otherwise the sodium hypobromite is apt to decompose into sodium bromide.

Method of Performing the Determination.—The urea content of the urine is first estimated from the specific gravity (see above) and the urine diluted so as not to contain more than one per cent. of urea. Of this diluted urine exactly 5 c.c. are allowed to flow from a long pipette into the small receptacle, *C*, care being taken not to spill any of the urine in *A*, the pipette is carefully rinsed with water, and these washings also allowed to flow into *C*, until the latter receptacle is filled to the cock, *B*. The cock is now closed. *A* is now filled to overflowing with hypobromite solution; the dish, *D*, and the eudiometer tube, *E*, are then filled with concentrated NaCl solution and the latter inverted in the former and held over the open upper end of *A* by the clamp, *F*. The cock, *B*, is now opened. As the hypobromite solution is heavier than the urine, it runs down through *B* into *C* and at once causes an active development of gas (CO_2 and N). The CO_2 is absorbed in the sodium hydrate solution contained in *A*, while the N rises up through *A* and collects in the tube *E*. The reaction is over in about twenty minutes. The eudiometer is then transferred to a deep vessel filled with water of room temperature and allowed to stand there for fifteen minutes; the reading is finally made in such a way that the levels of the fluid in the vessel and in the tube are made equal. At the same time the temperature of the water and the barometric pressure are noted.

The volume of gas must now be reduced to 0° C., 760 mm. and absolute dryness; this is done according to the formula:

$$V' = \frac{V\,(B - W)}{760\,(\,1 + 0.0036\,t\,)\,354.3}$$

V′ = Volumes of nitrogen (corrected).

V = Volume indicated on eudiometer.
B = Barometric pressure.
W [*] = Tension of water vapors at temperature t.
t = Temperature of water.
0.0036 = Coefficient of expansion of gases for 1° C.

As urea only yields 354.3 c.c. of N instead of the theoretic amount of 372.7 c.c., when it is disassociated with hypobromite solution, V' must be divided by 354.3 in order to obtain the correct amount of N developed, for

$$354.3 : 1 = V' : x$$
$$x = \frac{V'}{354.3}$$

If 5 c.c. of urine were employed for the determination, V' multiplied by 20 gives the percentage of urea.

A simpler apparatus, called a ureometer, has been constructed on a similar principle as Hüfner's apparatus, but the results obtained with this modified apparatus are altogether inaccurate and essentially valueless. These ureometers are unfortunately in common use.

Method of Mörner and Sjöquist..—The method is based on the following principle: If the urine is treated with barium chloride and barium hydrate in certain proportions, all nitrogenous constituents, with the exception of urea, are precipitated from the solution by a mixture of ether alcohol. In the filtrate the N is determined after Kjeldahl and the urea calculated from this amount of N.

Execution: Five cubic centimetres of urine (if necessary after removal of any albumin that it may contain) are treated in a small flask with 5 c.c. of baryta mixture (saturated solution of barium chloride plus five per cent. barium hydrate) and 100 c.c. of a mixture of one volume of ether and two volumes of alcohol (97 per cent.). The flask is allowed to stand for twenty-four hours; the precipitate is then filtered off, repeatedly washed with ether-alcohol; the filtrate treated with magnesia usta in order to drive off any ammonia that may be in solution, and the ether-alcohol driven off at a temperature of 55° C. The temperature should never be allowed to rise above 60° C. When the volume of the filtrate is reduced to 10 or 15 c.c, the N determination is made with a measured proportion of the liquid. The urea is calculated from the N by multiplying the latter with $\frac{15}{7}$, or 2.143.

Purin Bodies, Uric Acid and Its Congeners.—Uric Acid. Uric acid is a normal constituent of the urine. A healthy adult excretes from 0.2 to 1.25 gm. of uric acid in the twenty-four hours to from 30 to 35 gm. of urea, *i.e.*, about one to two per cent. of the urinary N appears in the urine in the form of uric acid.

The excretion of uric acid is subject to many fluctuations in health and in disease. The chief and probably the only source of uric acid are the nucleins of cell nuclei, and as these nucleins may be derived either from the food or from the cells of the tissues of the organism, the excretion of uric acid is determined on the one hand by the amount of nuclein-containing food that is ingested and on the other hand by the catabolism of the proper tissues of the body. The old view that uric acid is an oxidation product of *any* form of albumin has been shown to be wrong. The administration of very large quantities of albuminous pabulum *containing no nucleins* is not followed by an increase in the uric-acid excretion. The administration, however, of nuclein or of nuclein-containing food is always followed by increased excretion of uric acid. On the other hand, a subject fed for a long time on a diet containing no nucleins, or a subject after a prolonged period of fasting, still excretes appreciable quantities of uric acid; in the former case the increase of uric acid was derived from the food nucleins ("exogenous uric acid"); in the latter case the excreted uric acid was derived from the tissue nucleins ("endogenous uric acid"). Whereas the former factor is constant and independent of the individual in the sense, namely, that a definite quantity of food nuclein leads to the excretion of a definite and calculable quantity of uric acid, the latter factor is inconstant, varies in different individuals, and cannot be calculated in advance. It varies from 0.1 to 0.2 gm. a day in normal adults.

All attempts to find "normal" values or to determine the significance of fluctuations in the uric-acid excretion are altogether fictitious as long as the purin bodies of the food are not included in the calculation. The diversity of opinions among different authors in regard to the effect of albuminous food on the uric-acid excretion can be explained as follows: Those who argue that an albuminous diet increases the urinary uric acid experimented with a diet containing much meat (and consequently xanthin bases, nucleins, etc.), whereas those who claim that a proteid diet exercises no effect on the uric-acid excretion worked with vegetable albumins, milk, eggs, etc., all articles that contain little purin.

Pathologically the excretion of uric acid is increased in febrile disorders and in other diseases in which there is loss of tissue albumin; here the uric-acid increase usually proceeds *pari passu* with the urea increase. In leukæmia the uric acid is often absolutely increased; here the catabolism of many leucocytes must be made responsible. In gout and the uric-acid diathesis (goutiness) there is much divergence of opinion. The consensus of newer writers who looked to a constant diet of known nuclein content during their investigations seems to be that the uric-acid excretion is somewhat increased *during* the attack, and that immediately *preceding* the attack the uric-acid excretion is slightly decreased. In the intervals between the attacks the uric-acid excretion in gouty subjects differs in no way from that in normal subjects.

Qualitative Tests for Uric Acid.—See under urinary sediments (below).

Quantitative Estimation.—Of the many methods for determining the uric acid in the urine the method of Ludwig-Salkowski is the best, the most accurate, and the most rapid.

The method of Heintz was in universal use for many years. It is so simple that even to-day many clinicians employ it. While the results of this method are very inaccurate in the sense, namely, that far too little uric acid is indicated, it nevertheless has a place in the clinical laboratory for determinations of a *relative* increase or decrease of uric acid in the same individual. The method is carried out as follows: Two hundred cubic centimetres of urine are treated with 10 c.c. of concentrated hydrochloric acid; the mixture is allowed to stand for forty-eight hours and the crystalline deposit of uric acid filtered off; the crystals are washed with alcohol and ether and dried at 110° C.

The Method of Ludwig-Salkowski.—Uric acid is precipitated from urine that has been treated with an ammoniacal magnesia solution by ammoniacal silver nitrate solution. The resulting precipitate consists of silver-magnesium urate. (The chlorides remain in solution.) If this precipitate is treated with alkali sulphide, the silver is precipitated as silver sulphide, whereas the urate goes into solution as alkali-urate. From the latter solution uric acid crystallizes after acidulation and evaporation to a small volume. The crystals are gathered on a filter, washed and weighed as above. The addition of ammoniacal magnesia solution causes precipitation of triple phosphate, and this mingling with the gelatinous urate precipitate renders the latter more flocculent and easier to wash, etc.

Execution: Three solutions are required, viz.:

1. An ammoniacal silver solution. Twenty-six grams of silver nitrate are dissolved in water and so much ammonia added until the brown precipitate that forms is redissolved in the excess of ammonia. The solution is then filled up to 1,000 c.c. with water and kept in a dark place.

2. Magnesia mixture. One hundred grains of crystal-

---

[*] The values for W at ordinary temperatures are the following:
10° C. = 9,126
11° C. = 9,751
12° C. = 10,421
13° C. = 11,130
14° C. = 11,882
15° C. = 12,667
16° C. = 13,519
17° C. = 14,009
18° C. = 15,351
19° C. = 16,345
20° C. = 17,396
21° C. = 18,505
22° C. = 19,675
23° C. = 20,909
24° C. = 22,211
25° C. = 23,582

lized magnesium chloride are dissolved in water and a large excess of ammonia added. This leads to the precipitation of magnesium hydroxide. A solution of ammonium chloride that is saturated in the cold is now added in such quantity that the precipitate of magnesium hydroxide is redissolved. The moderately clear solution is filled up to 1,000 c.c.

3. Solution of sodium (or potassium) monosulphide. Ten grams of NaOH or 15 gm. of KOH are dissolved in 1,000 c.c. of water. One-half of this solution is saturated with hydrogen disulphide gas and then added to the other half. The KOH or NaOH employed for this preparation must be free from nitrate or nitrite, for this solution is added to the urate solution before it is acidulated; on acidulation any nitric or nitrous acid would be liberated and these acids decompose uric acid.

The concentration of these reagents is arranged so that 10 c.c. of each suffice for 100 c.c. of urine. It has been established that this proportion precipitates all the phosphates and urates, and, on the other hand, redissolves all the uric acid from the precipitates that form even if the urine contains a very large proportion of uric acid.

One hundred cubic centimetres of urine are poured into a beaker. Ten cubic centimetres of solution 1 and 10 c.c. of solution 2 are mixed in another vessel and treated with so much ammonia that the precipitate of silver chloride that forms is redissolved; sometimes a flocculent precipitate of magnesium hydroxide forms, but this does not interfere with the reaction. The reagent is slowly poured into the urine. A gelatinous precipitate forms that is allowed to settle partially and is then filtered off and washed with very weak ammonia water until the washings are free from silver and from chlorides. The precipitate is then brought from the filter into a beaker, either by perforating the filter and squirting the precipitate through, or, if a suction pump is used, by transferring the bulk mechanically with a glass rod and then rinsing the balance into the beaker with the stream from a wash bottle. Ten cubic centimetres of solution 3 are now mixed with 10 c.c. of water and heated to boiling. The filter is rinsed with this solution and the whole added to the suspension of the precipitate; the mixture is then heated to boiling over a small flame, the deposit of silver sulphide filtered off, frequently washed with hot water, washings and filtrate acidulated with dilute HCl (5 c.c. of HCl [1.12 specific gravity] diluted one-fourth are sufficient), and evaporated to about 20 c.c. On cooling, the uric acid crystallizes out. Some writers claim that all the uric acid is deposited after an hour; it is better to allow the solution to stand for at least six hours. The uric acid is filtered off, washed with alcohol and ether and weighed. For every 10 c.c. of the mother liquor and washings 0.00005 gm. of uric acid is added to the result, for this small amount of uric acid is soluble in 10 c.c. of water and consequently remains in solution.

Salkowski has modified this method slightly. Instead of decomposing the silver urate precipitate with alkali sulphide, he passes a stream of hydrogen sulphide gas through the suspension of silver urate in acidulated water; the silver salt is decomposed in the same way, the sulphide of silver being thrown down, while the uric acid passes into solution; the mixture is heated to boiling, filtered, and the filtrate treated as above. This modification has no advantages over the original Ludwig method—in fact, requires more care and more paraphernalia.

If sugar or albumin is present in the urine, they must be removed before the uric-acid determination is made. Ludwig advises removing the albumin as follows: The urine is treated with concentrated sodium chloride solution (10 to 15 c.c. to every 100 c.c. of urine), acidulated with acetic acid and boiled. The albumins coagulate and can be removed by filtration; the filtrate must be filled up to the original volume of the urine.

If the urine contains uric-acid crystals, these must be dissolved by warming before the urine is measured off. The precipitation of urates may often be prevented by adding a pinch of sodium bicarbonate to the urine immediately after it is voided.

Of other methods for determining uric acid only the underlying principles will be given in this place; for details I refer to the text-books.

Method of Hopkins. Thirty grams of ammonium chloride are dissolved in 100 c.c. of the cold urine. This leads to the precipitation of ammonium urate; the latter is filtered off and washed, then dissolved in boiling water and acidulated with HCl; after concentration of the solution and cooling the uric acid crystallizes out and can be weighed as above.

Some authors prefer to determine the amount of uric acid by *titration*, either acid metrically or with permanganate of potassium, or as silver magnesium salts (see Huppert, "Harnanalyse," 1898, p. 814).

Method of Folin. The uric acid is precipitated with the following reagent: 500 gm. of ammonium sulphate, 5 gm. of uranium acetate, 60 c.c. of a ten-per-cent. solution of acetic acid dissolved in 650 c.c. of water; 75 c.c. of this reagent are added to 300 c.c. of urine. Soon a mucoid body separates from the urine that is removed by filtration; the filtrate is then treated with concentrated ammonia; this leads to the precipitation of ammonium urate. The latter is washed into a beaker, treated with concentrated sulphuric acid, and titrated at once with one-twentieth decinormal solution of potassium permanganate. Each cubic centimetre of the reagent corresponds to 0.00375 gm. of uric acid. As ammonium urate is slightly soluble a correction of 0.003 gm. must be made for every 100 c.c. of urine.

Purin Bases. (Synonyms: Xanthin Bases, Nuclein Bases, Alloxuric Bases). To this group belong many substances, of which the following have been found in human urine: Xanthin, heteroxanthin, paraxanthin, guanin, hypoxanthin, adenin, episarcin, carnin, epiguanin, and "the unknown basis of Krüger and Wulff." The most important of these bodies is xanthin. The quantity of purin bases occurring in the urine is very small. On a mixed diet the urine voided in twenty-four hours contains 87 gm., on an animal diet 44 mgm., and on a vegetable diet (peas and cabbage) 72 mgm., or (apples and carrots) 111 mgm. If the uric-acid nitrogen voided on these different varieties of diet is calculated at 100, the nitrogen of the purin bases (figured for xanthin) equals 18.1, 7.6, 18.1, and 35.8. The amount of xanthin bases excreted, therefore, equals only a fraction of the uric acid excreted. The daily normal excretion equals from 0.015 to 0.06 gm. Of this amount 0.015 to 0.03 is xanthin: hypoxanthin and guanin are next in importance, then come paraxanthin and heteroxanthin. The other members of the group are of rare occurrence and of very subordinate importance.

The purin bases are derived from nuclein; they may consequently, like uric acid, be derived from the food nucleins or from the tissue nucleins. Their relation to uric acid is as follows: If nuclein or nuclein-containing organs (spleen pulp) are allowed to stand at body temperature with free access of oxygen, uric acid is formed; if oxygen is withheld, the purin bases are formed instead. It is possible to convert purin bases into uric acid by the aid of organ extracts, for the latter apparently contain an "oxydase" that can produce this oxidation. Pathogenetically the purin bases probably play a rôle in the uric-acid diathesis, for, as I have shown, they can cause certain renal lesions that are identical with the lesions of granular nephritis in gout, and also certain cardiovascular changes that are similar to those seen in nephritis, arteriosclerosis, etc. Much has been written in regard to the relation existing between the elimination of uric acid and of the xanthin bases. It was believed for a time that a decrease of the uric-acid excretion was compensated by a corresponding increase in the purin-base excretion in gout and goutiness. These findings, including my own, have since, however, been shown to be uncertain, owing to the fact that the method for the determination of purin bases (Krüger and Wulff) was deficient. Both uric acid and purin bases may, of course, also be increased or decreased together. In leukæmia the greatest amount of purin bases (and of uric acid) is excreted. Tea and coffee, owing to the theobromine (dimethyl xanthin) and caffeine (trimethyl xanthin) they incorporate lead to the excretion of methylated xanthin and heteroxanthin. Xanthin sometimes forms a crystalline sediment in the urine. This will be described under urinary sediments.

For the present the quantitative determination of the purin-base excretion is of subordinate clinical importance; the method, moreover, is complicated and requires more skill and more apparatus than are usually at the disposal of the clinician and practitioner. The following *method of Salkowski* gives accurate results. The method is based on the precipitation of uric acid and purin bases together as silver salts and the subsequent separation of the latter from this precipitate.

Execution: A measured quantity of urine is treated with ammoniacal magnesia mixture and ammoniacal silver solution, as described above (Ludwig-Salkowski method) under "uric acid." The uric acid is removed as in the Ludwig method, and the final filtrate, which contains the purin bases, together with the washings, treated with ammoniacal silver solution. This reprecipitates the purin bases. The precipitate is collected on a filter, washed, dried, incinerated. The ash is dissolved in dilute nitric acid and the silver estimated in this solution by titration. The best method of titration is with potassium sulphocyanide, using ammonio-ferric alum as an indicator. In a compound of the silver salts of xanthin, hypoxanthin, etc., one atom of silver represents 0.277 gm. of nitrogen, or 0.7381 gm. of the bases. Consequently 1 c.c. of the sulphocyanide solution will correspond to 0.002 gm. of nitrogen, or 0.00542 gm. of the bases. The sulphocyanide solution is made up as follows: The solution should contain 12.9849 gm. to a litre. The salt is very hygroscopic, so that it cannot be weighed accurately. Therefore a concentrated solution is made and standardized against a silver solution containing 29.042 of silver nitrate to the litre, using ammonio-ferric alum as an indicator.

The separation and identification of the different members of the group of purin bases is possible, but it requires very much time and considerable chemical skill. As this separation is of no clinical value, but merely of physiological interest, it will not be described in this article.

Nucleinic Acid.—This body occurs in small quantities in the urine either in combination with a proteid molecule (see nucleo-albumin), or occasionally free. Nucleinic acids are a combination of purin bases, phosphoric acid, and of a nitrogen-free molecule (possibly pentose). They contain as much as 9.5 per cent. of phosphorus; nucleo-albumins contain about 1.5 per cent. of phosphorus. Nucleinic acid is precipitated from the urine together with chondroitin sulphuric and taurocholic acids (icterus) if the greater portion of the inorganic salts are removed from the urine; the latter are therefore removed by dialysis, the liquid treated with dilute acetic acid, and the precipitate removed by filtration; the filtrate of urine containing no albumin is now treated with a small quantity of blood serum (1.5 c.c. to a litre) and allowed to stand. The precipitate contains the nucleinic acid, together with chondroitin sulphuric and taurocholic acids (icterus). The presence of nucleinic acid is finally determined by determining the presence of phosphorus and of purin bases.

Allantoin.—This body is occasionally found in the urine of new-born children (during the first week of life), in the urine of pregnant women, and occasionally in the urine of men. It is a normal constituent of cat's, dog's, and rabbit's urine. It appears to be an intermediary product in the oxidation of uric acid; but it does not occur in the urine of man after excessive feeding with nuclein-containing food (Loewi). Its clinical significance is so small that methods for detecting and estimating allantoin will not be given.

Kreatin (Kreatinin).—Kreatin has occasionally been found in the urine of man. It is rapidly converted into kreatinin, however, and the latter substance is constantly found in the urine in quantities varying from 0.6 to 1.3 gm. in the twenty-four hours' quantity. It is derived from the disassimilation of muscle tissue either of the food or of the organism proper. In the muscles of the body kreatin is always formed first, and this is secondarily converted into kreatinin in its further passage through the blood and tissues. The excretion of kreatinin is chiefly dependent on the diet—much meat, much kreatinin. But even if all muscle meat is withheld, or if the meat is first leached out with water (Rubner) a certain amount of kreatinin continues to be excreted. Physical exercise seems to increase the kreatinin excretion.

Pathologically kreatinin has been found increased in febrile disorders of various kinds, and in diabetes. It has been found decreased in chronic nephritis, in diabetes insipidus, and in the period of convalescence from acute diseases, also in anæmia, chlorosis, tuberculosis. The clinical significance of a plus or minus in the kreatinin excretion is so far not understood. More casuistic data must be collected before this sign can be utilized in the interpretation of morbid states.

Tests.—Qualitative. Weyl's Test.—A small quantity of the filtered urine is treated with a few drops of a ten-per-cent. solution of sodium hydrate and one drop of a ten-per-cent. solution of sodium nitroprusside. If the urine contains kreatinin, it turns ruby red and then yellow. If the urine, after it has turned yellow, is now acidulated with acetic acid and heated, it turns green, then blue, and finally precipitates a blue sediment. This reaction does not occur in the cold. Instead of acetic acid certain other organic acids can be employed.

Kreatin does not give this test, neither do allantoin, xanthin, leucin, tyrosin, and other bodies that are genetically related to kreatinin. The only other urinary constitutent (with the exception of certain rare hydantoins) that gives a similar color test is *acetone;* on acidulation with acetic acid the liquid, however, turns red with acetone, whereas with kreatinin it turns blue. It is easy to drive off any acetone that may be present by first boiling the urine for a few minutes.

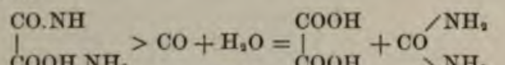
Test of Jaffé.—The urine is treated with a few drops of dilute sodium hydrate and a few drops of picric acid; the liquid at once turns red, even in the cold. This reaction can still be obtained in the presence of 1 part of kreatinin to 5,000 parts of water. No other known constituent of the urine gives this test.

Quantitative Determination.—Kreatinin forms a double compound with chloride of zinc—that is essentially insoluble in alcohol (1 to 9,217). This property is utilized for the quantitative determination.

Execution: Two hundred to 300 c.c. of urine are rendered alkaline with lime water and treated with a solution of calcium chloride so long as a precipitate continues to form. The mixture is allowed to stand for one or two hours and filtered. The filtrate is slightly acidulated with sulphuric acid and evaporated to a syrupy consistence in the water-bath. While still warm it is treated with 40 to 50 c.c. of alcohol of 95 per cent. The mass is thoroughly mixed washed into a beaker with a small quantity of 95-per-cent. alcohol and allowed to stand in a cool place for from six to eight hours. The precipitate is filtered off and washed and the filtrate and alcoholic washings evaporated back to about 50 c.c. This solution is now treated with 0.5 c.c. of an alcoholic chloride-of-zinc solution and allowed to stand for two or three days. The crystals of kreatinin-zinc chloride are then gathered on a weighed filter, repeatedly washed with alcohol until the filtrate shows no chlorine reaction, dried and weighed. One gram of kreatinin-zinc chloride represents 0.6242 gm. of kreatinin. In order, therefore, to determine the amount of kreatinin present in the quantity of urine employed for the determination, the figure obtained from weighing the zinc compound must be multiplied by 0.6242.

The reagent employed for precipitating the kreatinin-zinc compound (*i.e.*, the alcoholic solution of zinc chloride) is made by treating a saturated watery solution of zinc chloride with alcohol until the mixture has a specific gravity of 1.200.

Oxaluric and Oxalic Acids.—Oxaluric acid occurs only in insignificant traces in normal urine, usually in the form of the ammonium salt. Oxalic acid is always present in normal urine. It usually occurs as the calcium salt, which is held in solution by diacid sodium phosphate. It precipitates with facility on standing and then forms characteristic crystals (see urinary sediments). Whereas oxalic acid $\begin{array}{l}\text{COOH}\\ |\\ \text{COOH}\end{array}$ contains no nitrogen, it may nevertheless be discussed in this place in connection with oxaluric acid, as both these substances are chemically and, probably, genetically closely related. Oxaluric acid readily splits up into oxalic acid and urea according to the formula:



$$\begin{array}{l}\text{CO.NH}\\ |\\ \text{COOH.NH}_2\end{array} > \text{CO} + \text{H}_2\text{O} = \begin{array}{l}\text{COOH}\\ |\\ \text{COOH}\end{array} + \text{CO}\begin{array}{l}\diagup\text{NH}_2\\ \\ \diagdown\text{NH}_2\end{array}$$

Oxaluric acid. Water. Oxalic acid. Urea.

Both may be derived from uric acid, although oxalic acid may also be derived from other sources. It has recently been shown to be an intermediary produced in the degradation of dextrose. It may further be derived from certain articles of food, as asparagus, apples, grapes, and spinach. It is possible that a certain amount of the urinary oxalic acid is derived from this source.

The normal oxalic-acid excretion is about 0.02 gm. in twenty-four hours. Oxalic acid is occasionally found increased in diabetes. Some clinicians speak of vicarious oxaluria in this disease, for it seems that the sugar excretion decreases occasionally as the oxalic-acid excretion increases. If oxalic acid could ultimately be shown to be an oxidation or a splitting product of blood-sugar (see above), this peculiar relation would be easily explained. Oxaluria has finally been vested with the dignity of an independent clinical entity (oxalic-acid diathesis, idiopathic oxaluria). The syndrome of this condition. is rather vague: the chief manifestations being a variety of subjective symptoms, emaciation, and a great increase in the excretion of oxalic acid (as much as 0.5 gm. in 1,000 c.c. of urine). No pathologic organic lesions are discoverable.

Estimation of Oxalic Acid. Qualitatively crystals of oxalic acid can be recognized by their solubility in HCl and their insolubility in acetic acid (see also "urinary sediments"). The quantity of oxalic acid is determined as follows:

Method of Neubauer.—The total quantity of the urine excreted in twenty-four hours is treated with calcium chloride and ammonia, then slightly acidulated with acetic acid and allowed to stand until the sediment settles at the bottom of the vessel. It is advised to add a few drops of an alcoholic thymol solution in order to prevent the excessive development of micro-organisms, for the latter may render subsequent clearing of the urine by filtration difficult. The precipitate is filtered off and placed into dilute hydrochloric acid together with the filter, the liquid heated a little, filtered, and the residue washed with water until the filtrate is no longer acid. The filtrate and washings are then evaporated to a small volume; while still hot this liquid is oversaturated with ammonia and colored with a few drops of litmus tincture as an indicator of the reaction. The solution is allowed to stand for twenty-four hours and the crystals of calcium oxalate gathered on a weighed filter; the weight of the filter ash must be known. The precipitate is washed free from chlorides, dried, incinerated in a platinum crucible and glowed to constant weight. This converts the oxalate of calcium into the oxide of calcium. Fifty-six parts of calcium oxide correspond to ninety parts of oxalic acid. The weight of the calcium oxide must, therefore, be multiplied by $\frac{90}{56} = 1.6071$, in order to give the amount of oxalic acid present in the total quantity of urine used for the estimation.

There are several sources of error in this method that render the results not quite accurate in the sense that too little oxalic acid is indicated. In view of the small quantities of oxalic acid excreted in the urine these small errors become relatively large. Other methods (Baldwin [Dunlop], Salkowski) in the writer's experience are fully as complicated as the old method of Neubauer, and no more accurate. In view of the slight clinical significance of small fluctuations in the oxalic-acid excretion and the small need of performing quantitative estimations these other methods will not be described in this article.

CARBOHYDRATES.—Normal urine always contains small quantities of carbohydrates, notably the following three: animal gum, dextrose, and isomaltose. Chemically related to these are the conjugate glycuronates, and certain glucosides (chondroitin-sulphuric acid, nucleinic acid, and "mucin"). Occasionally pentose is also found in normal urine. Under pathological conditions the urine may contain levuloses (laiose) and certain polysaccharides, viz., erythrodextrin and glycogen.

Carbohydrates in General.—Certain reactions are common to all carbohydrates occurring in normal urine. They may consequently be utilized for the detection of these bodies.

(1) *The Benzol-ester Reaction* (*Baumann*). If the urine is shaken with benzoyl chloride and a quantity of sodium hydrate added sufficient to decompose the latter, a precipitate of benzoyl compounds is formed that incorporates dextrose, isomaltose, and animal gum.

(2) *The Furfurol Reaction.* Carbohydrates are decomposed by sulphuric acid, and one of the products of this decomposition is furfurol. The latter, even in very minute quantities, gives definite color reactions with certain reagents, viz., α-naphthol, thymol, xylidin, and resorcin. In addition to glucose, isomaltose, animal gum, and pentoses, albumen also gives this reaction with α-naphthol. In performing the test albumen should therefore be removed first.

(3) *The Reduction of Metal Oxides.* Normal urine reduces cupric and mercuric oxide in alkaline solution, and can also convert orthonitrophenyl propionic acid in alkaline solution into indigo blue. This method can hardly be utilized, however, to determine the presence of carbohydrates in normal urine. It is important merely to remember that normal urine, owing to the presence of certain reducing carbohydrate bodies possesses slight reducing powers, and that this factor must be included in determining the cupric-reducing powers of pathological urines.

Carbohydrates are commonly divided into monosaccharides, disaccharides, and polysaccharides. The di- and polysaccharides may be considered condensation products of monosaccharides with loss of water. Inversely di- and polysaccharides can be split by hydrolytic decomposition (addition of water) into the original component monosaccharide molecules.

Monosaccharides.—We distinguish among the monosaccharides trioses, tetroses, pentoses, hexoses, heptoses, etc., according to the number of carbon atoms the molecules contain. Of these different sugars the pentoses and the hexoses (*i.e.*, the sugars containing five and six combinations) are alone of physiological and pathological interest.

Pentoses. See article on *Pentosuria.*

Hexoses. *Glucose* (grape sugar, glycose, dextrose) $C_6H_{12}O_6$. As already stated, normal urine always contains traces of glucose. After the abundant ingestion of glucose, of disaccharides and polysaccharides, the excretion of monosaccharides (dextrose or levulose) in the urine may increase. This condition is called *alimentary glycosuria* (*e saccharo*).

Glycosuria (synonyms glycuria, melituria), *i.e.*, the excretion of dextrose in the urine, may occur in a great variety of conditions.

Certain drugs, as *uranium salts, corrosive sublimate, phosphoric acid* (intravenously), lead to the excretion of dextrose: certain other drugs, as *chloralamide, chloral, nitrobenzol*, and *nitrotoluol, orthonitro propionic acid*, lead to the excretion of reducing substances that are frequently taken for sugar. On careful examination it will be found, however, that these reducing substances rotate the plane of polarized light to the left, and are therefore not dextrose, and that they do not ferment with yeast, and are therefore not levulose. As a matter of fact, the bulk of these reducing substances consists of glycuronic acid compounds that these drugs form in their passage through the body. It is interesting to note, however, that in addition to these conjugate glycuronates, dextrose may appear in the urine at the same time.

Certain drugs that lead to cellular *asphyxia*, as *carbon monoxide, amyl nitrite, curare, methyldelphinin, strychnine, morphine, chloroform, ether*, and other drugs that produce asphyxia by narcosis, may all produce glycosuria.

Phloridzin produces sugar excretion in a different way than any of the other poisons enumerated. Whereas in all the glycosurias mentioned the excretion of sugar is preceded by the accumulation of abnormally large quantities of sugar in the blood, *scil.* hyperglycæmia, in phloridzin glycosuria the blood-sugar is not increased above normal. The exact pathogenesis of phloridzin glycosuria is still a subject of controversy. Phloridzin is a glucoside made from the bark of the roots of apple and cherry trees. On boiling with acids it decomposes into phloretin and phlorose, the latter being a monosaccharide that is closely related to glycose. One gram of phloridzin per kilogram of body weight administered to dogs by the mouth leads to the excretion of as much as eighteen per cent. of dextrose in the urine; the excretion of sugar may continue for two or three days after the administration of a single dose. In man von Mering caused the daily excretion of about 100 gm. of dextrose for thirty consecutive days by injecting 2 gm. of phloridzin every day. As soon as the exhibition of phloridzin was stopped, the excretion of dextrose also ceased.

Phloridzin glycosuria is without doubt due to some *renal* process. This is clearly shown by the absence of hyperglycæmia, even though the ureters are ligated or the kidneys extirpated. In fact, phloridzin injected into one of the renal arteries at first leads to the excretion of dextrose only from this one kidney; later the other kidney also begins to excrete sugar.

Two possible explanations can be proffered in the light of our present knowledge, viz.: either phloretin damages the renal epithelium in the sense that the latter becomes abnormally permeable for dextrose, or phloridzin is disintegrated into its two components in the kidney—the sugar component being excreted, the phloretin returning into the circulation, recombining with sugar to form phloridzin, and finally again undergoing decomposition in the kidneys. If the latter assumption is correct, the process of sugar excretion would be continued until finally the phloretin itself would be completely eliminated. A strong argument in favor of this theory is the observation that phloretin itself can produce glycosuria. In view of the fact finally that changes in the renal epithelia have never been observed after the administration of phloridzin, the latter pathogenesis is the one now almost universally accepted.

Glycosuria also appears after injuries to the *liver*, and in many chronic diseases of this organ. It may appear in the course of a great variety of *nervous disorders* (viz., apoplexy, brain tumor, encephalomalacia, cerebrospinal meningitis, dementia paralytica, multiple sclerosis, tabes dorsalis, traumatic neurosis, various functional neuroses, and in certain psychoses). In many of these disorders the sugar does not spontaneously appear in the urine, but only after the administration of carbohydrate pabulum in quantities so small that it would not lead to sugar-excretion in a normal subject. Here, then, the power of *assimilating* carbohydrate is merely reduced, hence the glycosuria.

Glycosuria may accompany *Basedow's disease, myxœdema, acromegaly*, and *Addison's disease*; sugar appears in the urine after the *injection of thyroid and suprarenal extracts.*

In *gout, obesity*, and *arteriosclerosis*, in certain *diseases of the pancreas*, in *syphilis*, in *cholera, malaria, carbuncle*, and other infections, sugar may appear in the urine.

Finally, glycosuria is the most typical symptom of *diabetes mellitus* and of *experimental diabetes* occurring in depancreatized animals.

Tests for Glucose. No simple test exists for the quantitative detection of glucose to the exclusion of all other sugars that may appear in the urine. From a clinical standpoint this differentiation is fortunately not very important; hence I will not describe the complicated methods we possess for isolating and identifying dextrose in a mixture of sugars and other carbohydrates and carbohydrate derivatives. Of the many urinary sugar tests we possess the following are the most practical and the most simple:

Fehling's Test (modification of Trommer's test).—Trommer's test was carried out as follows: The urine was rendered alkaline with potassium hydrate solution; a strong solution of copper sulphate was then added drop by drop until a portion of the cupric hydrate remained undissolved; the mixture was then heated. If appreciable quantities of sugar were present, yellow or red cupric oxide was precipitated even before the boiling point was reached, while at the same time the liquid became somewhat decolorized. This test is quite sensitive. Trommer was able to detect the presence of 0.001 per cent. of sugar. Unfortunately a large number of substances other than sugar can produce the same reaction—for instance, uric acid, kreatinin, allantoin, nucleoalbumin, bile pigments, conjugate glycuronates, etc. If the reduction occurs before the mixture is boiled, this reaction is always due to sugar. It only occurs, however, if the percentage of sugar is large.

Fehling modified this test by substituting a mixture of potassium-sodium tartrate (Rochelle or Seignette salts) and caustic alkali for the simple caustic alkali solution. Fehling's alkaline solution is made up as follows: 173 gm. of Rochelle salt and 120 gm. of sodium hydrate are dissolved in 500 c.c. of water. For quantitative work (see below) it is best to first prepare a sodium hydrate solution of 1.34 specific gravity and to dissolve 100 c.c. of this lye with 173 gm. of Rochelle salt in the necessary amount of water. The copper-sulphate solution should contain 34.63 gm. of copper sulphate to 500 c.c. of water. The two solutions should be kept separately. Before performing the test equal parts of the solutions are mixed and diluted with five volumes of water. As sugar is the only important urinary ingredient that reduces an alkaline copper solution at a temperature below the boiling point (*i.e.*, at about 80°), the author prefers to perform the Fehling test as follows: Equal portions of the urine and of the reagent are poured into two test tubes and each tube heated to boiling; both tubes are then allowed to cool off a little and the reagent then poured into the urine. If sugar is present, the yellow or red oxide of copper will appear almost at once and all through the liquid. This method of performing the test, aside from being more positive for sugar, is much more delicate for small quantities of dextrose.

Nylander's Bismuth Test.—This test is based on the same principle as the Trommer-Fehling test—*i.e.*, the power of dextrose to reduce metallic salts. Here the reduction of subnitrate of bismuth is utilized instead of the reduction of sulphate of copper. The test has this advantage over the Fehling test—that uric acid, kreatinin, and homogentisinic acid do not reduce bismuth subnitrate. After rheum, senna, salol, antipyrine, quinine, the urine, however, always gives this test. The presence of uroerythrin or of hæmatoporphyrin may simulate a reduction. If the urine contains much ammonia salt, the test may fail even in the presence of dextrose.

Nylander's reagent consists of 4 gm. of sodium and potassium tartrate, 2 gm. of bismuth subnitrate, and 10 gm. of sodium hydrate dissolved in 90 c.c. of boiling water. The solution, after cooling, must be filtered and preserved in a dark bottle.

Ten parts of the urine are treated with one part of the reagent and boiled for several minutes (at least two to three minutes!). It is imperative to *boil for some time.* If dextrose is present, a gray or dark-brown precipitate of bismuthous oxide or a black precipitate of metallic bismuth will form.

Fermentation Test.—Glucose is split into alcohol, carbon dioxide, and certain other products (*i.e.*, succinic acid, glycerin, etc.) by the action of yeast.

$$\underset{\text{Glucose.}}{C_6H_{12}O_6} \quad = \quad \underset{\text{Alcohol.}}{2C_2H_6O} \quad + \quad \underset{\text{Carbon dioxide.}}{2CO_2}$$

According to this formula, which represents the chief reaction that occurs, a given quantity of sugar should yield 51.1 per cent. of alcohol and 48.9 per cent. of carbon dioxide. As a matter of fact, only 48.67 per cent. of alcohol and 46.54 per cent. of carbon dioxide are formed, the deficit being made up by 3.71 per cent. of glycerin and succinic acid and 0.94 per cent. of unknown substances. It will be seen, however, that the proportion between the two main products remains the same, viz., as 1.045 : 1 as called for by the equation. The temperature optimum for the alcoholic fermentation of sugar lies at 34° C. Below 15° C. the process is not completed, and above 45° C. it does not take place at all. Sugar solutions of from four to eight per cent. ferment more rapidly than more or less concentrated solutions. The proper proportion of CO_2 (46.54 per cent.) is only obtained if not more than one-half part of fresh doughy yeast is used for one part of sugar. More yeast leads to the development of more CO_2, owing to the auto-fermentation (development of buds) of the yeast that in itself leads to the generation of CO_2.

The test is performed as follows: A little compressed yeast is shaken with about 25 c.c. of urine and the mixture placed into a saccharometer (Einhorn's saccharometer). If glucose is present CO_2 will be developed at room temperature, or better at 34° C. The gas accumulates at the top of the tube. Before performing this test the yeast should be placed into a glucose solution in order to determine whether it is active. As normal urine frequently ferments a little, a control tube should be compared with the tube to be tested. If the percentage of sugar is very small, the CO_2 may be absorbed before it rises to the top of the tube. In case the urine gave a positive Fehling or Nylander test, but apparently does not ferment, it is well to repeat one of the reduction tests after the urine has been kept in the fermentation tube for twenty-four hours. If at the end of this time the urine no longer reduces copper or bismuth salts, then we may know that the original reduction was due to fermentable carbohydrate (glucose). If it still reduces Fehling's or Nylander's solution, then we may conclude that the original reduction was wholly or in part due to the presence in the urine of unfermentable carbohydrates.

The Phenylhydrazin Test.—This test was formerly considered quite pathognomonic for pathologic sugars in the urine. Since it has been shown, however, that normal urine, when treated with phenylhydrazin may occasionally precipitate crystals that resemble in appearance the typical glucosazon, the validity of this test seems impaired. The author, it is true, has never so far succeeded in obtaining such crystals from normal urine, but statements to this effect are made by competent authorities.

In addition to certain sugars (see below) the pentoses and glycuronic acids give osazons with phenylhydrazin. Acetone and diacetic acid give a hydrazin that is almost insoluble; oxalic acid gives a salt that is not very soluble; urea in concentrated urines gives a peculiar compound with phenylhydrazin. While acetone and oxalic acid will probably never be confounded with sugar, and while urea is probably never present in sufficient amounts in human urine to produce the formation of the phenylhydrazin compound, and while, finally, free glycuronic acid probably never occurs in the urine, nevertheless all these possible sources of error must be considered when interpreting the significance of a phenylhydrazin crystallization.

Our chief aid in differentiating the different osazons that are formed from various sugars is the melting point,* as this differs so considerably that the osazons can usually be distinguished by this means alone.

The test is performed as follows: 10 c.c. of urine are poured into a test tube and to it are added 0.5 to 0.75 gm. of phenylhydrazin, and not quite twice as much (1 to 1.5 gm.) of sodium acetate. With a little practice the amount of phenylhydrazin and the proportion of sodium acetate can be estimated with sufficient accuracy. The mixture is heated to boiling, and if all the salts do not dissolve readily, a little water is added. The tube is then placed into boiling water for from twenty to thirty minutes and then allowed to cool slowly. It is best to turn off the flame under the water-bath and to allow the tube to cool in the bath. At the expiration of half an hour the tube is placed into cold water. In this way better crystals are obtained. A number of rapid tests have been described; but I find the technique described above to be absolutely reliable, whereas I have on several occasions known the "five-minute tests" to fail; this applies particularly to urines containing only small amounts of sugar. As soon as the tube is placed into cold water, if not before, a yellow crystalline precipitate of phenyl-glucosazon appears. Sometimes this sediment appears amorphous on naked-eye inspection. On microscopic examination, however, it will be found to consist of fine needles that are arranged in bundles and sheaths. They are of a bright yellow color. The precipitate must present this microscopic appearance; flakes and plates of yellow material prove nothing in regard to the presence of sugar. In doubtful cases a melting-point determination of the crystals must be made. (For the technique see text-books on chemistry.)

This test can be performed even if the urine contains small quantities of albumin. Large quantities of albumin are preferably first removed by boiling and filtration. The test is very delicate and indicates the presence of 0.1 per cent. of sugar. The test requires a little practice, but after the technique is once mastered it constitutes one of the most satisfactory and reliable tests for sugar, particularly in combination with one of the reduction tests.

Polarimetric Examination.—For the qualitative recognition of glucose in the urine the polariscopic test is not very satisfactory because many other substances besides sugar can turn the plane of polarized light to the right or the left. The presence of glucose should, therefore, never be diagnosed from dextro-rotation alone. If a specimen of urine gives one of the above tests, and if in addition it shows marked dextro-rotation, this evidence may be considered highly corroborative of the presence of dextrose. Normal urine turns the plane of polarized light slightly to the left; albumen is also levorotary; biliary acids are dextrorotary. All these bodies can be precipitated from the urine by sugar of lead. This source of error can, therefore, be eliminated by treating the urine with sugar of lead and making a polarimetric examination of the filtrate; dextro-rotation may appear in the latter, whereas it was previously neutralized by the presence of levorotary substances in the urine. Other levorotary bodies that may mask the dextro-rotation produced by small quantities of glucose are levulose, conjugate glycuronates, and β-oxybutyric acid. If the urine is allowed to ferment and is examined with the polariscope before and after fermentation, the error introduced by the presence of these levorotary reducing substances may occasionally be detected and controlled (see Glycuronates below).

For a detailed description of the polarimeter and the technique of polarimetry I refer to special text-books on physics.

---

* *Melting Points of Various Osazons.*

Glucose	204-205° C.
Levulose	204-205° C.
Galactose	193° C.
Maltose	206° C.
Isomaltose	150-153° C.
Lactose	200° C.

There are many other qualitative tests for sugar, but their description lies beyond the scope of this article. The ones given are the best; they are sufficient for all clinical purposes.

Quantitative Estimation of Glucose.—By Titration. (*a*) According to Fehling.—In pure sugar solutions the sugar percentage can be determined by weighing the cuprous oxide precipitate. In the case of the urine this cannot be done because a portion of the oxide is held in solution by the ammonia that develops when urine is boiled with Fehling's alkaline solution. It is possible, however, to determine the volume of urine that is required to reduce the cuprous oxide salt in a definite volume of Fehling's solution. The correct volume of urine is determined by observing the exact point at which the blue Fehling's solution becomes discolored. In observing the color change one should not wait too long, but should examine as soon as the cuprous oxide begins to settle and leaves a narrow zone of clear fluid on top. If one waits too long, a bluish tinge may return owing to the oxidation of that moiety of the cuprous oxide that is held in solution by ammonia. In case the cuprous oxide does not settle rapidly the addition of some sodium hydrate hastens the precipitation.

The specific gravity of the urine having been determined in order approximately to estimate the amount of sugar it contains (see above), it should be diluted so far that it does not contain more than 0.5 per cent. It is good practice to always dilute diabetic urine five to ten times. The dilute urine is poured into a burette; 5 c.c. of the alkaline and 5 c.c. of the cupric solution (see above for Fehling's solution) are now mixed and diluted with 40 c.c. of water. The solution is heated to the boiling point and the urine allowed to flow into it slowly and carefully. A red or yellow precipitate of cupric or cuprous oxide forms and the blue color of the fluid disappears. The test should be repeated several times until the exact quantity of urine required to bring about the discoloration is determined to 0.1 c.c. A number of methods have been devised to determine the point of discoloration more accurately, but none of these methods have proven useful in the author's practice. For clinical purposes the above simple method is sufficiently accurate. In order to calculate the sugar percentage it must be remembered that each cubic centimetre of Fehling's solution corresponds to 5 mgm. of sugar; if 10 c.c. of Fehling's solution were reduced by a given quantity of urine, then this quantity of urine contained ten times 5 mgm., or 50 mgm., or 0.05 gm. of sugar. As the urine used for the test was diluted, the quantity of the original urine, that contains an equal amount of sugar, can be determined by dividing the cubic centimetres of diluted urine by the figure indicating how often the urine was diluted. For example, if 8.4 c.c. of diluted urine were required to reduce 10 c.c. of Fehling's solution, and if the urine was diluted six times, then the 0.05 gm. of sugar were contained in $\frac{8.4}{6}$ c.c. = 1.4 c.c. of the original urine; 100 c.c. of this urine, therefore, would contain 3.57 gm., or 3.57 per cent.

Method of Knapp.—This method does not require as much practice as Fehling's quantitative method. It is based on the fact that mercuric cyanide in alkaline solution is reduced by glucose to metallic mercury. In this test, too, however, there is an unavoidable source of error, for the urine always contains substances that can reduce the mercuric cyanide solution. For very accurate estimations the urine should, therefore, be fermented and its mercuric-reducing powers after fermentation determined. The figure obtained in this way should then be subtracted from the values for the total reducing powers; for ordinary clinical purposes this correction is superfluous.

For performing this test the urine should be freed from albumin by boiling with dilute acid and filtering. The urine should not contain more than one per cent. of sugar by a preliminary test or by estimation from the specific gravity; the sugar percentage should first be estimated, and, if the percentage is too high, the urine correspondingly diluted.

The reagent should contain 10 gm. of pure dry mercuric cyanide and 100 c.c. of sodium-hydrate solution of the specific gravity of 1.145 (or 13.3 gm. of sodium hydrate) to the litre. The reagent is conveniently made by dissolving 10.754 gm. of chemically pure mercuric chloride in a little water and adding so much cyanide of potassium that a drop of sodium-hydrate solution no longer produces a precipitate; to this mixture are added 100 c.c. of NaOH (specific gravity 1.145) as above. Then the whole is filled up to 1 litre.

Twenty cubic centimetres of this reagent are diluted with 75 to 85 c.c. of water. The dilution depends somewhat on the percentage of sugar in the diluted urine; the smaller the amount of sugar the less the dilution. The diluted reagent is heated to the boiling point and titrated with urine. From 1 to 3 c.c. of the urine should be allowed to flow in *at once* and the mixture boiled for half a minute after each addition of urine. As soon as approximately enough urine has been added to reduce all the mercuric cyanide, the mercury (and the phosphates) settle to the bottom and the liquid becomes clear. The reaction is complete when the supernatant fluid contains no more mercury salt. In order to determine the absence of the latter, a number of reagents have been recommended (viz., ammonium sulphide by Knapp, the originator of the method; sulphureted hydrogen by Leussen, and stannous oxide solution by Brumm). The writer has found the last-named indicator to be the best and uses it exclusively. The alkaline solution of stannous oxide is prepared by dissolving 50 gm. of stannous chloride in soda lye and diluting the solution to 1 litre. This reagent does not keep for a long time, as the stannous salt is soon oxidized. The addition, however, of a little metallic tin prevents this oxidation and preserves the reagent indefinitely. A drop of the clear supernatant fluid described above is placed on a porcelain dish and a drop of the stannous chloride solution added. If the fluid still contains mercury the drop turns gray; if it does not, it remains clear.

The calculation of the sugar percentage of the urine to be tested is based on the composition of Knapp's reagent; for the latter is compounded so that 20 c.c. correspond to 0.05 gm. of glucose. The calculation is similar to the one outlined above under "Fehling's test."

The Method of Pavy.—By the addition of ammonia to Fehling's solution the cuprous oxide formed in Fehling's test is held in solution, and the color change indicating the end-reaction is consequently not masked by the precipitate in suspension.

Pavy adds 300 c.c. of ammonia (specific gravity 0.880) to 120 c.c. of Fehling's solution, and fills the mixture up to 1 litre. Of this solution, from the Fehling's solution which it contains, 1 c.c. should indicate 0.6 mgm. of glucose. In reality, however, it only indicates 0.5 mgm. In other words, it is exactly 0.1 time as strong as Fehling's solution. The solution can be kept indefinitely. The above error, according to a later communication by Pavy, can be corrected by dissolving 20.4 gm. of potassium hydrate, 20.4 gm. of Rochelle salt, 300 c.c. of ammonia (specific gravity 0.880), and 4.158 gm. of copper sulphate in 1 litre of water; of this mixture 1 c.c. = 0.5 mgm. of sugar or 10 c c. indicate 5 mgm. of sugar as the original Fehling's solution.

The titration should be performed with exclusion of the air. A small flask holding 80 c.c. is closed with a stopper with two perforations. Through the one hole passes the burette, through the other a **U**-tube filled with pumice stone that is saturated with dilute acid in order to bind the escaping fumes of ammonia. Ten cubic centimetres of the reagent are diluted with an equal volume of water and boiled for a few minutes until all the air is driven out of the flask. Then the diluted urine is allowed slowly to flow into the boiling reagent until discoloration is complete. This method is very convenient, very easy of execution, and sufficiently accurate to merit the universal popularity that it enjoys.

Other methods of quantitative sugar determination by titration have no advantages over the three described. They are, therefore, omitted.

By Fermentation. (*a*) Direct Determination.—With the aid of a saccharometer (see above), provided with a scale, the percentage of sugar may be read off directly, the amount of carbonic-acid gas developing during a stated time, at a certain temperature, and in urine diluted to a certain strength, indicating the amount of sugar disassociated by the yeast. The results of this test, even in complicated apparatus, are very inaccurate, for the sources of error are many. For clinical purposes of comparison, Einhorn's saccharimeter is nevertheless a useful instrument.

(*b*) Differential Density Determination before and after Fermentation.—The density of the urine before and after fermentation is determined and the difference in the densities multiplied by an empirical factor: the latter is obtained by dividing the figures for sugar (obtained by some other method) by the difference in the densities of such a stated sugar solution of known percentage before and after fermentation. It is known empirically that a diminution in the density of 0.001 corresponds to the loss of 0.234 per cent. of sugar by fermentation. In order to accelerate fermentation certain nutritive salts may be added to the urine. The best addition is a mixture of 2 gm. of Rochelle salts and 2 gm. of diacid potassium phosphate to each 100 c.c. of the urine; on addition of 10 gm. of compressed yeast to 100 c.c. of urine prepared in this way fermentation (at 30 to 34 c.c.) is usually complete within three hours. Before determining the specific gravity the suspended yeast cells should be precipitated by lead chromate; 100 c.c. of the urine are treated with 10 c.c. of a solution of neutral potassium chromate, saturated in the cold, and 10 c.c. of a solution of lead acetate. For purposes of comparison the original urine should be treated with the same precipitating mixture and the same nutritive salts, as the presence of these salts naturally changes the specific gravity. It has been found empirically, however, that the addition of 0.0178 to the specific gravity of the original urine corrects this error. The density determinations are best performed with the pyknometer, as aerometers do not, as a rule, give readings that are accurate for a sufficient number of decimal points. The difference in the specific gravities multiplied by 0.234 indicates the amount of sugar in per cent. If the urine contains more than 0.5 per cent. of sugar, this method yields excellent results. When less than 0.5 per cent. is present, the method is not so accurate.

Polarimetric Determination. See under qualitative tests; for the details I refer to text-books of chemistry and physics.

Levulose.—Two levuloses occur in human urine, *i.e.*, *fructose* and *laiose*. The former is the more important of the two.

Levulosuria (Fructosuria).—In the older literature a few isolated cases are on record of dextrosuria in which at the same time a small quantity of levulose was excreted. Quite recently Rosin and Labaud (*Zeitschr. f. klin. Med.*, 1902, vol. lxxiv, p. 182) have shown that considerable quantities of levulose are excreted in a large proportion of cases of diabetes, and that in addition there is a group of cases in which levulose alone is excreted, or in which only minimal quantities of dextrose are excreted together with large quantities of levulose. In the latter group of cases there is at the same time levulosuria.

The presence of levulose is not easy to detect if the urine at the same time contains much dextrose. The characteristic features of such urine are the following: The urine in the first place must give the so-called Seliwanoff reaction (see below). This indicates the presence of levulose (and of certain rare ketoses that need not be considered clinically). The reaction of the urine must be acid (diabetic urine that has not undergone decomposition usually *is* acid), for in alkaline urine dextrose seems spontaneously to undergo metamorphosis into levulose and mannose. In alkaline urine, therefore, the value of Seliwanoff's reaction as an indicator of levulose is impaired.

Seliwanoff's Reaction for Levulose.—Equal parts of urine, fuming hydrochloric acid, and a few grains of resorcin are rapidly heated; a deep red color appears and a dark precipitate forms that is soluble in alcohol with a bright red color.

In order to determine, in the second place, the proportion of levulose to dextrose the following plan may be pursued: The sugar of the urine is, first, determined by use of the reduction tests, and, second, by polarization. If there is a considerable difference in the amount of sugar indicated by these two tests, if, *e.g.*, more sugar is indicated by reduction than by polarization, then the urine is subjected to fermentation until no rotation can be obtained and until the reaction of Seliwanoff is negative. If the reducing power of the urine disappears at the same time, then the difference between the figures obtained from reduction and polarization of the original urine must be attributed to the presence of considerable quantities of levulose, for no other urinary substance excepting fructose (levulose) is fermentable and gives Seliwanoff's reaction at the same time.

The following example (quoted from Rosin and Labaud, *loc. cit.*) may illustrate the method:

Case IV.—Urine gives marked Seliwanoff reaction. Titration (Fehling) indicates 7.1 per cent., polarization 6.4 per cent. After fermentation: Seliwanoff reaction negative, polarization 0. Titration: The urine contains less reducing substance than would correspond to 0.1 per cent. dextrose. Difference between titration and polarization, 0.7 per cent.

The presence of levulose in many cases of diabetic urine may aid in explaining the well-known fact that titration of diabetic urine so frequently indicates higher values for sugar (dextrose) than polarization. We must imagine that the tendency of the dextrose to rotate the plane of polarized light to the right is in part neutralized by the opposite tendency of the levulose present in such urines to rotate it to the left.

Other reducing bodies like pentose and glycuronic acid occur in too small quantities to impair the validity of the viewpoint enunciated above. Urines, moreover, that do not give Seliwanoff's reaction do not reveal the differences described. Levulose, therefore, is in all probability the chief and only cause. Rosin and Lebaud succeeded in strengthening this view by manufacturing levulose as such from urine giving the above tests (they employed the method of C. Neuberg, *i.e.*, they precipitated the levulose with methyl-phenylhydrazin as a methyl-phenylosazon).

Other methods have been proposed to determine the presence of levulose in diabetic urines; but all of these are complicated, and, moreover, ambiguous; none of them gives results that are so conclusive as the above method, so that they will not be discussed in this article.

Laiose (Syn: Leo's Sugar). This sugar was found by Leo in three out of twenty-one diabetic urines. Here, too, titration revealed from 1.2 to 1.8 per cent. more sugar (calculated for dextrose) than polarization. In order to identify this interesting sugar it must be isolated from the urine as follows:

The urine is treated with lead acetate and the lead precipitate filtered off; the filtrate is treated with ammonia; the precipitate contains laiose and dextrose. It is washed out with water and decomposed with H_2S; the lead sulphide is filtered off and the filtrate evaporated to a syrupy consistence in the vacuum over concentrated H_2SO_4. The syrupy residue is dissolved in methyl alcohol and the dextrose precipitated by a solution of barium hydrate in methyl alcohol. So much of the reagent should be added that the liquid becomes alkaline. The mixture is filtered, the ammonia removed by placing the dish under a bell jar or over H_2SO_4. This leads to the precipitation of barium carbonate and some barium dextrose. The barium is removed from the filtrate by CO_2. The methyl alcohol is removed by distillation in vacuo; the residue is dissolved in water. It contains any laiose that may be present.

Laiose is distinguished from other sugars by the following properties: It is not so sweet as dextrose; has smaller reducing powers, and does not ferment so actively. It has a specific rotatory power, and it forms a compound with phenylhydrazin. Although laiose possesses all these properties that seem to class it with the sugars, it is not identical with any known sugar. In fact, it appears doubtful whether it is a hexose or a pentose. (See also Leo: *Virchow's Archiv*, vol. cvii., p. 108, 1887).

Disaccharides.—Isomaltose has been isolated from the urine in small quantities. It is precipitated with other carbohydrates as a benzol ester when the urine is treated with benzoyl chloride (see above, page 38). It is possible that it is formed from dextrose in process of isolation. This sugar is clinically altogether unimportant.

Lactose (*Sugar of Milk*).—This sugar is found in small quantities in the urine of nursing women if there is stasis of milk ("lactosuria"). After the ingestion of 100 gm. of lactose this sugar may appear in the urine of men, or of women who are not nursing. On an abundant milk diet lactose may also appear in the urine. In diabetics the ingestion of lactose leads to the excretion of dextrose. Inversely in nursing women excessive quantities of dextrose (150 gm.) may lead to the excretion of lactose. In new-born children with gastric catarrh lactose has been found in the urine.

Tests. Rubner's Test.—The urine is boiled for two or three minutes with an excess of lead acetate. If lactose is present, the liquid turns yellowish-brown; the precipitate that forms is dissolved in a little ammonia. The liquid now turns brick-red. On standing, a cherry-red or copper-colored sediment settles at the bottom of the tube, while the supernatant fluid becomes clear and colorless. If dextrose is present, this test cannot be applied because a similar reaction is obtained with this sugar. Sometimes lactose and dextrose can be differentiated by heating the urine gently to about 80° (not to boiling). If lactose alone is present, the liquid will not turn red, but yellow or brown, whereas if dextrose alone is present it will turn red.

Fermentation Test.—Lactose does not ferment, but it reduces metal oxides. If, therefore, the urine after fermentation still possesses reducing powers, the presence of lactose may be suspected if the case is a woman in the puerperium, or if the subject is living on a milk diet. The test is by no means, however, conclusive, for lactose, as other non-fermentable sugars, notably pentoses, may be present. In order fully to identify lactose it must be isolated from the urine (see Hofmeister, *Zeitschr. f. phys. Chem.*, vol. i., p. 105).

Polysaccharides.—Animal Gum (Syn.: *Achroglycogen, Urinary Dextrin*). Animal gum is always present in the urine. It is precipitated as a benzol ester with benzoyl chloride (see page 38.) In certain chronic disorders animal gum is increased. Together with isomaltose (that is also precipitated by benzoyl chloride) urinary dextrin forms the group of *unfermentable urinary carbohydrates*, a class of bodies that are attracting much attention and that promise to attain considerable clinical importance.

Animal gum can be isolated from the benzoyl chloride precipitate that forms in a mixture of the urine and sodium hydrate by a complicated method that is described in detail in Huppert's "Harnanalyse," p. 144, 1898. The body is not of sufficient interest for the present to warrant a full description of this method in an article of this limited scope.

Glycogen (Erythrodextrin?). In the urine of diabetics a body is occasionally found (particularly after the dextrose has been caused to disappear) that gives a brown color with iodine. Such urine reduces Fehling's solution only after prolonged boiling. This body has so far never been found in the urine of healthy subjects. From the material published so far it is impossible to determine whether this body is glycogen or erythrodextrin. On physiologic grounds presumptive evidence is in favor of the former supposition.

To test the urine for glycogen (erythrodextrin) a first specimen should be treated with several volumes of alcohol. The alcoholic precipitate, if the urine is diabetic, should be freed from sugar by repeated washing with alcohol or by repeated solution in water and reprecipitation with alcohol. Certain portions of the precipitate, if glycogen is present, assume a brown tint if treated with iodine. By boiling the precipitate for half an hour with ten-per-cent. H_2SO_4 any glycogen or erythrodextrin that may be present is hydrolyzed and converted into dextrose, and the latter, after neutralization of the liquid with sodium hydrate solution, will reduce Fehling's solution, give a phenyl glucosazon, and (after removal of salts by dialysis) ferment (method of Leube).

AROMATIC CONSTITUENTS.—The aromatic constituents of the urine are derived from the degradation of albumins. These degradation products may either enter the body preformed in the food, or they may be formed in the gastro-intestinal tract by bacterial putrefaction, or they may be formed in the tissues proper with or without the intervention of bacteria. Occasionally these aromatic bodies appear in the urine as such. As a rule, however, they appear in combination with sulphuric acid, glycuronic acid, or glycocoll, so that we can conveniently subdivide the combined aromatic constituents of the urine into three groups, viz.: (1) *the conjugate sulphates*, (2) *the compound glycuronates*, (3) *the compound glycocolls.* A fourth group of aromatic bodies, *i.e.*, the aromatic oxyacids, more frequently occurs as such and not combined, so that these substances will be discussed separately under the heading of (4) aromatic oxyacids.

(1) *Conjugate Sulphates.*—The conjugate sulphates include the following bodies: Phenols (kresol, pyrocatechin, hydroquinon), indol (indican), and skatol. Of these bodies the majority are eliminated as the sodium or potassium salt of the ethereal sulphates (*e.g.*,) $(HO.C_6H_4.SO_2OK)$. Indol and skatol, however, are not eliminated as indol or skatol sulphuric acid salt, but undergo preliminary oxidation to indoxyl and skatoxyl, and consequently appear in the urine as indoxyl sulphuric acid (indican) or as skatoxyl sulphuric acid. The most important member of this group is *indican.* The amount of ethereal sulphates excreted in man varies according to the character of the food, the ingestion of certain drugs that are excreted as ethereal sulphates (carbolic acid, *scil.* phenol, etc.), the degree of putrefaction going on in the intestine, the character of the putrefactive bacteria, and the existence of certain morbid conditions of the system that lead to perverted tissue metabolism. The total average quantity of conjugate sulphates approximately equals 0.1 of the mineral sulphates, *i.e.*, on an ordinary mixed diet from 0.15 to 0.3 gm. of SO_3. We do not know where in the body the synthesis of the aromatic conjugate sulphates occurs.

The presence of aromatic ethereal sulphates can be detected as follows: Not less than 25 c.c. of urine are acidulated with acetic acid and the mineral sulphates precipitated with barium chloride. The precipitate of barium sulphate is filtered off and the filtrate heated with hydrochloric acid. As the ethereal sulphates are not precipitable by barium chloride and as they can be decomposed by heating with hydrochloric acid, the mixture now contains ordinary sulphuric acid and alcohols derived from the splitting of the ethereal sulphates. In this liquid the liberated sulphuric acid can be precipitated by barium chloride, so that the appearance of a barium sulphate precipitate speaks for the presence of conjugate sulphates in the original urine. This method can also be employed for the quantitative determination of the conjugate sulphates (see paragraph on "Sulphates" under Inorganic Constituents).

Phenols.—The most important of the phenols is parakresol. Phenol itself is less abundant, and pyrocatechin and hydroquinon are excreted only in very small quantities.

Phenol.—Phenol given by mouth appears as conjugate sulphate. If more is given than can be combined with available sulphuric acid, the excess appears as compound glycuronate (see below). Phenol is not found in the urine of the new-born, because their intestine is sterile, nor is it found in the urine of animals whose intestine is maintained sterile from birth. All local putrefactive and gangrenous processes lead to the elimination of urinary phenol.

Phenol appears in quantities that vary from 0.017 to 0.5 gm. (Munk) in the urine. The average excretion is 0.03 gm. It is more abundant on a vegetable than on an animal diet. Phenol is increased in all conditions of coprostasis, particularly in the lower portions of the small intestine and in the colon; in peritonitis, in pyæmia, in suppurative processes, in phosphorous poisoning, and in diabetes mellitus. Tyrosin and benzol given by mouth also lead to increased phenoluria. When the urine contains much indican, it also always contains much phenol; but the reverse is not the case. As the methods employed for determining phenol also include kresol, the figures given really indicate the combined excretion of the two aromatic alcohols.

Detection: Phenol itself gives a large number of very sensitive tests. Unfortunately, however, more of these reactions give satisfactory results with phenol as conjugate sulphate, *i.e.*, with urinary phenol. In order to detect its presence the phenol must first be liberated as follows: One litre of urine is treated with so much H_2SO_4 that the strength of the mixture is five per cent. The solution is then distilled until the distillate gives no clouding with bromine water. This distillate contains phenol. The following tests can be performed: (*a*) Bromine water is added until the solution is yellow; on standing a crystalline, yellow precipitate of tribromphenol is deposited. (*b*) Millon's reaction is positive (Millon's reagent: Mercury is dissolved in an equal portion by weight of sixty-three per cent. $HNO_3(4HNO_3 + 8H_2O)$ first in the cold, then by warming. One volume of this solution is diluted with two volumes of water and the precipitate that forms filtered off. The clear filtrate is the reagent). With phenol this reagent gives a rose-red color. (*c*) Phenol treated with sodium hypochlorite gives a blue color; care must be taken not to add too much hypochlorite. (*d*) Heating phenol with iodine and sodium-hydrate solution to 50 to 60° C. gives a dark-red amorphous precipitate of triiodine phenol. The latter reaction has been employed in a quantitative method for determining phenols, the amount of mono-oxybenzols being calculated from the amount of iodine that is employed. The method is complicated and does not indicate individual phenols, but merely the phenols as a group. The reaction that occurs may be schematized by the equation:

$$\underset{\text{Phenol.}}{C_6H_5OH} + \underset{\text{Iodine.}}{6I} = \underset{\text{Triiodine phenol.}}{C_6H_2I_3OH} + \underset{\text{Hydriodic acid.}}{3HI}$$

Kresol.—Kresol, as has already been stated, is the most abundant of the phenols. Much that has been said of phenol, particularly in regard to occurrence and detection and estimation, applies with equal force to kresol. Kresol is a methylated phenol. The relation between the two may be illustrated by the formulas: $H.C_6H_4.OH$, phenol, $CH_3.C_6H_4.OH$, kresol.

There are three kresols that are isomeric, viz., parakresol, orthokresol, and metakresol, as the substituting methyl group may occupy any one of three different positions in the phenol ring. Of the three isomers parakresol is the most abundant in man; some orthokresol is usually also present. Metakresol has so far not been found in human urine, but it occurs in horses. The differentiation of kresols from phenol is possible, but the process is complicated. Clinically this differentiation is unimportant; hence it will not be described.

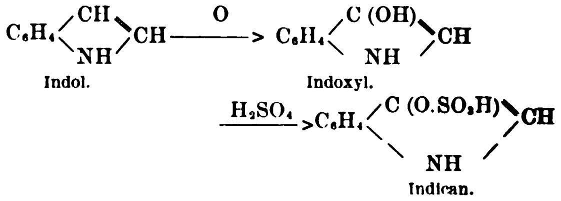
Pyrocatechin, $C_6H_4(OH)_2$.—This is a constant constituent of human urine. It is derived from pyrocatechu acid, that is of common occurrence in many plants. It is excreted after the administration of carbolic acid or of benzole.

Urine containing pyrocatechin soon turns dark on standing, provided the reaction is alkaline. The presence of pyrocatechin may be suspected if this change in the urine occurs, but hydroquinone and alkaptonic acid (see below) produce a similar change. A few drops of chloride of iron added to the urine give a dark green color if pyrocatechin is present. If a little tartaric acid is added and the mixture is treated with ammonia, the urine first turns violet and on addition of more ammonia cherry-red.

Hydroquinone, $C_6H_4(OH)_2$.—This body only occurs in the urine after the administration of carbolic acid (phenol), benzol and hydroquinone itself. It always appears as conjugate sulphate. Urine containing hydroquinone turns dark on standing. If urine containing hydroquinone is boiled with a dilute solution of iron chloride, quinon is formed, and this body can readily be recognized by its penetrating odor.

As pyrocatechin and hydroquinone frequently appear in the urine after carbolic-acid poisoning, it is important occasionally to isolate them from the urine in order positively to demonstrate their presence. For this purpose the urine is acidulated with hydrochloric acid, heated for half an hour on the water-bath, and after cooling extracted with ether. The ethereal extract is repeatedly shaken with sodium-carbonate solution, the ether evaporated and the residue treated with small quantities of a saturated sodium chloride solution. This salt solution takes up the pyrocatechin or hydroquinone that may be present. The solution is diluted with water and distilled to remove volatile phenols. The residue is again extracted with ether and the ether evaporated; the residue is dissolved in water and precipitated with lead acetate; the precipitate contains the pyrocatechin, while the hydroquinone remains in solution. The precipitate is decomposed with H_2SO_4 and extracted with ether. From this ethereal solution pyrocatechin crystallizes in prisms. The solution containing hydroquinone is treated with H_2SO_4, heated with barium carbonate, and the filtrate extracted with ether. From the ethereal extract hydroquinone crystallizes in the form of rhomboid crystals that can be recrystallized from benzol and melt at 160°.

Indoxyl (*Indican*), C_8H_7NO. Indican, the sulphate of indoxyl in combination with sodium or potassium, was originally believed to be identical with vegetable indican, the chromogen of the indigo plant. It has been shown, however, that animal indican is derived from indol and is the ethereal sulphate of indoxyl, an oxidation product of indol, while vegetable indican is a glucoside of the formula $C_{26}H_{31}NO_{17}$. The relation of indol, indoxyl, and indican may be illustrated by the following scheme:



Indol, like the phenols, is a product of the putrefaction of albumin somewhere within the organism. Consequently, we always find phenol in abundant quantities whenever indican is excreted in the urine. Inversely, however, the presence of phenol does not necessarily indicate the presence of indican. In the new-born indican is never found in the urine. In adults it is always present in small quantities. From 2 to 50 mgm. of indigo-blue can be isolated from the twenty-four hours' urine on a mixed diet. A meat diet leads to an increase of the urinary indican, and a vegetable diet to a decrease. Pathologically indicanuria is increased in all conditions that favor abnormal intestinal putrefaction, particularly if there is at the same time some stasis of the intestinal contents. Thus marked indicanuria is common in ileus, typhoid, acute and chronic peritonitis, intestinal tuberculosis. In cholera, gastric ulcer, gastrectasis, gastro-intestinal catarrh, lead colic, perityphlitis and appendicitis indican has also been found increased in the urine. Occlusion of the colon does not lead to increased indicanuria. Large quantities of indican have finally been reported in cases of carcinoma of the liver, the stomach, the uterus, in empyema and putrid bronchitis, and in melanosis. Fever *per se* exercises no effect on the excretion of indican. Opium does not increase indicanuria. Laxatives, however, reduce it.

It will be seen, therefore, that indicanuria is a normal phenomenon, and that the excretion of large quantities of indican is a very common sign. Diagnostically, therefore, the appearance of abnormally large quantities of indican in the urine indicates merely that there is abnormal putrefaction of albumin somewhere in the body. Further than this we can rarely go, and it is a precarious matter to make a special diagnosis on the basis of increased indicanuria, for we must never forget that simple coprostasis may lead to a great increase of the urinary indican.

Other products of indoxyl that may appear in the urine are indigo red (indoxyl *plus* isatin), indoxyl glycuronic acid (see above), and a variety of more or less defined pigments that are variously known by the names urohæmatin, urrhodin, urorubin, indirubin, indigo-purpurin, etc.

Tests for Indican. 1. Jaffé's Test.—Hypochlorite of sodium oxidizes indican in acid solution to indigo blue. This pigment is soluble in chloroform. Equal parts of the urine and of concentrated hydrochloric acid are mixed in a test tube, and to the mixture are added a few cubic centimetres of chloroform and, drop by drop, a dilute solution of sodium hypochlorite. On the addition of each drop of the latter reagent the mixture should be thoroughly shaken. The layer of chloroform will gradually turn blue. Care must be taken not to add too much of the hypochlorite, as otherwise the indigo blue is oxidized further, and is converted into a colorless compound. Instead of using hypochlorite, the oxidation may also be performed with dilute chlorine or bromine water. If the urine contains albumin, the latter must first be precipitated by lead acetate and the test performed in the filtrate. If the urine is very dark, it may also be decolorized by precipitation with lead acetate.

2. Obermayer's Test.—As chloroform forms an emulsion with the urine that frequently renders it difficult to recognize the blue color of the indigo in chloroform solution, Obermayer first precipitates the urine with lead acetate, filters, oxidizes the indican in the filtrate with ferric chloride in concentrated hydrochloric acid, and then shakes out the indigo with chloroform. The blue solution then settles at the bottom of the tube. An excess of lead acetate must be avoided, otherwise lead chloride will precipitate when the hydrochloric acid is added, and this would render the chloroform cloudy. The addition of lead acetate has the additional advantage of removing bile pigment that may be present in the urine.

The filtrate from the lead-acetate precipitate is shaken with an equal volume of fuming hydrochloric acid containing 3 gm. of ferric chloride to the litre. The mixture should be agitated for about two minutes.

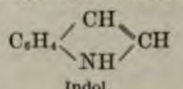
Quantitative Estimation of Indican.—Obermayer's test can be utilized for the quantitative determination. The urine, after treatment with Obermayer's reagent (3 gm. iron chloride to 1 litre of fuming hydrochloric acid) is repeatedly extracted with chloroform. In the chloroform solution the amount of indigo-blue can be determined: (*a*) by weighing, (*b*) colorimetrically, (*c*) spectrophotometrically.

(*a*) By Weighing.—The chloroform is driven off in a weighed dish and the residue dried at 110° C. and weighed.

(*b*) Colorimetrically.—The chloroform solution is compared with solutions of pure indigo-blue in chloroform of known percentage. By diluting the urinary chloroform extraction with measured quantities of chloroform until its color corresponds exactly to that of one of the standard tubes, the amount of indigo-blue in the urine can be estimated by a simple calculation.

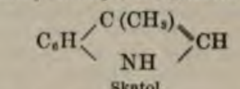
(*c*) Spectrophotometrically (F. Müller).—This method requires much practice and a complicated apparatus, a spectrophotometer. I refer for a description of the method to Huppert, "Harnanalyse," p. 692 *ff.*). This method is not any more accurate than those given under (*a*) and (*b*).

Skatoxyl. This body is an oxidation product of skatol, and skatol is indol in which one hydrogen atom of one of the CH groups is substituted by methyl, CH_3, as follows:



$$C_6H_4\begin{matrix}\diagup CH \diagdown \\ \diagdown NH \diagup\end{matrix}CH$$

Indol.



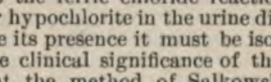
$$C_6H\begin{matrix}\diagup C(CH_3) \diagdown \\ \diagdown NH \diagup\end{matrix}CH$$

Skatol.

Skatoxyl combines with sulphuric acid, and appears in the urine as the sodium or potassium salt of skatoxyl-sulphuric acid. If more skatòl is formed than can be combined with available sulphuric acid, the excess appears in the urine as skatoxyl glycuronic acid (see below). Skatol is a normal constituent of human fæces; whether it occurs normally in the urine remains doubtful for the present. This is due to the fact that the only qualitative index of the presence of skatol (skatoxyl) in the urine is the appearance of a red pigment when the indican tests are performed, and this red pigment may be indigo-red and due to the presence of indican. Skatoxyl sulphuric acid has been found in large quantities in cases of diabetes suffering from digestive disorders. It is possible that some of the many red pigments that have been found in the urine by many different observers are skatol derivatives.

The presence of skatol can be suspected if the urine turns dark on standing: the color usually becoming dark reddish or violet, or even black. If Jaffé's indican test is made the addition of hydrochloric acid alone will color the urine dark red or violet; nitric acid alone or with the addition of a little potassium nitrate produces a cherry-red color; ferric chloride with or without hydrochloric acid also a cherry-red color. The pigment separates out on boiling, and can be extracted with ether. These color tests unfortunately are not typical for skatol, for similar reactions are given by indol red. For order to differentiate the two the pigment must be precipitated from the urine, according to the method adopted in Jaffé's indican test; the pigment is then treated with zinc powder and indol or skatol liberated in this way. Numerous tests are given that are more or less typical for either body. If enough indol or skatol is present to yield a few crystals, the difference in the melting points may decide (indol 52° C., and skatol 95° C.). For other tests I refer to Huppert, "Harnanalyse," pp. 169 and 170).

Skatol can appear in the urine as skatoxyl sulphuric, skatoxyl glucuronic, and skatoxyl carbonic acid. The chemistry and formation of the former is analogous to that of indoxyl sulphuric acid, and much that has been said in regard to indol and its urinary congeners applies with equal force to skatol. Skatoxyl glycuronic acid forms if more skatoxyl is thrown into the circulation than can be combined with available sulphuric acid. This compound glycuronate will be presently discussed. Skatoxyl carbonic acid is never present in large quantities. It gives the ferric chloride reaction with hydrochloric acid or hypochlorite in the urine direct. In order to demonstrate its presence it must be isolated from the urine. As the clinical significance of this substance is not very great, the method of Salkowski (*Zeitschr. f. phys. Chem.*, vol. ix., 32) will not be described in this place.



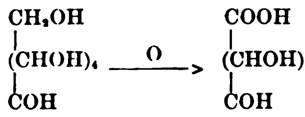
$$C_6H_4\begin{matrix}\diagup C(CH_3) \diagdown \\ \diagdown NH \diagup\end{matrix}C.COOH$$

Skatoxyl Carbonic Acid.

Conjugate Glycuronates.—*Glycuronic acid* does not occur free in the urine, but only in combination with certain aromatic bodies, as phenol, paracresol, indoxyl, and skatoxyl (see above), certain drugs, as naphthol, camphor, toluol, menthol, oil of turpentine, morphine, chloral, and many others. Some of these bodies appear only in combination with glycuronic acid, others, as the phenols, combined first with all the available sulphuric acid to conjugate sulphates, and with glycuronic acid, only after all the supply of sulphuric acid is exhausted. The resulting compounds partake of the character of glucosides.

The conjugate glycuronates are monobasic acids; all rotate the plane of polarized light to the left. The different members of this group, however, show individual peculiarities in other respects. By hydrolysis the glycuronates can be split into free glycuronic acid and the component alcohol. In some cases this disassociation occurs on gentle heating or even at ordinary temperatures, whereas in others boiling with dilute acids or heating with superheated steam is necessary. Some of the conjugate glycuronates reduce cupric oxide in alkaline solution; others do not. Some are precipitable by lead acetate and others are not. These differences are determined by the character of the alcohol in combination with the glycuronic acid molecule.

Glycuronic acid may be considered an oxidation product of glucose, the relation between the two being the following:



$$\begin{array}{l} CH_2OH \\ | \\ (CHOH)_4 \\ | \\ COH \end{array} \xrightarrow{O} \begin{array}{l} COOH \\ | \\ (CHOH)_4 \\ | \\ COH \end{array}$$

Glucose. Glycuronic acid.

As the greater portion of the glucose circulating in the blood is derived from the stored glycogen, it may be said that glycuronic acid is derived from glycogen *viâ* glucose. The acid must be formed in the tissues of the body, for if camphor or chloral, *e.g.*, are administered to a starving animal these bodies will appear in the urine as glycuronates. It is very probable, therefore, that glycuronic acid in this case is derived from the stored glycogen in the liver and muscles. If glycuronic acid, moreover, is fed to animals, the glycogen content of the liver is apparently spared, for after such feeding the liver glycogen increases. Another possible source of glycuronic acid is chondroitin-sulphuric acid (see under "Mucin"), for the latter can be split into glycuronic acid and glycosamin *viâ* chondrosin by a process of hydrolytic disassociation.

Free glycuronic acid and its salts rotate the plane of polarized light to the right, whereas, as we have seen, the aromatic glycuronates are levorotatory. As the free acid, its salts and esters, can reduce metal oxides, glycuronates may readily be taken for glucose. This confusion may be still more enhanced if phenylhydrazin compounds are made, for the free acid forms a crystalline phenylhydrazin compound that melts between 114° and 115° C. Glycuronic acid is not, however, fermentable.

Glycuronates will only be looked for in urine that is levorotatory. In order to demonstrate the presence of glycuronic acid, the latter must be liberated from its compounds. This can be done as follows:

Fifty cubic centimetres of the urine are treated with so much dilute sulphuric acid that the strength of the resulting mixture equals one per cent. The solution is heated over the free flame in a porcelain dish in order to bring about the disassociation of the various glycuronic acid compounds. Boiling for two or three minutes is sufficient. Without filtering, the *orcin test* is performed as follows: A saturated solution of orcin in concentrated hydrochloric acid containing a slight excess of orcin is the reagent. A few drops of this reagent are added to the above mixture and the solution boiled for one or two minutes; a red color should appear. If it does not appear after two minutes' boiling, it is useless to boil longer. for by prolonged boiling any glycuronic acid that might have been present would be decomposed. The orcin test can only be considered positive if certain characteristic absorption bands are found in the spectrum (see Salkowski: *Zeitschr. f. phys. Chem.*, 1899, No. 27).

In diabetes the appearance of glycuronic acid has attracted much attention of late years. As glycuronic acid is an oxidation product of glucose that may be considered intermediary between glucose and the terminal products of its disassimilation, viz., CO_2 and H_2O, the appearance of glycuronic acid in the urine of diabetics has been interpreted to signify incomplete oxidation of sugar. Several writers go so far as to claim that a "delayed Fehling test" in urine that is free from glucose but that contains glycuronic acid is evidence of deficient sugar destruction, and should be considered a warning of impending glycosuria and diabetes. This field is promising and the above hypothesis very seductive. The subject is not sufficiently worked out, however, to merit elaborate discussion in this place. I content myself with referring to it thus briefly. In looking for glycuronic acid in diabetic urine the sugar should first be removed by fermentation. If the liquid is levorotatory after fermentation, the presence of glycuronic acid or its compounds may be suspected; if it still reduces Fehling's or Nylander's solution, and if it gives the orcin reaction after boiling with one-per-cent. sulphuric acid, the existence of glycuronic acid may be considered demonstrated.

Compound Glycocolls.—Glycocoll is amido-acetic acid. It combines with certain aromatic decomposition products of the albumins that are formed in the intestinal tract by putrefaction or in the proper tissues by perverted katabolism—the resulting compounds appear in the urine as compound glycocolls. The two most important members of this group are *hippuric acid* and *phenaceturic acid*, the former a compound of phenylpropionic acid (after its oxidation to benzoic acid) with glycocoll, the latter a compound of phenylacetic acid with glycocoll.

Hippuric Acid. The source of the glycocoll entering into the composition of hippuric acid is obscure. It may be formed from albuminous putrefaction, as all albumins contain a glycocoll radical. The phenylpropionic acid and its oxidation product, benzoic acid, are derived from the degradation of albumins by intestinal putrefaction. In addition certain articles of diet—in particular, certain vegetables—contain bodies like cinnamic and quinic acid, toluol, etc., which may lead to the formation of benzoic acid. We find, therefore, that the elimination of hippuric acid is greater on a vegetable diet than on a meat diet, greater in herbivora than in carnivora. The excretion of hippuric acid in carnivora is exclusively due to the intestinal putrefaction of albumins. In man the ingestion of cranberries, plums, prunes, leads to an increased excretion of hippuric acid. The total hippuric-acid excretion may fluctuate from 0.1 to 1 gm. a day. The normal average excretion on an ordinary mixed diet containing more of the above-named fruits may be placed at 0.6 gm.

Test.—In order to demonstrate the presence of hippuric acid in the urine it is necessary to isolate it. The best method for the isolation of hippuric acid on a small scale is that recommended by Bunge and Schmiedeberg. About 500 c.c. of the urine are rendered alkaline with sodium carbonate, evaporated almost to dryness, and the residue repeatedly extracted with alcohol. The alcohol is driven off, the watery residue acidified with HCl and repeatedly extracted with acetic ether. The acetic ether extract is decanted off and washed with water, then evaporated at a low temperature. The residue contains hippuric acid and any benzoic acid or fat that may be present in the urine. If the residue is treated with petroleum ether, these impurities can be removed and pure hippuric acid remains behind. The hippuric acid is then crystallized from warm water at 55° C.

The crystals of hippuric acid can be recognized from their form, for they constitute milk-white, semitransparent, quadrilateral prisms and columns that are frequently united to form rosettes. On dry distillation (*i.e.*, on heating in a dry test tube) hippuric acid first melts to an oily fluid (that again becomes crystalline on cooling), that gradually turns red if the temperature is raised sufficiently, and finally gives off benzoic acid that sublimes on the walls of the test tube and emits an agreeable odor at first of hay, later of prussic acid. The crystals of hippuric acid are very soluble in alcohol and hot water, and this property, too, may aid in identifying them. Confusion with phenaceturic acid (see below) can be avoided by performing a melting-point determination (melting point of hippuric acid 187.5° C.; melting point of phenaceturic acid 143° C.).

Phenaceturic Acid. This body is only rarely found in the urine of human subjects, but is common in the urine of horses and other herbivorous animals. It is derived from phenyl-acetic acid, a body that can arise from the intestinal putrefaction of albumin. It usually occurs together with hippuric acid, and can be separated from the latter, as shown above, by treating the mixture with petroleum ether. The acid crystallizes in rhombic plates with rounded angles. It is decomposed into phenyl-acetic acid and glycocoll by boiling with concentrated HCl. It assumes a red color when heated above its melting point (143° C.), and emits an aromatic odor.

Other Compound Glycocolls. In addition to hippuric and phenaceturic acid a number of other compound glycocolls have been found in the urine after the administration of certain drugs and chemicals that belong to the group of aromatic organic compounds. Thus salicylic acid appears in the urine as salicyluric acid, nitrobenzoic acid appears as nitrohippuric acid, furfurol appears as furfuracryluric acid, and p-toluylic acid as toluric acid, etc. Clinically these bodies are not very important, but chemically this synthesis to glycocoll compounds is very interesting.

Aromatic Oxyacids.—To this group belong para-oxyphenyl acetic acid, para-oxyphenyl-propionic acid, two bodies that are constantly present in human urine and that are derived from the intestinal putrefaction of albumin, or possibly, too, from proteid disassimilation in the tissues. A litre of normal human urine contains from 0.01 to 0.02 gm. of these acids. In acute phosphorus poisoning and after the administration of phenol or of tyrosin the urine may contain eight times as much as the normal quantity. These oxyacids either appear in the urine as such or as conjugate sulphates.

The clinical importance of these two oxyacids is so subordinate that their properties and the methods for isolating and identifying them will not be given in this article (see Huppert, "Harnanalyse," p. 237 *ff.*).

Other members of this group are para-oxyphenyl-lactoic and oxyamygdalic acid that may both appear after feeding tyrosin or in acute yellow atrophy of the liver where much tyrosin and leucin are thrown into the circulation. All the acids enumerated may, in fact, be considered (chemically) as derivatives of tyrosin.

The two members of this group that are clinically most interesting and most important are dioxyphenyl-acetic acid (*homogentisinic acid*) and trioxyphenyl-propionic acid (*uroleucinic acid*); the two are known by the name of *alkaptonic acids.*

The Alkaptonic Acids. Alkaptonuria.—Alkaptonic acids in solution turn dark on standing. This is also the most striking feature of alkaptonuric urine. Alkaptonuria is commonly believed to indicate abnormal intestinal putrefaction. It is possible that an abnormally large amount of tyrosin is formed that after absorption leads to the formation and excretion of alkaptonic acids. Feeding with tyrosin, as a matter of fact, leads to the excretion of hæmogentisinic acid. Alkaptonuria occasionally appears in several members of a family. Such individuals may be considered chemical (*scil.* metabolic) "sports." Alkaptonuria may persist for a lifetime without any disturbance of the individual's health. It may also appear in certain diseases that are accompanied by intestinal derangement. The excretion of alkaptonic acids is always greater on a meat diet than on a vegetable diet. Antifermentative drugs and laxatives exercise no effect on its excretion.

The alkaptonic acids reduce copper and silver salts, but they do not ferment with yeast, nor are they optically active. They both give a lemon-yellow precipitate with Millon's reagent (see above under Albumin) in the cold that gradually turns orange and, on heating, becomes brick-red.

Homogentisinic Acid. The separation of the two acids is clinically unimportant, for the recognition of alkaptonuria from the above urinary characteristics is sufficient for all purposes. The recognition of pyrocatechin and hydroquinone, that may also cause darkening of the urine, has already been discussed. The presence of these bodies should be ruled out.

For completeness sake, however, the following method for isolating the alkaptonic acids from the urine and for separating the two may be given:

To 1 litre of urine 150 c.c. of twelve-per-cent. H_2SO_4 are added and the mixture extracted with ether by repeatedly shaking it with renewed quantities. In this way nearly all the alkaptonic acids can be extracted. It is a good plan to concentrate the urine before extracting with ether, care being taken that the urine is acid while evaporating. The ether is driven off, the residue, which becomes crystalline on cooling, dissolved in a large volume of water, the solution heated almost to the boiling point and treated with a concentrated solution of lead acetate. The precipitate that forms is filtered off at once and the filtrate allowed to cool. From this solution the lead salt of homogentisinic acid crystallizes within twenty-four hours in the form of large prismatic crystals. In order to manufacture the free acid the lead salt is disassociated with a stream of sulphureted hydrogen, the lead sulphide filtered off, the filtrate freed from H_2S by heating, and concentrated on the water-bath until it begins to assume a dark color. The concentration is then continued *in vacuo* over H_2SO_4. The acid crystallizes in large crystals of characteristic shape that give off 9.08 per cent. of their weight at 100° and melt at 146.5° to 147° C. They are almost insoluble in chloroform, benzol, and toluol. Their watery solution gives the above-named reactions for alkaptonic acid, and turns blue with a few drops of ferric chloride.

Uroleucinic acid has been found only in one case of alkaptonuria. It can be differentiated from homogentisinic acid by the ferric chloride reaction, for whereas the solution of the former turns blue on addition of ferric chloride, the solution of the latter turns green. Its melting point is at 190° to 193° C. It gives the reactions common to the alkaptonic acids.

FATTY ACIDS.—*Volatile Fatty Acids.*—Normal urine always contains traces of volatile fatty acids, chiefly *formic*, *acetic*, *propionic*, and *butyric* acids. According to different estimations, from 0.04 to 0.06 gm. of volatile fatty acids are excreted in twenty-four hours. In febrile states this quantity is increased (0.17 gm.—chiefly acetic). When the urine undergoes ammoniacal decomposition, large quantities of these acids are formed, the source of these volatile acids in this case being the carbohydrates of the urine. Of other acids of the fatty series, both volatile and non-volatile, *valerianic* acid has been found in typhoid, variola, and acute atrophy of the liver. (In these states this acid is probably a putrefaction product of leucin.) In hæmatoporphyrinuria, and in a case of phosphorus poisoning, *oleic* acid and *solid fatty acids* (melting point 49° to 51° C.) have been recovered from the urine. In diabetic urine acetic, butyric, formic, and propionic acids have been found by different investigators. In the urine of various herbivorous animals particularly large quantities of this group of acids have been found. The bulk of the volatile fatty acids excreted in the urine is unquestionably derived from carbohydrate fermentation in the intestine. A portion may also be derived from the putrefaction of albumins in the bowel or from abnormal degradation of the tissue albumins.

Isolation and Identification. The urine (preferably large quantities) is acidified with phosphoric or sulphuric acid and distilled in a current of steam. The acid that is added converts the urea into carbonate of ammonia and is bound by the latter. The distillation is continued as long as the distillate remains acid. The distillate is then neutralized with soda, evaporated to dryness, and the residue repeatedly extracted with absolute alcohol. The alcoholic solution contains sodium salts of the fatty acids, sodium benzoate, and traces of paracresol. The benzoic acid can be removed by treating the residue obtained from the evaporation of the alcoholic extract with sulphuric acid in the cold, removing the precipitate by filtration and allowing the filtrate to stand in the cold until all the benzoic acid is precipitated. The filtrate is again neutralized with soda and shaken with ether. This removes the paracresol. The ether is removed in a separating funnel, the watery residue heated to drive off the last traces of ether, and the analysis for fatty acids undertaken in the watery solution that remains behind.

For the identification of the different acids of this group I refer to text-books of organic chemistry. The total quantity of the fatty acids present in a stated quantity of urine can be determined by preparing the distillate as above, removing benzoic acid and paracresol as indicated, precipitating the watery solution of the fatty acids with barium hydrate, evaporating to dryness, weighing the residue of barium salts of the fatty acid, redissolving in water, determining the barium by precipitation with sulphuric acid, incinerating the barium sulphate and extracting the residue with hydrochloric acid and subtracting the weight of the barium from the weight of the barium salts of the fatty acids.

Lactic Acid (*Sarcolactic, paralactic, dextrorotary lactic acid*).—Lactic acid has been found in the urine in dyspnœa, in perversions of the liver function, after excessive muscular exercise and in certain affections of the muscles accompanied by disturbances of muscular nutrition (trichinosis), and finally in certain forms of poisoning. Normal urine never contains lactic acid. Paralactic acid in the form of its ammonia salt is probably a normal constituent of the blood entering the liver. In this organ it is converted into urea. Hence it appears in the urine when the urea-forming function of the liver is impaired, as in destruction of the liver parenchyma (phosphorus poisoning, acute yellow atrophy), and in asphyxia or carbon-monoxide poisoning when the available supply of oxygen is reduced. After epileptic seizures lactic acid has been found in the urine. Here its appearance may be explained either by the increased muscular catabolism incident to the spasm or by asphyxia incident to the tonic contractions of the diaphragm. Whether or not lactic acid is a disassimilation product of carbohydrates (*i.e.*, whether or not glycogen [dextrose] is destroyed to CO_2 and H_2O viâ lactic acid) remains for the present undetermined. In this case, too, a perversion of glycolysis, or excessive disassimilation of glycogen with lack of oxygen, might account for the appearance of lactic acid in the urine.

Isolation and Estimation. In order to estimate the quantity of lactic acid excreted the lactate of zinc must be manufactured as follows: The urine is treated with a large excess of phosphoric acid and repeatedly extracted with ether. The ethereal extract is evaporated. The residue constitutes a syrupy liquid containing any lactic acid that may be present—also phenols, urea, and hippuric acid. By dissolving the residue in water and boiling the liquid with lead hydrate the extraneous matter can be removed. The solution is filtered hot and the lead precipitated by a stream of H_2S. The sulphide of lead is filtered off, the filtrate boiled in order to drive off the H_2S, and then boiled again with carbonate of zinc. The solution is then evaporated to a small volume and allowed to crystallize, the crystals of zinc lactate washed with a little absolute alcohol, dried in the air and weighed. They are then heated in a small porcelain crucible to 100° to 110° C., and the loss of water of crystallization determined. The paralactate of zinc contains 14.58 per cent. of water of crystallization (ordinary racemose lactate of zinc 18.16 per cent). In addition a zinc determination must be made further to identify the compound. The dried and weighed salt is treated with concentrated nitric acid in a porcelain crucible, the HNO_3 driven off by gentle heat, and the residue first evaporated to dryness and then glowed. The substance at first turns brown, and is finally converted into white zinc oxide. This is glowed to a constant weight. From the zinc oxide the amount of zinc present in the quantity of zinc lactate employed for the analysis can easily be calculated. The dried lactate of zinc contains 33.43 per cent. of ZnO or 26.84 per cent. of Zn.

β-OXYBUTYRIC ACID, DIACETIC ACID, AND ACETONE.—The chemical relation existing between these three substances may be illustrated by the following scheme:

$$\underset{\beta\text{-Oxybutyric acid.}}{CH_3,CHOH,CH_2:COOH} + O = \underset{\text{Diacetic acid.}}{(CH_3CO).CH_2COOH}$$
$$= \underset{\text{Acetone.}}{CO(CH_3)_2} + CO_2$$

The three substances may appear in the urine together. Every urine containing oxybutyric acid contains diacetic acid, and usually acetone. It is possible that in process of determination the precursors of acetone are frequently converted into the latter body so that acetone may apparently appear alone. Diacetic acid may also appear without β-oxybutyric acid, but urine containing diacetic acid always contains acetone; at least for the reason just stated acetone is always detected in the distillate. This at least is the author's experience.

The source of β-oxybutyric acid and its congeners is not positively known. The preponderance of evidence speaks for an albuminous origin, although there are some facts on record that speak for a carbohydrate or a fat origin of these bodies.

β-oxybutyric acid never occurs in normal urine. It is common in diabetic urine. It has been found in scarlatina and measles, but in no other febrile disease. It has been reported in scurvy, in cacrinoma (coma), in uræmia, and in a case of hysteria. The acid usually appears in the form of its alkali or ammonia salts—occasionally free. There is no definite relation in diabetes between the excretion of sugar, ammonia, and β-oxybutyric acid.

Tests.—β-Oxybutyric acid should be looked for only in urine that gives the ferric-chloride test for diacetic acid (see below). Every urine, however, that gives this test does not necessarily contain β-oxybutyric acid (see above). If the urine is levorotatory (after removal of dextrose in diabetic urine by fermentation), the presence of β-oxybutyric acid is still more probable.

Method of Külz. If the urine gives the above tests, it should be evaporated to a syrupy consistence (diabetic urine after fermentation), treated with an equal volume of concentrated sulphuric acid and distilled. The distillate should be collected in a test tube. Cooling is unnecessary. If β-oxybutyric acid was present, the distillate will contain α-crotonic acid, and this body should crystallize on cooling the liquid.

$$\underset{\beta\text{-Oxybutyric acid.}}{CH_3.CH(OH).CH_2.COOH} = \underset{\alpha\text{-Crotonic acid.}}{CH_3.CH = CH.COOH}$$
$$+ H_2O$$

The mother liquid is removed from the crystals by pressing them between filter paper. The dry crystals should have a melting point of 71° to 72° C. If the urine contains only small quantities of β-oxybutyric acid, and if consequently the distillate contains only very little α-crotonic acid, the latter may not form crystals. The distillate should then be extracted with ether, the ethereal solution separated from the water in a separating funnel and evaporated to dryness. The melting point of the residue may then be determined.

For quantitative determinations one litre of the urine is extracted with alcohol, the alcoholic extract treated with sulphuric acid and ether, the ethereal extracts evaporated, the residue dissolved in a small quantity of water, the solution precipitated with lead acetate, the lead removed by H_2SO_4, the filtrate brought to a definite volume (20 to 25 c.c.) and submitted to polarimetric analysis (Coefficient $[\alpha]_D = 20°$). (See also Wolpe, *Arch. f. exp. Path. u. Pharm.*, vol. xxi., p. 138, 1886.)

Diacetic Acid.—This body is common in diabetes, in malignant febrile diseases, during the eruptive stage of scarlatina and measles. It has been described in cholera, in gastric cancer, in many different digestive disorders, in inanition from starvation, and in persons living on an abundant animal diet. Diacetic acid, as shown above, often occurs together with β-oxybutyric acid and acetone. It may occur without the former, but it never occurs without the latter. As a matter of fact, normal urine always contains traces of acetone (see below).

Tests.—As diacetic acid is rapidly decomposed (within twenty-four hours at the latest), the specimens of urine should be fresh.

(1) Arnold's Test. This is the most useful clinical test, as it does not respond to acetone, nor to β-oxybutyric acid. It has the additional advantage that certain bodies (salicylic acid, antipyrin, phenols, acetates, skatoxyl sulphuric acid, thallin, etc.) that may be present in the urine and that respond to the popular iron chloride reaction, to be described presently, do not interfere with this test. The same applies to bile pigments that may be present. In order to make the color reaction more striking the urine may profitably be filtered through animal charcoal.

The reagents needed consist of a one-per-cent. solution of sodium nitrite and a solution of para-amido-acetophenone (1 gm. of para-amido-acetophenone dissolved in 100 c.c. of water is treated with HCl until the yellow solution becomes colorless); one part of the nitrite solution is mixed with two parts of the acetophenone solution. A small quantity of the urine is shaken with an equal volume of this reagent and then treated with a few drops of ammonia. An amorphous reddish-brown precipitate forms. This, however, does not alone denote the presence of diacetic acid. If the mixture, however, is treated with a large excess of concentrated hydrochloric acid (10 to 1), and if a violet-purplish color appears, the urine contains diacetic acid.

(2) The Ferric Chloride Reaction (Gerhardt's Test). The urine is treated with a ten-per-cent. solution of ferric chloride as long as a precipitate continues to form. After filtration (or without filtration) the liquid on addition of more ferric chloride should turn a Bordeaux-red. As other substances (see above) give the same reaction, the test is not quite reliable. The color produced with ferric chloride by most of these bodies can, however, be distinguished from the typical Bordeaux-red with a little practice. Salicylic acid produces a color that is more violet, the antipyretics a color that is more purple, and that, moreover, requires longer (two to three minutes) to appear. The diacetic acid color disappears very soon, whereas all the other colors remain permanently. The test may finally be modified in such a way that the diacetic acid is partially isolated from the urine by treating it with sulphuric acid until it is strongly acid and then extracting it with ether. The ethereal extract, when shaken with a small quantity of the ferric chloride solution, assumes the typical Bordeaux-red color that disappears again on boiling.

(3) Mörner's Test. The urine is treated with a little iodide of potassium and ferric-chloride solution in excess. On boiling, acetone-iodine(?) develops a substance that is very irritating to the mucous membranes. This test is as delicate as Gerhardt's test, but also ambiguous in the sense that the same reaction is obtained with urine containing acetone alone.

Quantitative Estimation. This can only be performed for diacetic acid and acetone together. See, therefore, quantitative estimation of acetone.

Acetone.—Normal urine always contains traces of acetone—usually about 0.001 gm. (7 to 10 mgm.). If the carbohydrates are withdrawn, the acetone excretion increases. In certain pathological conditions as much as 0.5 gm. of acetone may be excreted in twenty-four hours. The chief source of acetone are the tissue albumins. Increased catabolism of the body proteids and decreased oxidation lead to acetonuria. Whether or not urinary acetone is ever derived from intestinal fermentation of albumins remains undetermined. Acetonuria may occur in any of the following pathological conditions: Inanition from starvation, dyspnœa (asphyxia), poisoning with hæmolytic drugs, during narcosis, diabetes (here the amount of acetone excreted stands in no relation to the sugar—or the N-excretion); in hydrophobia, morphinism, phosphorus poisoning, many digestive disorders (autointoxications), in long-continued febrile diseases, and in eclampsia. It will be seen that acetonuria is a very common sign.

Tests. Legal's Test.—The urine may be treated with a few drops of a twenty-per-cent. solution of sodium nitroprusside and a small quantity of sodium hydrate solution. If acetone is present, the urine will turn red—this color rapidly fades; if a few drops of acetic acid are now added, the liquid becomes purple or violet-red. If no acetone is present, the liquid remains colorless even after the addition of acetic acid.

This is the only one of the acetone tests that can be performed with the urine itself. For all the other tests from 200 to 300 c.c. of urine, after the addition of a little phosphoric acid, must be distilled and the tests performed with the first 20 to 30 c.c. of the distillate that pass over.

Lieben's Iodoform Test.—A few cubic centimetres of the distillate are treated with a few drops of potassium hydrate solution and iodopotassic iodide added. If acetone is present, a yellow precipitate of iodoform will form, that consists of fine hexagonal plates and emits a characteristic odor of iodoform. This test is very delicate. Unfortunately a number of other bodies give the same test, notably alcohol and aldehydes.

Gunning has modified the test as follows in order to avoid this confusion with alcohols and aldehydes: He performs the test with an alcoholic iodine solution and ammonia. In the beginning a black precipitate of iodine-N develops that soon disappears, however, and brings the yellow crystalline deposit of iodoform to view. This test is not quite so sensitive as the original test of Lieben.

Reynolds' Test.—This test is based on the property of acetone to dissolve freshly precipitated mercuric oxide. The mercuric oxide is obtained by precipitating a solution of corrosive sublimate with an alcoholic potassium hydrate solution (yellow precipitate). Some of this mercuric oxide is added to the distillate and the mixture thoroughly shaken and filtered. The filtrate is superposed with a solution of ammonium sulphide. If acetone was present in the distillate, a black ring of mercuric sulphide will form at the plane of contact.

Quantitative Estimation. The Underlying Principle.—Acetone in alkaline solution is converted into iodoform by the action of iodopotassic iodide. The reaction proceeds in two stages that may be illustrated as follows:

$$(I_2 + KOH = KOI + HI)$$

$$(1)\ \underset{\text{Acetone.}}{CH_3.CO.CH_3} + 3KOI = \underset{\text{Tri-iodine-acetone.}}{CH_3.CO.CI_3} + 3KOH$$

$$(2)\ CH_3COCI_3 + KOH = \underset{\text{Acetate of potassium.}}{CH_3.COOK} + \underset{\text{Iodoform.}}{CHI_3}$$

The amount of iodine consumed in this reaction is determined by titrating with sodium thiosulphate. The chemism of this reaction is complicated. I will limit myself to describing the execution of the method. An exhaustive explanation of the reaction will be found in text-books of chemistry.

Execution: The urine is distilled and the distillate must be free from phenols, ammonia, nitrous acid or formic acid, for all these bodies interfere with the titration or the formation of iodoform. The ammonia can be kept back by the addition of an acid; 2 c.c. of fifty-per-cent. acetic acid to 100 c.c. of urine do not liberate phenols (as stronger acids or more acid would do), but this amount allows a little ammonia to escape. The distillate should, therefore, be distilled a second time with 1 c.c. of twelve-per-cent. sulphuric acid. In order to prevent the passage of nitrous acid and of formic acid a little calcium carbonate is added to the urine prior to distillation.

LANE LIBRARY

To the second distillate is added an excess of a one-tenth normal iodine solution (12.685 gm. of iodine to 1,000 c.c.) and then drop by drop so much of a fifty-per-cent. solution of sodium hydrate that the color of the iodine disappears completely and the yellow iodoform precipitate appears. The mixture is thoroughly shaken and allowed to stand for five minutes. The liquid is now acidified with concentrated hydrochloric acid. The fluid turns brown from the iodine in excess that is liberated. This excess is titrated with a solution of sodium thiosulphate (one-tenth normal, *i.e.*, containing 24.8 gm. of the salt to 1,000 c.c. of water), using starch solution as an indicator. The starch should not be added until the liquid has become faint yellow on addition of a sufficient quantity of the thiosulphate. As soon as the mixture turns blue, the thiosulphate is slowly added drop by drop until finally the blue color disappears. Every cubic centimetre of the sodium thiosulphate solution corresponds to a cubic centimetre of the iodine solution. The number of cubic centimetres of the former employed in the titration can, therefore, be subtracted from the amount of iodine solution added to the distillate in order to give the amount of iodine consumed in the reaction. The figure obtained multiplied by 0.967 indicates the number of milligrams of acetone present in the amount of urine employed for the estimation.

PIGMENTS.—Indican, indigo-red and skatol-red, alkaptone, pyrocatechin, hydroquinone have already been discussed. The rare or clinically unimportant pigments urochrome, uromelanin, humin bodies, uroerythrin, urorosein, urorubrohæmatin, urofuscohæmatin, and the large number of undefined urinary pigments cannot be described in this article. The following urinary pigments are important: (1) The bile pigments (and bile acids); (2) urobilin; (3) melanin; (4) hæmatin; (5) hæmatoporphyrin.

The Bile Pigments (and Bile Acids) (Choluria).—(*a*) *Bile pigments* are never found in normal urine. They appear in the urine whenever there is stasis of bile and diapedesis of bilirubin from the bile channels into the lymph spaces and blood-vessels of the liver ("hepatogenous" icterus). Thus choluria is one of the signs of occlusion or stenosis of bile ducts, impairment of the diaphragmatic excursions, thrombosis of the portal vein, etc. Some forms of choluria are due to so-called "hæmatogenous" icterus, *i.e.*, the development of bile pigments from the blood pigment of extravasations, hæmatomata, etc. The writer has shown that bile pigments can be formed outside of the liver whenever hæmoglobin undergoes disintegration in the tissues. The appearance of bile pigment in the urine by no means, therefore, always indicates an affection of the liver or of its ducts and vessels.

Urine containing bile pigment is usually yellowish or greenish-brown. The foam that forms on shaking the urine is usually yellow, even if the urine only contains very minute quantities of pigment. The only bile pigment that is found in freshly voided urine is bilirubin. The other bile pigments—viz., biliverdin, bilifuscin, and biliprasin—develop secondarily from bilirubin if the urine is allowed to stand. All the bile pigment voided in the urine may occasionally be found in the sediment. The differentiation of the different bile pigments is clinically unimportant. Of the many chemical tests for bile pigment only the two most practical ones will be described.

(1) Gmelin's Test.—A few cubic centimetres of yellow nitric acid are superposed in a test tube with an equal volume of urine. If bile pigment is present, a *green* ring will form at the plane of contact, in addition usually to a number of other multicolored zones. Only the *green* color is characteristic for bile pigment (biliverdin). The urine must be free from alcohol, as this substance also gives a bluish-green ring with nitric acid. Rosenbach has described a convenient modification of the test. A piece of filter paper is moistened with the urine to be tested and a drop of yellow nitric acid placed on the paper; a number of concentric colored rings form around the drop, and again only a green ring is characteristic for bile pigment. Large quantities of albumin in the presence of small quantities of pigment interfere with Gmelin's test; they had better, therefore, be removed. Small quantities of albumin in the presence of large quantities of pigment do not interfere.

(2) Huppert's Test for very Small Quantities of Bile Pigment.—Ten cubic centimetres of the urine are treated with lime water. The precipitate is removed by filtration and brought into a test tube containing sulphuric-acid alcohol. The suspension is acidified with a few drops of sulphuric acid and heated to boiling. If bile pigment is present, the liquid turns green. Again, the green color is important; indican may give a yellowish or reddish color, but only bile pigment gives a green tint to the alcoholic solution.

(*b*) *Bile acids* in the urine are always pathological. They usually appear together with bile pigment and possess the same clinical significance (see above). It is useless to attempt the direct demonstration of bile aids in the urine, as the most typical reaction for bile acids, viz., Pettenkofer's reaction, is given by a number of other normal ingredients of the urine. The bile acids must, therefore, first be isolated as follows: Albumin, if present, is removed by coagulation; the coagulate filtered off and the filtrate evaporated to dryness, the residue extracted with absolute alcohol, the alcoholic extract diluted with water and precipitated with basic lead acetate and ammonia, the precipitate filtered off, extracted with absolute alcohol and filtered hot. This solution contains any bile-acid salts that may be present and can be submitted to the following tests:

(1) Pettenkofer's Reaction (modified by Udranszky).—In the original Pettenkofer test cane-sugar and sulphuric acid were employed. Since it was shown that the sugar was converted into *furfurol* by the action of the sulphuric acid and that the furfurol gave rise to the typical color reaction with bile acid, Udranszky advised the use of furfurol in the first place. One cubic centimetre of the bile-acid solution is treated with one drop of a one-tenth-per-cent. solution of furfurol and slowly superposed upon 1 c.c. of concentrated sulphuric acid, care being taken by immersing the tube in cold water to prevent too great heating of the mixture. A purple color appears at the plane of contact that gradually extends upward into the superposed solution; on standing, the color turns bluish. In alcoholic solution a green fluorescence is seen. The pigment gives a typical spectrum, viz., two bands, the one near F, the other between D and E, near E.

(2) Platner's Crystals.—An attempt may be made to obtain crystals of the bile acids by evaporating the solution with soda, extracting the residue with absolute alcohol, and adding enough ether to produce a slight clouding. On standing, Platner's crystals of the sodium salts of the bile acids form. These may further be identified as above or by testing their effect on the heart of a curarized frog (retardation).

Urobilin.—Normal urine never contains urobilin. It does, however, contain the chromogen of urobilin, viz., urobilinogen, from which urobilin develops by the action of sunlight. Only very minute quantities of urobilin (urobilinogen) are found in normal urine (not more than from 20 to 130 mgm. in the quantity passed by a healthy adult in twenty-four hours). The high figure (130 mgm.) is only obtained if the urine is first allowed to stand so that all the urobilinogen it contains is converted into urobilin. Urobilin is produced in the bowel by putrefaction, *i.e.*, directly by the action of reducing bacteria on bile pigments. Consequently the excretion of urobilin is increased if intestinal putrefaction is great. It is absent from the urine of the new-born (first to third day) because the intestinal contents remain sterile for some time. It is also absent from the urine if the entrance of bile into the intestine is prevented (occlusion of the bile ducts as by carcinoma of the gall bladder or pancreas, catarrhal swelling, etc.). In these diseases, therefore, the *absence* of urobilin from the urine may be of diagnostic value. *Urobilin is increased* whenever hæmolysis occurs (even if the bile ducts should be occluded at the same time—urobilin-icterus). I propose the name of "*hæmatogenous urobilinuria*" for this condition. Thus we find urobilinuria in many infectious diseases, particularly those forms that are accompanied by rapidly progressive anæmia, in poisoning with hæmolytic substances (potassium chlorate, mushrooms, etc.), in absorption of hemorrhagic exudates, effusions, cysts, etc.

Immediately after the removal of some biliary obturator (passage of a gall-stone, relief of catarrh, etc.) the urobilin excretion is increased—a direct result of the entrance of much bile into the bowel. Urobilin has also been found increased in pernicious anæmia, after chloroform narcosis, in a case of melanotic sarcoma (alternating with melanin), in lead colic, atrophic cirrhosis of the liver, and in certain valvular heart lesions that lead to passive congestion of the liver and pleiochromia.

Tests.—Urine containing much urobilin is usually very dark. The color is no index, however, of the amount of urobilin, for very dark urines may be colored by other ingredients, and may contain very little urobilin, whereas light urines may contain much urobilin, as the coloring properties of urobilin are slight. Sometimes the presence of urobilin can be demonstrated in the urine direct. Occasionally it may be necessary to isolate it from the urine.

To test the urine direct we have two tests, viz.:

(1) Fluorescence. The urine is treated with an excess of ammonia and a few drops of a one-per-cent. alcoholic solution of chloride of zinc. If the urine contains urobilin, a beautiful green fluorescence will appear.

(2) Spectroscopic Examination. Only such urine can be utilized for this test that does not contain too many other pigments. It is well, therefore, to treat the urine first with mercuric sulphate, to filter off the pigment precipitate, and to examine the filtrate spectroscopically. Ten cubic centimetres of the urine are treated with 5 c.c. of a solution of mercuric sulphate, made by dissolving 5 gm. of mercuric oxide in 20 c.c. of H_2SO_4 and 100 c.c. of water; the mixture is allowed to stand for five minutes, then filtered. The filtrate should show the absorption bands of mercuri-urobilin. The urine itself and extracts made from the urine show either the spectrum of urobilin itself or of acid urobilin. (For descriptions and illustrations of these different spectra I must refer to text-books of physiological chemistry.)

If the urine contains too little urobilin to give these tests positively, the urobilin should be extracted. One may use amyl alcohol, chlorform, phenol, ether, or acetic ether. Amy alcohol is the best.

Extraction with Amyl Alcohol (Nencki and Sieber). Ten to twenty cubic centimetres of the urine are treated with a few drops of hydrochloric acid and shaken with 6 to 10 c.c. of amyl alcohol. The alcoholic solution is submitted to spectroscopic analysis. It is then treated with a few drops of a one-per-cent. solution of zinc chloride in ammonia-alcohol. In the presence of urobilin a green fluorescence appears.

Melanin (Syn. *Phymatorhusin*).—Patients with melanotic neoplasm occasionally void urine that turns dark on standing. The dark color can frequently be brought about more rapidly by the addition to the urine of oxidizing agents, as nitric acid, chromic acid, ferric chloride, bromine, etc. The dark color may occasionally be made to disappear again if the urine is treated with reducing agents. If the urine is kept in an air-tight vessel, darkening may be prevented. Indican and urobilinogen may lead to confusion. This error can only be ruled out by testing the urine for these two bodies. After their presence is excluded the presence of melanin can be established by the properties of melanotic urine, described above.

Hæmatin is occasionally found in the urine. It is a derivative of hæmoglobin and may be formed from the latter if bloody urine is heated, the urinary acids disintegrating the hæmoglobin into hæmatin and a proteid radical. It has also been described in a case of sulphuric-acid poisoning. The presence of hæmatin is recognized by spectroscopic examination of the urine. The spectrum of hæmatin may be confused with the spectrum of methæmoglobin; hence it is necessary to treat the urine first with ammonia and to re-examine the filtrate spectroscopically; finally to add ammonium sulphide and to examine a third time. Spectra that are characteristic for alkaline and for reduced hæmatin will successively appear on the addition of these reagents. As this body is clinically unimportant, other tests and reactions will not be included in this article.

Hæmatoporphyrin.—This pigment in very minute traces occurs in normal urine (Garrod and Saillet). In a number of cases of enteric fever, Addison's disease, exophthalmic goitre, in cirrhosis of the liver, in anæmia, in lead poisoning, rheumatism, and gout considerable quantities of hæmatoporphyrin have been found in the urine. The source of hæmatoporphyrin is obscure. It does not seem to occur regularly whenever many red blood corpuscles are destroyed. The theory that it is formed in the bowel from blood pigment has been exploded.

The most important clinical forms of hæmatoporphyrinuria occur in poisoning with sulphonal, trional, and tetronal, or after the prolonged use of these drugs. The author has reported a case of sulphonal poisoning with hæmatoporphyrinuria (together with J. Tyson) in which 1.683, 1.013, and 0.098 gm. of hæmatoporphyrin were voided on three successive days, this amount corresponding to 35.1 gm. of hæmoglobin. Here about one-seventeenth of the total hæmoglobin of the subject (computed at 600 gm.) was destroyed and appeared in the urine as hæmatoporphyrin. Salkowski in one case of sulphonal poisoning obtained 0.87 gm. of hæmatoporphyrin.

Tests and Determination.—Hæmatoporphyrin urine has a typical Burgundy-red color. On standing it may turn almost black. It is possible that such urine contains other pigments besides hæmatoporphyrin. The urine is precipitated with barium mixture (consisting of one part of saturated barium-nitrate solution and two parts of concentrated baryta water). The precipitate contains the bulk of the hæmatoporphyrin together with other pigments that may be present. The precipitate is filtered off, washed and extracted with dilute hydrochloric-acid alcohol. This extract is reddish or pink in color, fluoresces and turns darker on heating. Spectroscopically a narrow absorption band between C and D in the yellow and a second broader band between D and E between the yellow and the green will be found. If the solution is alkalinized four bands will appear, one between C and D, two between D and E, and a fourth very dark band between *b* and F, *i.e.*, between the green and the blue.

Quantitative Estimation.—One hundred cubic centimetres of the urine are rendered alkaline with a dilute soda solution and precipitated with calcium chloride, again rendered alkaline with soda and the precipitate filtered off. The dark-red precipitate is repeatedly washed with water until the filtrates are free from chlorine (no precipitate with $AgNO_3$), then washed with absolute alcohol, and finally extracted with dilute HCl-alcohol at a temperature of about 40° C. From the pink alcoholic extract the pigment can be precipitated with water after neutralization of the liquid with dilute ammonia. The flocculent precipitate is gathered on a filter, washed free from chloride, washed with alcohol and ether, desiccated *in vacuo*, dried at 115° C., and weighed. This precipitate, besides hæmatoporphyrin, contains inorganic salts. A weighed portion is therefore incinerated and the weight of the ash subtracted. The difference represents organic substance, *i.e*, hæmatoporphyrin.

FAT.—For fat in lymph cells, epithelia, casts, see section on "Urinary Sediments"; for fat concretions see section on "Urinary Concretions"; for fat in chyluria, see the article on this subject.

CHOLESTERIN has been found in chyluria (see article on this subject). It occasionally appears in the urine of pregnant women, and it has been found in the urine of epileptics. For cholesterin in urinary concretions and sediments see below.

Tests.—The urine is shaken with ether, the ethereal extract removed, the ether evaporated, and the residue examined microscopically for crystals of cholesterin (see Fig. 4869). If the residue contains so much fat that the cholesterin cannot crystallize or the crystals cannot be recognized, the residue is treated with alcoholic KOH, the mixture boiled, evaporated to dryness, the soaps that have been formed dissolved in water, the watery solution extracted with ether, the ether evaporated, the residue dissolved in boiling alcohol, the solution evaporated to a small volume and allowed to crystallize. Cholesterin crystals touched with concentrated sulphuric acid turn red or blue (cholesterilines).

Inosite (Hexahydro-hexoxybenzol).—This body is occasionally found in diabetes mellitus, in albuminuria, and after abundant water drinking. Pohl reports a case of diabetes mellitus in which the dextrose of the urine was gradually replaced by inosite. Inosite has been called a sugar, but it does not give the chemical reactions of any of the saccharides. It is, moreover, according to Maguenne hexahydroxybenzol. In order to demonstrate the presence of inosite it must be isolated from the urine. The best method is that of

Cooper-Lane.—The urine, after removal of any albumin it may contain, is precipitated with baryta water, filtered, and the washed filtrate treated with lead acetate until no further precipitation occurs. The lead precipitate is filtered off after twelve hours' standing, suspended in water and disassociated with H_2S. The lead-free filtrate is concentrated and treated with boiling alcohol (three to four volumes). The alcohol produces a precipitate that is removed by filtration; the filtrate is allowed to stand twenty-four hours; crystals of inosite may form. These are removed by filtration, washed with cold alcohol and identified (see below). If no crystals form, the alcoholic solution is treated with ether until the liquid becomes milky. The mixture after standing twenty-four hours precipitates fine shiny plates of inosite. The crystals give the following reactions:

(1) A few crystals are heated on a piece of platinum foil with a few drops of concentrated nitric acid and the mixture evaporated to dryness; the residue is treated with ammonia and a little $CaCl_2$ solution (to bind the excess of HNO_3) and again carefully evaporated to dryness; a bright rose color indicates the presence of inosite. One milligram of the substance gives this reaction distinctly. Carbohydrates do not give it.

(2) The water of crystallization may be determined in the crystals. At 100° C. the crystals should lose 16.67 per cent. of water.

(3) Inosite tastes sweet. It melts at 217° C. It crystallizes in clino-rhomboid crystals that are usually gathered together in rosettes.

Ptomaïns.—That urine is toxic has been known for a long time. The chief cause of this toxicity are the potassium salts the urine incorporates. After removal of the K-salts the urine, however, still remains toxic. The toxicity of the urine, moreover, is not proportionate to the quantity of K-salts it contains, and the urinary ash, finally, containing all the K-salts is not so toxic as the total urine. Bouchard and his pupils are the chief exponents of the toxicity of the urine. They have published a mass of investigations on the toxicity of the urine in health and disease. The results obtained from this work are out of all proportion to the labor expended; nothing really conclusive having so far been demonstrated. This is not the place to review this large field. It may suffice to say that a variety of organic bases, alkaloids and toxalbumins, have been found by different investigators in normal and in pathological urines.

The best method for isolating ptomaïns from the urine is that described by Brieger:

[illegible] n to twenty litres of the urine are acidified with HCl [illegible] porated to a syrupy consistence; the residue is [illegible] with alcohol and the solution precipitated with [illegible] solution of mercuric chloride. The precipitate is extracted with much boiling water; the mercury compounds of the ptomaïns will then be found in the solution. The mercury compounds are disassociated with H_2S, the mercuric sulphide filtered off and the filtrate evaporated to a small volume. From this liquid the bases crystallize in the form of the hydrochlorates.

Enzymes.—The urine seems normally to contain proteolytic and diastatic ferments. Of the former the most common one can digest fibrin in dilute HCl solutions. It appears, therefore, to be pepsin. Another protease is occasionally found that digests fibrin in an alkaline medium. It may be trypsin. A diastatic ferment (ptyalin) is apparently one of the constant constituents of normal urine. Rennet, too, has occasionally been found. Fat-splitting enzymes have so far not been positively demonstrated. It is probable that they would be destroyed in the bladder even if they were excreted in the kidneys and would consequently escape detection. The enzyme excretion fluctuates somewhat according to time of day, the time of eating, physical exercise, etc. So far similar fluctuations that a number of authors have described in various diseases have no clinical significance. For methods to identify the different enzmyes I refer to text-books of physiological chemistry.

Inorganic Constituents.

The inorganic constituents normally present in the urine are hydrochloric, sulphuric, phosphoric, and carbonic acids; potassium, sodium, ammonium, calcium, and magnesium. Other acids occurring in very small amounts are fluoric, silicic, nitric, and nitrous acids. In addition we sometimes find peroxide of hydrogen and sulphureted hydrogen, and, finally, of the bases, iron.

Urinary Ash.—The amount of urinary ash fluctuates from 9 to 25 gm. in the twenty-four hours' quantity; the chief fluctuations being due to variations in the sodium-chloride excretion.

Quantitative Estimation of the Urinary Ash.—In determining the total ash of a given quantity of urine, the urine after evaporation to dryness should not be directly incinerated, for the alkaline chlorides are volatile at glow temperatures; the sulphates are reduced to sulphides by carbonaceous material, and the monophosphates are decomposed (escape of phosphorus). The urine is therefore evaporated and the residue merely carbonified, not incinerated, at a low temperature; the soluble salts leached out with water, the residue dried and then incinerated, and, finally, the watery extract evaporated to dryness in the crucible containing the ash and the whole weighed. This method gives very accurate results. See also "Electric Conductivity of the Urine."

Acids.—1. *Hydrochloric Acid* (Chlorides).—The quantity of HCl in the urine is largely dependent on the ingestion of salt (NaCl). The daily excretion rarely exceeds an amount that would correspond to more than 15 gm. of NaCl. The excretion of HCl salts is greatly diminished in fasting and in pneumonia during the formation of the exudate. In nephritis, with retention of solids and in certain gastric disorders (hyperchlorhydria) the urinary chlorides are also decreased. After large meals containing much salt, during the absorption of fluid transudates, in interstitial hepatitis (?), after the administration of thyroid, after inhalation of chloroform, and in the stage of convalescence from acute nephritis, the urinary chloride excretion is increased. Hydrochloric acid appears in the urine as sodium, potassium, ammonium, calcium, and magnesium chloride. Of these salts the most important and the most abundant is the sodium salt. All these chlorides are readily soluble in water.

Tests.—The urine is treated with nitric acid and a few drops of a ten-per-cent. silver-nitrate solution. The precipitation of a cheesy sediment that is readily soluble in an excess of ammonia indicates the presence of chlorides. Other substances that react similarly are iodides, bromides, and cyanides. Their presence should, therefore, be excluded in interpreting this test.

Quantitative Estimation of the Chlorides.—1. Method of Volhard. Solutions: (1) 29.042 gm. of chemically pure silver nitrate dissolved in 1,000 c.c. of water.

(2) Concentrated solution of ferric-ammonium alum (free from chlorine!).

(3) Nitric acid of 1.200 specific gravity.

(4) Solution of ammonium-sulphocyanide. This solution should be of such a strength that 25 c.c. would correspond to 10 c.c. of the silver solution. Theoretically there should be 12.984 gm. of the salt to a litre, but as ammonium sulphocyanide is very hygroscopic, it cannot be weighed accurately. Consequently the strength of the solution must be determined by titrating against the silver solution: 6 to 7 gm. of the sulphocyanide are dissolved in 400 c.c. of water and a part poured into a burette; 10 c.c. of the silver solution diluted with 100 c.c. of water are poured into a flask treated with 4 c.c. of the nitric-acid solution, and 5 c.c. of the ferric-ammonium solution, and the whole thoroughly mixed by shaking. To the mixture so much of the sulphocyanide solution is allowed to flow from the burette that the liquid in the flask assumes a faint but permanent reddish tint. Several tests of this kind are made and the average quantity of the sulphocyanide solution required determined. If it is found, for instance, that 22 c.c. of sulphocyanide produce the end reaction (red color), then the volume of water that must be added to one litre of the sulphocyanide solution is found according to the formula: $22:25 = 1{,}000 : x$; $x = 1136.3$. In other words, in order that 25 c.c. of the sulphocyanide solution correspond to 10 c.c. of the silver-nitrate solution, 136.3 of water must be added to the sulphocyanide solution. With these four solutions the chloride determination in the urine is performed as follows: 10 c.c. of the urine are poured into a flask holding 100 c.c.; to the urine are added 50 c.c. of water, 4 c.c. of the nitric acid, and 15 c.c. of the silver-nitrate solution. The contents of the flask are agitated until the precipitate settles and the supernatant fluid becomes clear. The flask is now filled to a mark that indicates 100 c.c.; 80 c.c. of the contents are then filtered through a dry filter into a dry measuring cylinder. These 80 c.c. are poured into a flask holding about 200 c.c. and are treated with 5 c.c. of the ferric-ammonium-alum solution, and with so much of the sulphocyanide solution, prepared as above (from a burette), that a faint red hue persists. The amount of sulphocyanide solution required to bring about this end reaction is determined in a series of tests and the average taken. It is assumed that the 15 c.c. of silver-nitrate solution suffice not only to precipitate all the chlorides, but also to leave an excess of silver nitrate in solution. It is this latter excess precisely that is now determined by titration with the sulphocyanide solution. The percentage of chlorides in the urine is then calculated from the deficit, according to the following formula:

$$x = (37.5 - \tfrac{5}{4}\,R),\ \tfrac{4}{10}$$

x = Amount of sodium chloride contained in one litre of urine (expressed in grams).

R = Number of cubic centimetres of the sulphocyanide solution required to bring about the end reaction.

The rationale of this formula is the following: 10 c.c. of the silver-nitrate solution correspond to 25 c.c. of the sulphocyanide solution, and 15 c.c. of the silver-nitrate solution consequently correspond to 37.5 c.c. of the sulphocyanide solution. For 100 c.c. of the test solution 37.5 c.c. of the sulphocyanide solution less $\frac{5}{4}$ of the amount of sulphocyanide solution used were needed, for 80 c.c. correspond to the amount of sulphocyanide solution taken from the burette, so that 100 c.c. would have required $\frac{5}{4}$ of this amount. As 25 c.c. of the sulphocyanide solution correspond to 10 c.c. of the silver solution, 1 c.c. of the former solution corresponds to 0.4 c.c. of the latter; and as 1 c.c. of silver solution indicates 0.01 gm. of sodium chloride (the silver solution used as a reagent is prepared in this proportion), 0.4 c.c. of the silver solution correspond to 0.004 gm. of sodium chloride. Hence in order to obtain the amount of chlorides present in 10 c.c. of urine the figure $(37.5 - \frac{5}{4}\,R)$ must be multiplied by 0.004. In order to determine the chlorides in one litre (1,000 c.c.) of urine the above figure must be multiplied by $0.4 = \frac{4}{10}$. (von Jaksch.)

The presence of albumin and sugar in the urine does not interfere with the accuracy of this method. It is the most accurate and the most convenient one for clinical purposes. All other methods, *i.e.*, the methods of Mohr, of Gay Lussac, of Zuelzer, are based on the same principle, viz., the titration of the chlorine with a solution of silver nitrate. As they have no advantages over Volhard's method, they will not be described in this place. A description will be found in Huppert, "Analyse des Harns," 1898, p. 705 *ff.*

Hydrofluoric Acid.—The urine contains traces of hydrofluoric acid (salts). It is clinically without any importance.

Test (*Berzelius*).—A large volume of urine is precipitated with ammonia, the precipitate calcined, treated with an equal volume of H_2SO_4 and heated in a platinum crucible. Over the crucible a glass plate is held. If HFl is present, it will etch the glass.

Sulphuric Acid (*Sulphates*).—Sulphates occur in the urine as mineral (preformed) and conjugate sulphates. For the latter see the chapter on Conjugate Sulphates above. The total SO_3 excretion fluctuates from 1.5 to 3 gm. in twenty-four hours on a mixed diet. The chief source of the sulphates are the albumins; the greater, therefore, the percentage of proteid pabulum, the greater the sulphate excretion. The conjugate sulphates constitute about one-tenth of the total sulphates. In certain pathological conditions the excretion of conjugate (ethereal) sulphates is greatly increased (see above), so that this proportion is changed in favor of the conjugate sulphates. In addition to preformed and conjugate sulphates the urine also contains sulphur in the form of sulphocyanides, thiosulphates, and sulphureted hydrogen, so-called "neutral sulphur" (see below).

The preformed sulphates of the urine are the sodium, potassium, magnesium, and calcium sulphate. The absolute increase or decrease of the preformed sulphates is of slight clinical significance. It is important, however, as pointed out above, to determine the relative proportion of preformed and conjugate sulphates; hence the quantitative estimation of the preformed sulphates is often necessary.

Qualitative Determination of Preformed Sulphates.—The urine is acidified with acetic acid and treated with barium chloride. A white, fine, powdery precipitate indicates the presence of preformed sulphates. This reaction is always obtained in normal urine. If the urine is not rendered sufficiently acid, the barium chloride may also precipitate phosphates or oxalates (or even uric acid). In order to differentiate the sulphates from these other bodies the precipitate is warmed with dilute HCl. This leads to the solution of oxalates and phosphates and leaves the sulphates behind.

Quantitative Determination of Preformed Sulphates. The preformed sulphates can either be determined directly or the total sulphates and the conjugate sulphates can be determined separately and the preformed sulphates calculated from the difference.

Total Sulphates.—The urine is treated with concentrated HCl and heated to boiling. This decomposes the conjugate sulphates into aromatic constituents and sulphuric acid. In the liquid the sulphates are precipitated with barium chloride, filtered off, and determined as barium sulphate.

Fifty cubic centimetres of urine are diluted one-half and treated with 5 to 10 c.c. of strong HCl heated to boiling and precipitated with a slight excess of barium chloride. The mixture is allowed to stand for twenty-four hours in the cold and filtered; the precipitate is washed with hot water, alcohol, and ether, and dried. The filter is then incinerated and weighed. One hundred parts of barium sulphate correspond to 34.28 parts of SO_3, or 41.13 parts of SO_4, or 41.99 parts of H_2SO_4, and the result may, therefore, be expressed as SO_3; or

SO_4, or H_2SO_4 by multiplying the weight of the barium sulphate by 0.3428, 0.4113, or 0.4199.

Determination of Conjugate Sulphates (*Baumann*).—The preformed sulphates are precipitated by barium chloride in the urine after it has been acidified by acetic acid. In the filtrate the conjugate sulphates are then determined.

Fifty cubic centimetres of urine are rendered acid with acetic acid, diluted one-half and precipitated with barium chloride in excess, heated on the water-bath until the barium sulphate settles at the bottom of the vessel, and filtered. The filtrate and washings are then treated as above, *i.e.*, the conjugate sulphates decomposed with HCl and the liberated sulphate determined as barium sulphate. By subtracting the value obtained for conjugate sulphates from the value obtained from the determination of the total sulphates the amount of preformed sulphates can be estimated.

Determination of Preformed Sulphates Directly.—As the barium sulphate precipitate obtained from the original urine often contains phosphates and oxalates, it cannot be weighed directly. In order to get rid of these impurities the precipitate must be repeatedly treated with HCl in a platinum crucible. The procedure is very tedious and is superfluous in view of the fact that the preformed sulphates can be estimated from the difference between total and conjugate sulphates with less trouble. They can also be determined directly by *titration* as follows:

Method of Freund.—Fifty cubic centimetres of urine are treated with ten drops of alizarin red. This colors the urine red. Then five-per-cent. acetic acid is added drop by drop until the red color disappears. When this point is reached, 5 c.c. more of acetic acid are added. The urine is then heated almost to boiling and barium acetate solution added until the liquid again turns red. The solutions required for this estimation are:

(1) A solution of 9.579 gm. of anhydrous barium acetate in 1,000 c.c. of water; 24 c.c. of this solution should correspond to 0.2101 gm. of $BaSO_4$.

(2) Five-per-cent. acetic acid.

(3) One-per-cent. solution of sodium alizarin monosulphate ("alizarin red").

As it is known that 24 c.c. of the barium solution correspond to 0.2101 gm. of $BaSO_4$, the calculation of the preformed sulphates in the 50 c.c. of urine employed in the analysis is simple.

The "Neutral Sulphur" (synonym: suboxidized sulphur, organic sulphur).—Some twelve to fifteen per cent. of the total sulphur of the urine consists of a number of bodies of which we know relatively little; among them are thiosulphates, sulphocyanides, and derivatives of taurin and cystin. A portion of these bodies is readily oxidized, whereas another portion is not oxidized so easily; the former can therefore be converted into sulphuric acid by chlorine or bromine water, the latter require fusing with nitre and potassium hydrate. Cystin belongs to the last-named group of bodies, also taurin, whereas the thiosulphates and rhodanates (sulphocyanides) belong to the former group. The quantity of neutral sulphur compounds is dependent on the quantity and the character of the albumins that are disintegrated in the organism. The neutral sulphur is increased after violent muscular exercise, after a long period of starving, in asphyxia, in chloroform narcosis, after the administration of chloral and of sodium carbonate and sodium citrate (Jawein). After the ingestion of sublimed sulphur a portion of this sulphur reappears in the urine as neutral sulphur. In icterus the neutral sulphur is increased from four to five times above normal (sixty-two per cent., Lépine). In pneumonia the neutral sulphur has also been found increased. In hepatic disorders the compounds that are hard to oxidize seem to be increased, whereas in pneumonia the compounds that are readily oxidizable are increased.

In *cystinuria* a peculiar urinary anomaly characterized by the excretion of cystin, the excretion of neutral sulphur is greatly increased (23.4 to 45.7 per cent.). In addition to cystin certain diamins (putrescin, cadaverin) are found in the urine, and as the disease seems to occur in families, and may persist for a lifetime, we are probably dealing with a peculiar metabolic anomaly in which the oxidation of the albumins is perverted. Some authors (v. Jaksch) are inclined to attribute cystinuria to a particular form of intestinal mycosis. I consider the former view more plausible. The disease is very rare. The chief clinical significance of the urinary excretion of cystin is the tendency to calculus formation that is thereby created. The appearance of cystin in the urine should always constitute a warning of impending cystin gravel or calculi. (See also Urinary Sediments.)

Tests for Neutral Sulphur.—The total sulphuric acid is first precipitated by hydrochloric acid and barium chloride, as explained above, the excess of barium removed from the filtrate by soda, the filtrate evaporated to dryness, the residue fused with nitre (and soda), the solution of this fused mixture treated with barium chloride, and the sulphuric acid precipitated. To determine the presence of sulphur that is readily oxidized the filtrate of the urine after removal of the total sulphuric acid, as above, is acidulated and treated with bromine; on addition of barium chloride any sulphuric acid formed by this mild oxidation will be precipitated.

The qualitative tests for thiosulphates and sulphocyanides will not be given in this article, because the clinical significance of these bodies is too subordinate.

The quantitative estimation of the neutral sulphur is performed according to the same principles as the qualitative tests for this group of bodies. The urine may first be oxidized and the total sulphur determined; then the total performed and conjugate sulphates may be determined separately and the quantity of the neutral sulphur calculated from the difference. In order to determine the total sulphur by oxidation a measured quantity of the urine is evaporated to dryness and the residue glowed with a fusing mixture consisting of four parts of nitre and one part of soda. The white ash is treated with hydrochloric acid and evaporated to dryness, this process being repeated three or four times in order to get rid of all the nitric acid. The residue is then dissolved in water and the sulphuric acid determined as described above. Other methods of oxidation, *i.e.*, with nitric acid (Mohr), with sodium superoxide (Clark), will not be described, as they possess no advantages over the oxidation with nitre soda.

Cystin may be precipitated from the urine by benzoyl chloride, and the sulphur determined in the precipitate. Two hundred cubic centimetres of the urine are treated with 10 c.c. of benzoyl chloride and 70 c.c. of a ten-per-cent. sodium hydrate solution and shaken until the odor of benzoyl chloride disappears. The precipitate consists of benzoyl cystin and can be used directly for a sulphur determination by oxidation. The presence of cystin in the benzoyl chloride precipitate is made probable if a black sediment forms when the precipitate is boiled with a solution of lead oxide in soda lye. The black sediment consists of lead sulphide, and consequently also denotes the presence of sulphur.

Sulphureted Hydrogen.—Sulphur may finally occur in the form of sulphureted hydrogen. Fresh urine rarely contains H_2S or sulphides, but nearly every old urine emits an odor of H_2S when treated with mineral acids. Hydrogen sulphide does not appear in the urine in diseases that are accompanied by putrefactive processes, nor does it appear after the ingestion of alkali sulphides, nor after sulphur baths. Occasionally H_2S passes into the bladder from the rectum if some abnormal communication exists between these two viscera. Certain bacteria may infect the bladder and may lead to the generation of H_2S in this viscus.

Tests.—The urine should of course be fresh. The *odor* may be characteristic. Lead acetate may form a black precipitate of lead sulphide. A piece of paper may be saturated with a solution of lead acetate, the urine poured into a bottle, and a current of air forced through the liquid. The lead paper is held over the neck of the bottle. If H_2S is driven off, the paper will turn brown or black. Quantitative determinations of H_2S in urine are clinically without value.

Phosphoric Acid (*Phosphates*).—The urine always contains phosphoric acid; the average daily excretion is 3.5 gm. of P_2O_5; the quantity is largely dependent on the character of the diet; increased catabolism of cell nuclein either of the food or of the proper tissues causes an increase of phosphoric acid.

Four phosphates appear in the urine, viz.: (1) NaH_2PO_4 = monosodium phosphate; (2) Na_2HPO_4 = disodium phosphate; (3) Na_3PO_4 = trisodium phosphate; (4) $Na_3PO_4\ (+NaOH)$ = basic sodium phosphate. (1), (2), and (3) are also called the acid, neutral, and basic phosphate respectively; (4) would then be "overbasic." Some writers speak of (1), (2), and (3) as primary, secondary, and tertiary phosphate. The designation adopted above is the most popular and the most rational one.

The monophosphates can be converted into the di- and triphosphates by the addition to the urine of alkali hydrates or carbonates. Inversely the tri- and diphosphates can be converted into monophosphates by acids.

Tests. In acid urine the addition of ammonia at once produces a precipitate of earthy phosphates. The filtrate contains normal alkali phosphate. The latter when treated with magnesia mixture gives a precipitate of triple phosphate; or the filtrate may be acidulated with acetic acid and tested for phosphoric acid with uranium nitrate or ferric chloride. The former produces a yellowish-white precipitate, the latter a white precipitate that stains yellow with an excess of ferric chloride solution. For the analysis of phosphatic sediments see below under Urinary Sediments.

Sometimes it is necessary to get rid of the urinary phosphates prior to undertaking certain other tests. For this purpose the urine is precipitated with neutral or basic lead acetate, or the urinary phosphates are converted into normal phosphates by treating the urine with alkali hydrate and the solution precipitated with some calcium or barium salt. The filtrate will be free from phosphates.

Quantitative Estimation. Solutions.—(1) Solution of uranium nitrate containing 35.461 gm. of the salt to a litre. Uranium nitrate is dissolved in a little less than 1,000 c.c. of water and titrated against a solution of disodium phosphate (10.0845 gm. of $Na_2HPO_4.12H_2O$ to 1 litre), 50 c.c. of which should correspond to 0.1 gm. of P_2O_5. In order to bind the nitric acid developed in this titration, 3 gm. of sodium acetate are added to the uranium nitrate solution. The results of the titration indicate how much the uranium nitrate solution must be diluted to correspond to the phosphate solution.

(2) A solution of 100 gm. of sodium acetate and 30 gm. of acetic acid to a litre, 5 c.c. of this mixture are used for every 5 c.c. of urine. The solution contains enough acetic acid to convert all the urinary phosphates into monophosphate.

(3) Tincture of cochineal to be used as an indicator, 5 gm. of cochineal are dissolved in the cold in 500 c.c. of a mixture of 4 parts of water and 1 part of alcohol. Any undissolved residue is removed by filtration.

The uranium solution is now standardized; 20 c.c. should exactly neutralize 50 c.c. of the phosphate solution; 50 c.c. of the latter solution are mixed with 5 c.c. of the acetate solution (2) and a few drops of the indicator (3) added. The mixture is heated to boiling and uranium solution added, drop by drop. The appearance and persistence of a green-colored precipitate indicates the end reaction. If in this titration only 18 c.c. of uranium solution were required to neutralize the 50 c.c. of phosphate, then the uranium nitrate solution must be diluted so that 2 c.c. of water are added to every 18 c.c. of the solution.

Execution: Fifty cubic centimetres of urine are treated exactly as the 50 c.c. of phosphate solution above. As 20 c.c. of the uranium nitrate solution correspond to 50 c.c. of the phosphate solution, and as these 50 c.c. represent exactly 0.1 gm. of P_2O_5, the phosphate content of the urine can be estimated by simple calculation from the number of cubic centimetres of the uranium solution required to bring about the end reaction in 50 c.c. of urine.

The separate estimation of the different phosphates cannot be discussed in this place. (I refer to Huppert, "Harnanalyse," p. 734 *ff.*, 1898.)

Carbonic Acid (*Carbonates*).—The urine may contain free carbonic-acid gas or carbonic acid combined with various bases as carbonates. Free carbonic acid can be driven off by physical means (boiling, passage of an air current, evacuation); the latter can only be removed by chemical means (acids). The proportion of the former to the latter is about as two to one. Normal urine of the specific gravity of 1.020 and of acid reaction on an average contains about 50 c.c. of free carbonic acid; urine of an alkaline reaction over 100 c.c. of carbonic acid. As the salts of vegetable acids appear in the urine as carbonates, a vegetable diet (citrates, acetates, tartrates, etc.) leads to an increased excretion of carbonates.

An important interrelationship exists between the free CO_2, the carbonates, and the phosphates of the urine. Monosodium phosphate liberates CO_2 from alkali carbonates. If the free CO_2 developed in this way is removed, more alkali carbonate is disassociated until finally only traces of it are left. Carbonic acid forms mono- (acid) and di- (normal) carbonates ($NaHCO_3$ and Na_2CO_3). The urine may contain the carbonates of Ca, Mg, and NH_3.

Tests. A current of air is passed through an alkali hydrate solution (to remove any CO_2 it may contain), then through the urine, and finally through a solution of barium hydrate (baryta water). The presence of CO_2 will be revealed by clouding of the barium solution. Fixed alkali carbonates must first be disassociated by treating the urine with mineral acids.

Quantitative Estimation. This is performed in the same way as the qualitative test. The vessel containing the baryta solution is weighed before and after; the difference represents the CO_2 absorbed. For details I refer to text-books of analytical chemistry.

Silicic Acid (*Silicates*), *Nitrates* and *Nitrites*, and *Hydrogen Peroxide* are all occasionally encountered in traces in human urine. The silicates, nitrates, and nitrites are derived from the ingesta, probably from drinking water that always contains all these bodies. The source and significance of the traces of H_2O_2 that are occasionally found are not understood. None of these substances have sufficient clinical importance to warrant a description of their properties, nor of the methods employed for their detection and estimation in the urine.

BASES.—The bases normally occurring in the urine have been in part discussed under the headings of chlorides, sulphates, phosphates, etc. For the exact quantitative determinations of K, Na, Ca, Mg, and Fe, that are of great scientific interest in metabolic work, but only of subordinate, practical, *i.e.*, clinical interest, I refer to text-books of quantitative chemical analysis. The quantitative determination of *ammonia* alone is of sufficient practical importance, however, to warrant description in this article (see below).

The bases of the urine can be conveniently discussed in groups (Na and K, Ca and Mg, NH_3, Fe). The facts given under acids (and salts) may be supplemented by the following information:

Potassium and Sodium.—The urine voided in twenty-four hours by a healthy adult contains from 2 to 4 gm. of potassium (K_2O) and from 4 to 8 gm. of sodium (Na_2O). The excretion of Na and K is largely dependent on the character of the diet. During inanition their quantity is reduced and more K is excreted than N. As soon as food is taken, the excretion increases only slowly and the normal proportion between Na and K is soon reestablished. Vegetable K salts increase the Na excretion. Muscular exercise increases the K excretion. In fever the K excretion may be doubled or trebled and the Na excretion be greatly reduced. As soon as the fever disappears the Na excretion rises and the K excretion falls (Salkowski). These peculiar fluctuations may, I think, in large part be explained by the small ingestion of food (containing NaCl) during fever and the increased feeding during convalescence.

Tests. Sodium.—The urine is evaporated to dryness. The residue held in a colorless flame colors it yellow. Spectroscopically an absorption line at D.

Potassium.—One hundred cubic centimetres of urine are acidified with HCl, and treated with a mixture of equal parts of alcohol and ether containing platinum chloride. In the course of three to four hours octahedric crystals of K platinum chloride from a yellow precipitate that presents characteristic microscopic features.

Calcium and Magnesium.—The average daily excretion of Ca(CaO) is from 0.2 to 0.3 gm., of Mg(MgO) from 0.1 to 0.25. Only a small proportion of the Ca absorbed from the intestine is excreted in the urine (five to fifteen per cent.); the greater portion passes into the bowel. Abundant water drinking increases the urinary Ca excretion. During inanition there is a slight increase in the Ca excretion (probably derived from osseous tissues). In osteomalacia the Ca excretion is increased; in rachitis it is not increased. The writer has shown that in tuberculosis the Ca excretion is often increased.

Tests. If the urine is treated with ammonia the precipitate that forms consists largely of Ca phosphate and Am-Mg phosphate. In order to demonstrate the presence separately of Ca and Mg the precipitate (or the sediment of alkaline urine) is dissolved in acetic acid, the solution treated with ammonium chloride and a solution of ammonium oxalate. The Ca is precipitated as Ca oxalate, while Mg remains in solution. By adding ammonia to the filtrate, Mg can again be precipitated as Am-Mg phosphate.

Ammonia.—The normal daily excretion of Am is from 0.3 to 1.2 gm. The urinary Am constitutes from 4.5 to 7 per cent. of the total N. On an abundant meat diet more Am is excreted than on a vegetable diet. As urine readily undergoes ammoniacal fermentation the urine should be examined fresh. Fixed alkalies and vegetable alkalies (that are excreted as carbonates) decrease the Am excretion, inorganic alkali salts increase it. Ammonia salts (carbonate and vegetable salts) appear in the urine as urea. As urea is formed from Am carbonate in the liver, the Am excretion (both absolutely and in proportion to urea) is increased in advanced affections of the liver (interstitial hepatitis, etc.). In amyloid liver and in splenic leukæmia the Am excretion is increased. Inorganic acids lead to an increased excretion of Am. Acidosis of the blood from whatever cause also increases the urinary Am. Asphyxia, febrile conditions with high temperatures, diabetes, phosphorus poisoning—all lead to an increased Am excretion, and this phenomenon can readily be explained either on the basis of acidosis or impairment of the liver function. Excessive Am excretion has been observed in the algid stage of cholera (2.075 [!] Rumpf).

Qualitative Test. As urea is readily converted into Am carbonate by micro-organisms the urine must be quite fresh. The urine is rendered alkaline with lime water. Am escapes and colors red litmus paper blue. KOH and NaOH cannot be used in this test because they may liberate Am from other nitrogenous bodies of the urine than Am salts. The precipitate of K platinum chloride described under Potassium may be treated with NaOH; it will also emit vapors of Am that can be recognized as above.

Quantitative Tests. The most popular method is that of Schlösing; it is not quite accurate and it has frequently been modified in minor details. The original method is, however, so simple of execution, and requires so little paraphernalia, that it is best suited for clinical work. The methods of Wurster (distillation), of Heintz, and of Schmiedeberg (determination as Am platinum chloride) are all good. I refer to Huppert, "Harnanalyse," 1898, p. 743 *ff.*, for details.

The Method of Schlösing. Twenty-five cubic centimetres of filtered urine are poured into a shallow crystallizing dish; upon this is placed a metal triangle that serves to support a second flat dish containing 20 c.c. of one-fourth normal H_2SO_4. To the urine are added 10 c.c. of lime water. The two vessels are at once covered with a bell jar with ground edge that is greased; it is pressed tightly down upon a ground glass plate. After three or four days all the ammonia is driven out of the urine and is absorbed by the sulphuric acid. The acid is then titrated back with one-tenth normal sodium hydrate solution, using methyl orange as an indicator. The ammonia absorbed by the acid, *i.e.*, originally contained in the urine, can readily be calculated from the number of cubic centimetres of the alkaline solution required to neutralize the free acid remaining. (The number of cubic centimetres of one-tenth normal NaOH may be subtracted from 50 and multiplied by 1.7 to indicate the milligrams of NH_3 found).

Iron.—Iron occurs in the urine only in organic combinations; hence its presence can only be demonstrated in the urinary ash. The uric-acid crystals of the urine usually contain some of the iron. The color of the uric-acid crystals is not, however, due to the traces of iron they may incorporate. The nature of the organic iron compound of the urine is not known. The average daily iron excretion is about 4 mgm. In fever and in pernicious anæmia the urinary iron is increased.

Test. The urinary ash is dissolved in a little HCl and boiled with one drop of nitric acid. After cooling the liquid is treated with potassium sulphocyanide solution. If iron is present even in traces a few drops of this reagent will produce a reddish color; if much iron is present, the liquid will turn dark red. Or the $HCl-HNO_3$ solution of the ash may be treated with potassium ferrocyanide solution. If iron is present, a blue flocculent precipitate will form.

ACCIDENTAL ADMIXTURES.—Many drugs and poisons may occasionally appear in the urine. See for this subject the article on *Poisons*.

URINARY SEDIMENTS.

The urine is usually quite clear or only slightly clouded when fresh. On standing, a small nubecula soon forms that, on microscopic examination, is found to consist of a small number of epithelial cells, a few leucocytes, and a scanty number of crystals. The size and the density of this nubecula varies greatly even in health. If the urine is concentrated, large urate precipitates may form in subjects who are perfectly well. Pathologically, many other organized and unorganized morphotic elements may appear in the urine that have great diagnostic significance. Pathologic urines containing many abnormal elements usually precipitate a distinct sediment after standing a short time. In other cases the pathologic constituents may be so scanty that they must be precipitated by centrifugation. If it is desired to preserve the sediment for a time the urine should be treated with chloroform water (5 c.c. to 1 litre). Staining the sediment is rarely necessary. The same methods and the same stains may be used as in other histologic work.

ORGANIZED SEDIMENTS.

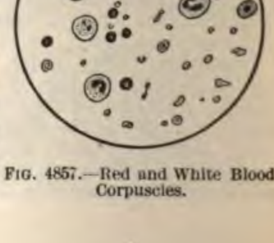


FIG. 4857.—Red and White Blood Corpuscles.

RED BLOOD CORPUSCLES.—These elements appear in the urine in extrarenal and renal hæmaturia (see these paragraphs). The cells appear under the microscope as yellow circular discs with a central depression; seen from the side they assume a biscuit form. They soon undergo morphologic changes, and either swell up or shrink and lose their circular contour. They also appear together with white blood corpuscles and can be distinguished from the latter by the absence of a nucleus, their yellowish color, the central depression, and their size. (See Figs. 4857 and 4858 *b* and *c*). There are always more red than white cells in simple hæmaturia; in pyuria there are more white than red. Occasionally the pigment is washed out of the red blood corpuscles, and they appear as rings ("shadows").

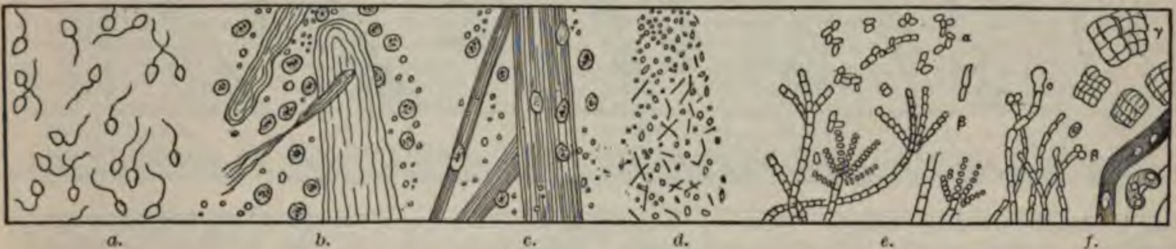

FIG. 4858.—*a*, Spermatozoa; *b*, cylindroids, pus (red and white blood corpuscles); *c*, fibrin, red and white blood corpuscles (hæmaturia); *d*, micrococcus ureæ, bacillus ureæ, large bacillus found in cystitis; *e*, yeast (α), penicillium glaucum (β); *f*, oïdium albicans (α), mycelial filaments (β), sarcina (γ). (Original.)

WHITE BLOOD CORPUSCLES (Leucocytes, Pus Cells).—A few leucocytes can always be found in normal urine. They appear as round colorless elements with one or more nuclei and with homogeneous, finely or coarsely granular protoplasm. The smaller leucocytes usually possess only one nucleus and homogeneous protoplasm (see Figs. 4857 and 4858, *b* and *c*). The finer differences can best be brought out with Ehrlich's triple stain, but for ordinary urinary diagnosis this is superfluous. Many degenerated forms are often seen, particularly in alkaline urine. The normal outline may be lost, the cells may be swollen, their protoplasm may be in all stages of fatty, hyaline, or granular degeneration. Sometimes nothing is left of the cells but the nucleus. The greatest number of leucocytes (pus cells) appears in rupture of an abscess into the urinary passages and in cystitis. The pus may be derived from any portion of the uropoietic apparatus. In renal suppuration the number of pus cells is usually small. The localization of the pus focus may occasionally be attempted from the examination of the other formed elements that appear in the urine at the same time (see *Epithelia*). Particular care should be exercised in women, as much pus may come from the genital apparatus. In order to differentiate pus cells from epithelial cells the sediment may be treated with iodic-potassium iodide. The leucocytes will turn mahogany brown (glycogen), while the epithelia will turn light yellow.

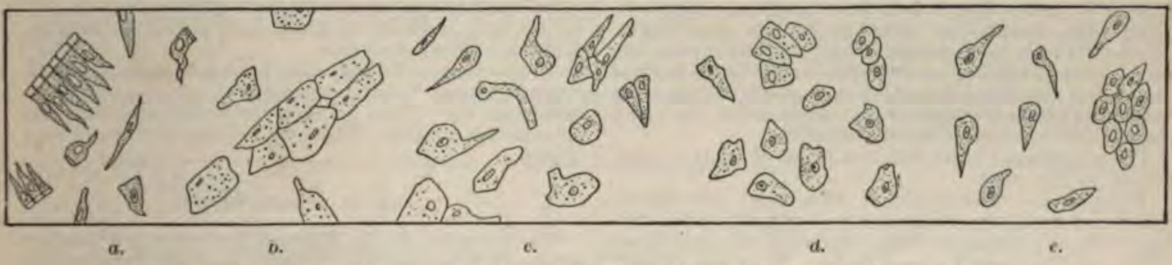

FIG. 4859.—Epithelia. *a*, Male urethra; *b*, vagina; *c*, vesical; *d*, renal; *e*, pelvis and ureter. (Original.)

SPERMATOZOA (Fig. 4858 *a*).—These consist of a head and a tail; the former thick and pear-shaped, the latter thin and filamentous, and becoming attenuated at its distal end. In some cases the spermatozoa are motile. They are about 50 μ long, the head usually being from 4 to 5 μ in length.

Spermatozoa are found after coitus or emissions (epileptic seizures, nocturnal pollutions, etc.) in male urine, and may also occasionally be found in the first urine voided by women after coition.

PARASITES.—For pathologic bacteria and for animal parasites I refer to other portions of this work. The urine may contain almost any one of the *pathogenic bacteria*. Particularly common are the gonococcus, the tubercle bacillus, and septic cocci. Of *animal parasites* (vermes) distoma hematobium, filaria sanguinis hominis, echinococcus, eustrongylus gigas, and occasionally ascarides are found in the urine. Various *infusoria* have also been described in the urine. Of non-pathogenic schizomycetes and hyphomycetes and non-pathogenic bacteria (cocci, bacilli, sarcinæ, etc.) a great many have been described. The most important ones of this group are micrococcus ureæ, bacillus ureæ, a long bacillus frequently found in cystitis urine, a sarcina, yeast, penicillium glaucum, oïdium albicans, and mycelia. The appearance of some of these organisms is pictured in Fig. 4858, *d*, *e*, and *f*. Few of them are ever found in fresh urine. They rapidly develop, however, in old urine, particularly in diabetic urine, so that they may form a film or zooglœa on the surface of the liquid. They bring about fermentative changes that have been referred to incidentally in the text above.

EPITHELIA are found in normal urine. Their number, however, is scanty. Occasionally normal urine contains large numbers of round epithelia that are derived from the prepuce in men or the meatus urinarius or the vagina in women. If such epithelia are present in very large number, this finding usually denotes catarrh of these parts. It is a very difficult matter to differentiate the epithelia of the kidneys, the pelvis, ureters, bladder, and urethra. As a rule, although not always, *renal epithelia* are smaller than the epithelia from lower portions of the urinary tract. They have a large oval nucleus, a polyhedric outline, and granular protoplasm. They may be single or arranged in groups. If cells possessing all the above characteristics are found arranged in cylinders (see also *Casts*) the diagnosis of renal epithelium is justified. The renal cells may be in all stages of degeneration, and occasionally a tentative diagnosis of the character of the renal epithelium may be permitted from the appearance of these cells. *Pelvis cells* are usually elongated with a thick rounded end containing a nucleus and a longer attenuated extremity (Fig. 4859, *e*). I never attach much importance to cells of this appearance, for I believe that they can be derived from the kidneys or the ureters as well, for the epithelia lining these portions of the urinary passages are after all of the same type, and any morphological differences that may occasionally be observed are probably accidental. Large islands of squamous epithelium speak for cystitis. In men they are in all probability derived from the bladder mucosa; in women they may be bladder or vaginal epithelia. When we consider finally that all these epithelial cells may be and usually are degenerated and consequently changed in outline and appearance, we should be warned not to place too great diagnostic importance on slight morphologic differences they may present. Fig. 4859 illustrates in a diagrammatic manner the different forms of urinary epithelia.

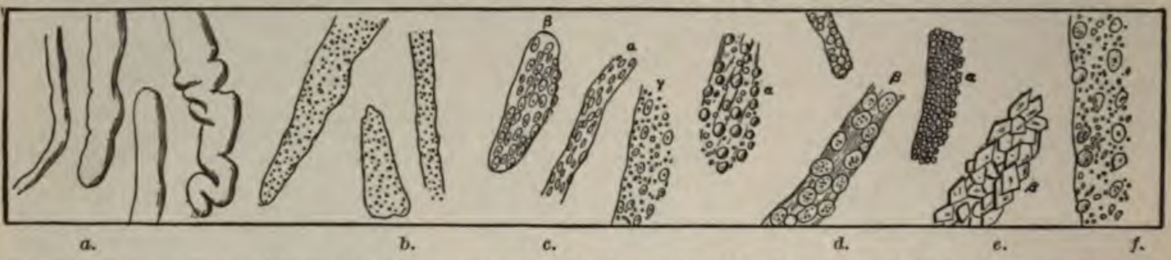

FIG. 4860.—Casts. *a*, Waxy and hyaline casts; *b*, granular casts; *c*, blood casts; (α) red blood-corpuscle cast; (β) leucocyte cast; (γ) mixed blood cast; *d*, (α) fat casts; (β) epithelial cast; *e*, pseudo-casts; (α) urate cast; (β) dicalcium phosphate cast; *f*, mixed cast. (Original.)

CASTS.—Urinary casts or urinary cylinders are clinically the most important morphotic elements of the urine. We can distinguish organized casts and unorganized casts, the former consisting of morphotic elements or the products of their metamorphosis (*scil.* degeneration), the latter consisting of crystals of inorganic urinary constituents. Some writers class the latter as *pseudo-casts*, and include under the category of casts proper only the former. I consider this differentiation to be more useful from the clinical standpoint.

Casts proper may again conveniently be subdivided into homogeneous (waxy, hyaline) casts, cell casts (epithelial, blood, etc., casts), and casts consisting of formed degenerated cell products (fatty, granular, etc., casts). Often we encounter *mixed casts, i.e.*, for instance a homogeneous cast with cellular elements and degeneration products and frequently crystals besides. Bacterial casts are also occasionally seen. All classification of casts is more or less artificial and serves no real purpose.

Casts may appear in varying numbers. They may appear in urine that is free from albumin, or even in urine that contains no other pathologic ingredients. Normal (?) urine may contain casts. To what extent the appearance of casts is ever "physiological" it is hard to say. (See also *Physiological Albuminuria.*) Slight toxic influences (alcohol, intestinal auto-intoxication, etc.) may lead to the excretion of casts in the urine.

The appearance of the different forms of casts is illustrated in Fig. 4860.

Waxy Casts.—The origin of these casts is obscure. They may result from coalescence of degenerated epithelia, from inflammation, from exudation of amyloid or fibrin into the uriniferous tubules. They are usually long, often segmentated, sometimes short and broad (fragments). They may either be smooth or shiny, or may be covered with morphotic elements. They always indicate some renal affection. They appear in acute and chronic nephritis, in amyloid kidney, and in contracted kidney. They occasionally give the amyloid reaction, but not always. A positive amyloid reaction does not necessarily indicate amyloid kidney.

Hyaline Casts.—These structures are usually very long, pale, and very delicate, so that they may readily escape detection. Hyaline casts alone are probably of no pathologic significance, and nephritic lesions should never be diagnosed from their presence alone. Frequently they are covered with morphotic elements that possess pathologic importance.

To the same category probably belong *cylindroids* (Fig. 4860, *b*). These constitute bands and cylinders that are similar in appearance to hyaline casts. They are very common. Occasionally they are found in normal urine. They seem to be a product of slight renal irritation, but their presence by no means indicates a renal lesion proper. They have been found in congestion of the kidney, from heart lesions, and in increased urate excretion.

Blood Casts.—These structures are formed whenever there is hemorrhagic exudation into the canaliculi of the kidney parenchyma. The origin of

Epithelial Casts is equally clear. They are the result of epithelial desquamation that may be due to a great variety of causes.

The presence of blood and epithelial casts always denotes acute nephritis or an acute exacerbation of a chronic nephritis. They are consequently of the greatest diagnostic importance.

Fatty Casts.—Fat droplets are frequently found on granular casts; sometimes casts consisting of fat globules alone are seen. Occasionally fat globules and fat needles (crystals of fatty acids and soaps) appear together. Fatty casts occur only in subacute and chronic forms of nephritis that lead to fatty degeneration of renal parenchyma, *i.e.*, of renal epithelia.

Granular Casts.—These casts probably result from granular degeneration of blood and epithelial casts. They indicate renal inflammation. They occasionally appear in cyanotic induration of the kidney. They usually appear together with the other forms of casts described, and they possess great diagnostic significance.

Bacterial Casts usually indicate embolic septic nephritic processes. They often resemble granular casts in appearance, but can usually be distinguished from the latter by their resistance to nitric acid, potassium hydrate, and other strong chemicals.

Pseudo-Casts.—To this class belong hæmatoidin casts, "detritus casts," and casts holding crystals of urates, sulphates, etc. They are common in the new-born and in nephritis uratica. Their clinical significance is very slight.

UNORGANIZED SEDIMENTS.

The character of the inorganic sediment is dependent on the reaction and the concentration of the urine and on the mixture of salts it contains. Much can be elicited in regard to the sediment from its behavior to heat, the reaction of the urine and its behavior to acids. Thus a red sediment in acid urine that is soluble on heating always denotes uric acid, whereas a white sediment in alkaline urine that is insoluble on heating the urine alone, but readily soluble in warm urine after the addition of a little acid, denotes phosphates (*plus* carbonates and urates). Phosphatic sediments always appear when the urine is alkaline when voided, or becomes alkaline on standing (fermentation). The sediment may be crystalline or amorphous. The composition of the sediment can be determined by microscopical and chemical analysis. Only the most important sediments and the methods employed for their recognition can be discussed in this article.

URIC ACID (see Fig. 4861).—This sediment, as shown in the drawing, may appear in a great variety of forms. Pure uric acid is white. The urinary uric acid is always colored red to dark brown from the admixture of urinary pigments. The crystals readily dissolve under the microscope on addition of potassium hydrate solution, and reappear in a short time as rhomboid crystals on addition of hydrochloric acid. Uric-acid crystals, as already stated, only occur in acid urine.

Urates.—Alkali urates appear as amorphous fine granules of yellow or reddish-brown color in acid urine, whereas ammonium urate occurs only in alkaline urine in the form of spheres that are surrounded by a wreath of fine needles or spiculæ. The morphologic characteristic of amorphous urates and of ammonium urate are represented in Fig. 4862. Urates are soluble under the microscope on addition of acids. On standing, crystals of uric acid appear.

Calcium Oxalate (see Fig. 4863).—These crystals present so typical a microscopical appearance that they cannot be confounded with anything else. They occur in normal urine, and may appear in large numbers after the ingestion of certain vegetables (asparagus, beans, carrots, etc.) that contain oxalic acid. If this factor can be ruled out, the appearance of much calcium oxalate sediment should lead to the chemical estimation of the urinary oxalic acid as described above.

Calcium Sulphate (Fig. 4864).—This is a rare urinary sediment. The crystals are soluble in acids and in ammonia. The pathologic significance of these crystals is small.

Calcium Carbonate (see Fig. 4865) is a rare sediment of subordinate clinical importance. On addition of mineral acids the sediment rapidly dissolves. Under the microscope effervescence can be seen.

Phosphates (Figs. 4866 and 4867).—These salts appear in two forms, amorphous and crystalline. As already stated, alkaline urine always precipitates phosphates. If the urine is acid when voided, increased excretion of phosphates may be taking place and still no sediment form. As a rule, therefore, a phosphate sediment has only slight clinical importance. There is, however, a metabolic disorder that may lead to phosphaturia. We distinguish: (1) Amorphous earthy phosphates (calcium and magnesium phosphate); (2) trimagnesium phosphate; (3) dicalcium phosphate (stellar phosphate); (4) ammonium-magnesium phosphate (triple phosphate). (1)

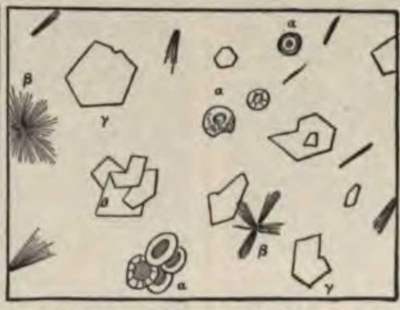

Fig. 4868.—Leucin, Tyrosin and Cystin. α, Leucin; β, tyrosin; γ, cystin. (Original.)

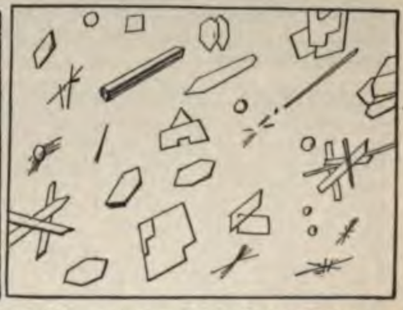

Fig. 4869.—*a*, Hippuric acid; *b*, cholesterin; *c*, fatty crystals; *d*, urea nitrate; *e*, fat globules. (Original.)

Occurs in alkaline or neutral urine; (2) in concentrated alkaline urine; (3) in neutral or slightly acid urine containing large quantities of calcium phosphate; (4) chiefly in alkaline urine, particularly after ammoniacal fermentation. It may also occur in feebly acid urine. Needless to say that several of these phosphates may and often do occur together.

LEUCIN AND TYROSIN (see Fig. 4868).—Leucin and tyrosin usually occur together. The microscopical appearance is characteristic. They appear in the urine in acute yellow liver atrophy, in phosphorus poisoning, and in a number of infectious diseases.

Chemically leucin crystals can be recognized by evaporating the crystals with HNO_3 on a piece of platinum foil. A colorless residue remains that forms an oily mass when touched with a solution of KOH.

Tyrosin treated in the same way with HNO_3 forms a yellow residue, that treated with NaOH gives a reddish color. If the mixture is evaporated to dryness a brown-black mass remains.

Or the crystals of tyrosin may be dissolved in hot water and the solution treated with KNO_3 and $HgNO_3$. The liquid turns dark red and precipitates a red sediment.

CYSTIN (see Fig. 4868, also section on "Cystinuria" above).—The appearance of cystin crystals calls for chemical analysis of the urine for cystin and quantitative estimation of the cystin excretion.

OTHER UNORGANIZED URINARY SEDIMENTS may be mentioned for completeness' sake. They have no clinical significance whatever. The microscopic appearance of sediments of *hippuric acid, cholesterin, fatty crystals, urea nitrate*, occasionally forming on addition of HNO_3 to the urine, and *fat globules* (Fig. 4869), should be familiar to the clinician in order to avoid confusion with more important sediments.

Urinary sediments may also contain xanthin, blood pigment, bile pigment, indigo, and numerous accidental contaminations. *Alfred C. Croftan.*

URISOLVIN is a mixture of acid lithium citrate and urea, used in 0.2 gm. (gr. iij.) dose as a diuretic and uric-acid solvent. *W. A. Bastedo.*

UROPHERIN, theobromine-lithium salicylate, lithium-diuretin, $C_7H_7N_4O_2Li + C_6H_4OH.COOLi$, is prepared by mixing theobromine with the hydroxide and salicylate of lithium. It is a white powder soluble in five parts of water, and differs from diuretin only in the substitution of lithium for sodium. It is strongly diuretic in 1 gm. (gr. xv.) doses repeated frequently.

Uropherin benzoate is prepared from the benzoate of lithium instead of the salicylate. *W. A. Bastedo.*

UROSIN, lithium quinate, is made by mixing quinic acid, which tends to prevent the formation of uric acid, with lithium citrate, which is a uric-acid solvent. It is held by Weiss and by Sternfeld to be almost specific in attacks of gout. The dose is 0.5 gm. (gr. viij.), frequently repeated. *W. A. Bastedo.*

UROTROPIN, hexamethylene-tetramine, aminoform, cystamine, cystogen, formin, ammonio-formaldehyde, etc., $(CH_2)_6N_4$, is made by combining six molecules of formaldehyde with four of ammonia. It forms rhomboidal crystals of neutral or faintly alkaline reaction, and is soluble in 1.2 parts of water, slightly in alcohol, and scarcely at all in ether. In the urine it may be detected by the formation of an orange precipitate with a few drops of a saturated solution of bromine.

Introduced in 1895 by Bordet, this remedy has come into universal use as a urinary antiseptic. It is very rapidly absorbed, Casper finding it in the urine in ten minutes; usually the urine continued to give off formaldehyde for several days. In a few cases no formaldehyde was demonstrable though urotropin was constantly excreted, and Citron calls attention to the fact that formaldehyde is sometimes not liberated in strongly alkaline urine. The blood of a rabbit, to which Casper administered urotropin hypodermically, was shown to contain formaldehyde.

The drug has been recommended as a diuretic, a uric-acid solvent, and a urinary antiseptic and acidifier. Thompson considers its diuretic powers to be very slight, though other observers report considerable increase in the flow of urine following large doses. As a uric-acid solvent Casper found that neither a urotropin solution nor the urine of a patient taking urotropin had any effect *in vitro*. He discovered accidentally, however, that it caused complete cessation of all visible phosphate excretion in a case of phosphaturia.

It is in bacterial conditions of the urine, however, that urotropin finds its chief indication. In typhoid fever there is much evidence that the bacilli are prevented from developing in the urine; at Johns Hopkins Hospital the typhoid bacilli did not completely disappear from the urine, but were much diminished in numbers. Osler recommended the drug very highly in typhoid cystitis. In suppurative pyelitis and cystitis urotropin has the power of greatly lessening bacterial action, while at the same time it tends to diminish the alkalinity or increase the acidity. When the urine is strongly alkaline it sometimes fails to act. Cohn found no improvement in tuberculous cystitis or in cystitis following acute gonorrhœa, but Bangs and others advise its routine employment in gonorrhœa, as it tends to keep the urine antiseptic and to lessen the tendency of the gonococcus to invade the posterior urethra and bladder. A. R. Elliott, of Chicago, gives up to 6 gm. (ʒ iss.) a day, though noting that the acidity of the urine may be so increased thereby as to cause irritation. But there are a number of reports of vesical irritation, hæmaturia, and even melæna following much smaller doses. W. Langdon Brown reports two cases of vesical hæmaturia from ten grains three times a day for eight days. Morton noted burning in the urethra and frequent micturition from twenty-four grains a day. Biss, in three hundred and eleven typhoid cases, noted irritation and slight hæmaturia twice. The general opinion seems to be that the blood comes from the bladder and not from the kidneys, though it is advised not to employ the drug in cases of nephritis. Eastman noted lowering of temperature and pulse. The ordinary dose of urotropin is 0.2–0.5 gm. (gr. iij.–viij.), and Nicolaier advises that 1.5 gm. (gr. xxiij.) a day should not be exceeded. It is best administered with plenty of water in small doses frequently repeated.

Loebisch has proposed the employment of urotropin as an intestinal disinfectant, its administration in intestinal putrefaction being more promptly followed by absence of indican in the urine than is the case with salol and other much-used drugs. It is absorbed very rapidly, however, and practically all of it is excreted in the urine; so it hardly seems probable that appreciable quantities of it can act in the intestine. Joseph Eastman thinks it may prove of value in puerperal sepsis. *W. A. Bastedo.*

URTICARIA.—Urticaria is an affection of the skin of which the salient characteristic is the occurrence of peculiar lesions called wheals. The description of wheals therefore covers in large part the objective symptoms of urticaria.

A wheal is a circumscribed elevation of the skin due to œdema of the corium. A typical wheal is the lesion produced in the average individual by the bite of a mosquito or flea. The typical wheal is slightly elevated, sharply circumscribed, with a flat or rounded surface, and of irregular or oval outline. The centre is usually pale and bloodless, but around this pale elevated centre there is an erythematous halo. The pressure of the edge of the finger nail on a wheal causes a slowly disappearing pitting, as in other œdema. The development of a wheal takes place suddenly. The first evidence of it is a rapidly appearing erythematous spot which itches, and upon which there suddenly develops a flat, œdematous swelling. The whole evolution of the lesion may occur in a few seconds. The duration is usually short, from a few minutes to an hour or two, though occasionally the lesions last for one or two days, and at times they persist for a week or more. Upon the disappearance of a wheal, if there has been no traumatism from scratching, no trace is usually left. At times, however, there is slight pigmentation, and if, as frequently happens, there has been vigorous scratching, inflamed papules or excoriations remain as a result of the traumatism.

As would be expected of so capricious a lesion there are numerous variations upon this typical wheal, and various subvarieties of urticaria are described according to the predominating form of wheals which characterize them. Wheals vary in size most widely. Typical wheals are usually from the size of a split pea to that of a finger nail. At times they are not larger than small papules and indeed are almost indistinguishable from ordinary inflammatory papules. They are frequently of the size of a twenty-five-cent piece, and in extreme cases are much larger. The writer has seen a wheal of which the elevation was not greater than a quarter of an inch, which extended around the chest from the median line in front to the median line at the back, and from the line of the nipple above to below the border of the ribs (*urticaria gigans*). Their shape is equally uncertain. Usually of more or less oval outline, they at times assume most irregular shapes, and, in persons whose skins are particularly susceptible to the production of wheals, they may be produced of any shape (*urticaria factitia*). In color they vary from inflammatory red to waxy white. If the œdema is intense enough to press out the blood from the capillaries, they show as a pale waxy centre with a narrow red periphery. Where the œdema is not so intense, or where the looseness of the tissues prevents extreme pressure from the œdema, the lesions are red in evidence of the hyperæmia. Occurring in tissues like the prepuce and eyelids, which are lax and offer, therefore, little resistance to the outpouring of serum, the lesions often form tumor-like œdematous swellings that closely resemble an inflammatory process in the same tissues (*urticaria tuberosa*). They are differentiated by their sudden appearance and equally sudden subsidence and the entire absence of pain. Very rarely the pressure of the extravasated fluid in the skin is sufficient to cause uplifting of the epidermis, so that the wheal is capped with a vesicle or bulla (*urticaria bullosa*). In still rarer instances the extravasation of serum is accompanied by enough red blood corpuscles to make the contents of these vesicles or bullæ hemorrhagic (*urticaria hæmorrhagica*).

In an acute attack of urticaria there is a sudden outbreak of wheals preceded and accompanied by more or less itching. There may be only a few lesions, or they may be innumerable. They occur on any part of the body, without symmetry and without any regularity of distribution. The acute attacks are often introduced by a transient systemic disturbance, with evidences of acute gastro-intestinal irritation. The temperature rises sharply three or four degrees, there are a rapid pulse, furred tongue, nausea and vomiting, and more or less prostration. At times evidences of a gastric crisis seem to indicate the involvement of the stomach in this peculiar angioneurotic process. The lesions themselves are characterized by intense itching. This itching may occur not only in the wheals themselves, but often at points where no wheals are present. The itching usually precedes for a few minutes the appearance of the wheals, and it persists during their continuance. It is somewhat paroxysmal in character, varying in intensity, without corresponding variation in the lesions. The itching varies in different cases and in different individuals, and according to the site of the lesions. Lesions in loose tissue may be accompanied by no itching whatever, while those occurring in dense thick skin and where the sensory nerve supply is richest, as on the hands and feet, are characterized by the most intense itching.

The course of an acute attack of urticaria usually extends over a few hours or at most a day or two, the disease passing away after the appearance of several crops of evanescent lesions. At times, however, the disease persists for weeks and months in successive outbreaks of the eruption, and in such cases is characterized as urticaria chronica, the term referring to the persistence of the process as a whole rather than to any peculiarity of the individual attacks. On the other hand, urticaria is persistent at times not only from the occurrence of repeated outbreaks of the eruption, but because the lesions lose their evanescent character and persist for days or weeks (*urticaria perstans*).

The *urticaria papulosa* of children, described by English dermatologists, is the best type of persistent urticaria. The characteristics of this form are the persistence of the lesions and the fact that the true urticarial wheals are followed by inflammatory papules which may persist for several weeks. It is readily seen that the occurrence of successive crops of wheals, which themselves persist for days or weeks and are followed by inflammatory papules which persist even longer, will produce an exaggerated picture of the urticarial skin. In such cases, as a result of scratching, we have inflamed papules, infected excoriations and more or less dermatitis, that results in thickening and induration of the skin. These cases in their most extreme type are strikingly similar to Hebra's prurigo. It is indeed not unlikely that they pass at times into true prurigo.

It is not an infrequent experience to see the vaso-motor mechanism so delicate that wheals may be produced at will by friction or other slight traumatism (urticaria factitia). In cases of acute urticaria this phenomenon is usual. In certain individuals this vaso-motor instability is inherent, so that factitious wheals may be produced at any time by slight traumatism, as drawing a line on the skin with a little force with a blunt stick or a finger nail. In such cases it is of course possible to produce wheals of any shape, so that names and elaborate designs may easily be written in wheals upon the skin (*dermographism*).

Urticaria tuberosa, urticaria bullosa, and urticaria hæmorrhagica have been referred to above. The peculiarities of the lesions of urticaria tuberosa depend almost solely upon their location at sites where the skin is very loose, and the lesions deserve no especial mention except to call attention to their somewhat confusing appearance at times. The lesions of urticaria bullosa and urticaria hæmorrhagica are usually seen in run-down individuals living under unfavorable conditions. Urticaria bullosa occurs most frequently in children. Urticaria hæmorrhagica is frequently associated with other evidences of hemorrhagic tendency, as hemorrhage from the mucous membranes, from the bowels and from the genito-urinary tract, and it is an evidence of a more profound systemic disturbance than usually exists in urticaria. Both of these forms of urticaria are rare.

The term giant urticaria is applied to urticaria which is characterized by the development of one or more wheals of very large size. They may be typical wheals, but most frequently they are rapidly developing œdematous swellings of pinkish color that bear a very striking objective similarity to an acute cellulitis. Such swellings at times present very slight if any resemblance to an urticarial wheal. They occur most frequently about the face and extremities, and often form tense, angry-looking swellings that for the time cause alarming distortion. Frequent sites of these lesions are the eyelid, the cheek, the nose, the lips, and the ear, and on such parts they may cause the most grotesque deformity. The larynx is not an uncommon site for their development, and their occurrence in that location may be the cause of distressing dyspnœa. Very rarely has it been found necessary to perform tracheotomy in such cases. Usually these large lesions occur singly, but they may occur in successive outbreaks or several large lesions may occur at one time. These lesions, like other urticarial wheals, develop rapidly, usually in the course of a few minutes, and after persisting for a shorter or longer time as rapidly subside. They are painless, usually unaccompanied by itching, and, unless they interfere with some important function through their size, are the source of little discomfort. There may be slight constitutional disturbance such as occurs in other forms of acute urticaria, and typical urticarial wheals may accompany or alternate with these giant lesions.

Giant urticaria is frequently described as a separate disease under the title of Angioneurotic Œdema, or Acute Circumscribed Œdema. It presents, however, no essential difference from other forms of urticaria. Its etiology, its course, and the fact of its being frequently accompanied by ordinary urticarial lesions show its essential relationship to urticaria, and for that reason it is included here. All that is to be said about etiology, pathology, prognosis, and treatment of other forms of urticaria applies with unessential variations to giant urticaria or angioneurotic œdema. The original description of this condition is usually credited to Quincke (*Monatshefte f. prakt. Derm. u. Syph.*, 1882). The condition, however, had been accurately described, and its character recognized previously, by Bannister (*Chicago Medical Review*, June 20th, 1880).

ETIOLOGY.—Urticaria occurs at any time of life, but is most frequent in childhood. Among young children acute attacks of urticaria are very common, as a result of imprudent eating or slight disturbance of digestion.

In most urticarias two factors stand out prominently in the etiology. The first is individual predisposition; the second is the presence of some toxic substance which disturbs the local vaso-motor tone. There are other forms of urticaria besides those due to the disturbance of the vaso-motor mechanism of the skin by toxic substances, but they are relatively few.

Underlying the development of urticaria from all sorts of causes is individual predisposition. In certain individuals urticaria can be produced by the most trivial causes, such as the crawling of a caterpillar upon the skin, or the ingestion of the minutest quantity of some particular substance. In other individuals its occurrence is unknown. So violent an irritant as even the sting of a bee may not produce the smallest wheal.

The causes of urticaria may be divided into local and constitutional. Among the local causes of urticaria are especially to be mentioned the bites of parasites, such as fleas, mosquitoes, the various forms of pediculi, bedbugs, and the stings of wasps and bees. The lesions may also be caused by contact with stinging nettle, jelly fish, or caterpillars.

The constitutional causes of urticaria are numerous, but they are largely comprehended under various forms of intoxication. In certain individuals the ingestion of a particular article of food or of a particular medicine is followed by the development of an acute outbreak of urticaria. Among food-stuffs that may cause urticaria are: oysters, crabs, lobsters, and other shell fish; pork, sausage, and other similar highly seasoned meats; mushrooms, strawberries, tomatoes, cucumbers, and nuts. Among medicines: opium, chloral, the salicylates, copaiba, cubebs, quinine, turpentine, valerian, and various coal-tar products. The most frequently offending substances among the above perhaps are shell fish and strawberries, opium, quinine, copaiba, and cubebs. Another form of intoxication from without, which is now a very common cause of urticaria and is a connecting link between the causes of urticaria introduced from without and those developed within, is that from the antitoxins. Urticaria is the most frequent cutaneous manifestation following the use of diphtheria antitoxin. Somewhat similar are the urticarias which have been described from the absorption of hydatid fluid.

The forms of intoxication from within which may cause urticaria are numerous, but far and away the most important is auto-intoxication arising from the gastro-intestinal tract. Over-eating, constipation, and defective elimination are the group of factors most frequently seen in the causation of urticaria. Disturbances of the liver, particularly those which are accompanied by the presence of bile in the circulation, are at times responsible for outbreaks of urticaria. And the conditions which are vaguely described under lithæmia, gout, and rheumatism, of which the essential characteristic is a disturbance of the balance between assimilation and excretion or the presence of suboxidation products in the blood, are frequently responsible for chronic urticarias. Urticaria is also at times a result of malaria, and Matas has reported a case in which outbreaks of urticaria seemed to take the place of the usual malarial attacks. Anæmia is a factor which has to be frequently combated in the management of urticaria, and it occurs also at times in connection with albuminuria and glycosuria.

After auto-intoxication, in the etiology of urticaria, come the various factors which may be included under the head of the nervous causes of urticaria. The condition is seen with considerable frequency as a result of the nervous disturbances accompanying disorders of the genito-urinary tract, in pregnancy, at menstruation, and during lactation. It is excited at times by violent emotional disturbances, as grief, the dread of some impending crisis, or the shock of surgical operations. In particularly unstable individuals it may occur from such slight mental disturbances as anger, confusion, or surprise. Its occurrence as a result of rectal worms, phimosis, and similar forms of local irritation seems to indicate that at times it is due to reflex nervous irritation. The occurrence of urticaria in connection with nervous diseases is well recognized. This is rather frequent in functional nervous disturbances like hysteria. It is rarer in connection with organic diseases of the central nervous system.

PATHOLOGY.—Urticaria is distinctly an angioneurotic disturbance. There is a temporary disturbance of the vaso-motor control which results in a dilatation of the capillaries of the part and local hyperæmia. There is a rapid outpouring of serum into the tissues producing an intense œdema. This shows as a swelling of the skin which at first is pink, but as the pressure becomes greater the blood is driven out of the capillaries at the centre and there develops a pale bloodless area surrounded by a halo of hyperæmia. Microscopically the tissues show the evidences of intense serous effusion with more or less diapedesis of leucocytes.

DIAGNOSIS.—The diagnosis of typical urticaria offers no difficulties. Indeed this is usually made without the physician's aid. The rarer varieties of urticaria, urticaria hæmorrhagica, urticaria bullosa, and angioneurotic œdema, may lead to some confusion. In the first two types there are usually evidences of typical urticaria sufficiently manifest to give the key to the diagnosis. In angioneurotic œdema or giant urticaria the suddenness of its onset, its rapid development, the freedom from pain, and the accompanying evidences of typical urticaria usually make the diagnosis from cellulitis, with which it is most likely to be confused, easy. The diagnosis of urticaria in itself, however, is the smallest part of the problem with which one has to deal in the cases. The far more difficult part is the determination of the causative factors. This, in cases of chronic urticaria, often taxes one to the utmost.

PROGNOSIS.—In acute urticarias relief is easy. In chronic urticarias the success of treatment depends altogether upon the difficulty which attends the relief of the underlying condition, and the prognosis as to ready relief in such cases should be very guarded.

TREATMENT.—The curative treatment of urticaria is altogether a question of the elimination of the underlying trouble and the management of the various cases is along the line of rational therapeutics. In all cases the possibility of the disease being due to parasites should be borne in mind. Where any of these are found to be the cause, the treatment is of course that necessary for the destruction of the particular parasite.

The constitutional treatment of acute attacks of urticaria is simply a matter of the relief of the digestive disturbance which usually is the cause of it. If the cases are seen early an emetic may be indicated. More frequently, however, a brisk cathartic, such as magnesium sulphate, is all that is necessary. The after-treatment of these cases consists of keeping the bowels open, and keeping the patient upon a careful diet until the digestive disturbance is relieved. Frequently an acute urticaria is the culmination of more or less continued digestive disturbance. In such cases the mercurial cathartics are particularly valuable.

In the chronic forms of urticaria permanent relief is usually the result of painstaking investigation into the causation. The questions of defective elimination, constipation, lithæmia, or some lack of balance between assimilation and excretion, particularly have to be taken into consideration. The first attention has to be paid to the digestion. The diet should be regulated, indigestible foods generally prohibited, and a bland, simple dietary followed for a time. The free use of fruits, contrary to the advice sometimes given, is in my opinion usually indicated, and the patient should drink plenty of water. Careful attention should be paid to elimination, especially by the bowels, and for this purpose the rather liberal use of aperients for a time is advisable. Of the aperients I think that calomel and blue mass easily head the list in value; after them come senna, podophyllin, sodium phosphate. In the gouty and lithæmic, alkalies and colchicum are useful. In stimulating elimination I have had excellent results from the daily hot bath, the patient staying in the bath for from ten to thirty minutes each day, so that free sweating occurs. In certain cases the nervous sedatives prove distinctly valuable; the bromides, acetanilid, phenacetin, and sulphonal are all at times useful. The various forms of opium are to be avoided, not only because of their adverse effect on elimination, but because of the marked tendency of opium itself to cause urticaria.

It cannot be emphasized too strongly that in all persistent cases of urticaria the question of elimination and the condition of the digestive tract deserve first consideration. After that the other factors, such as malaria, jaundice, anæmia, and other less frequent causes, are to be investigated, and when found present are to be treated along the usual lines. Rational treatment failing, certain remedies, used more or less empirically, have been found helpful. Quinine, the salicylates, belladonna, and strychnine are useful in certain cases. Calcium chloride has been recommended by Wright, and it has at times seemed to me to be of service. Among the remedies used empirically the one which has given me the greatest satisfaction has been pilocarpine. Given to the point of producing the slightest evidence of its physiological effects, it is valuable in relieving itching and giving the patients rest. In certain intractable cases without gastro-intestinal trouble arsenic is recommended.

Local Treatment.—The local treatment of urticaria is almost entirely directed to the relief of itching. For this purpose in acute attacks of urticaria one of the commonest and most useful measures is the alkaline or acid bath. A general bath or sponge bath with sodium bicarbonate usually immediately stops the itching. Equally good results are frequently obtained with similar baths of common salt. Either the salt or the soda bath is most effective when it is rather strong. In place of soda or salt, borax or ammonium chloride may be used with equally good effect. The strength, for ammonium chloride, is one or two ounces to the bath.

Similar baths with vinegar or other acids are often equally effective, but they are not quite so agreeable, and usually nothing is gained by substituting them for the salt or soda bath. In place of the bath alkaline or acid lotions may be substituted. As acid lotions, water and vinegar equal parts, water two parts and vinegar one part, or alcohol two parts and vinegar one part, may be used with good effect. A one- or two-per-cent. solution of carbolic acid with glycerin in water or in a boric acid solution is a most excellent antipruritic in these cases. In place of the water the lotion is sometimes made more agreeable, and perhaps more effective, by the substitution of distilled extract of hamamelis. Other antipruritic lotions are made with liquor carbonis detergens, or camphor chloral, or resorcin in the strength of one to three per cent. in water. A lotion which I have found particularly useful in severe itching, where the skin is not broken, is camphor chloral and carbolic acid, each one to three per cent., in equal parts of distilled extract of witch hazel and alcohol. This may be made more cooling and more powerful by the addition of one to two per cent. of menthol. In certain cases the addition of an insoluble powder in suspension to these lotions is advantageous. For this purpose suitable powders are zinc oxide and calamine. These may be added to such lotions as have been suggested above in the strength of one or two ounces to the pint. A type of such a lotion, which has given me excellent service, is the well-known calamine and zinc-oxide lotion, with the addition of one or two per cent. carbolic acid and glycerin. A good formula for this lotion is as follows: Acid carbolic, glycerin, āā ʒ i.–ʒ iij.; zinc oxide, calamine, āā ℥ i.–℥ ij.; lime water, Oj. Frequently a most agreeable application, in conjunction with these other measures, is a dusting powder to be applied after the bath or after the application of a lotion. Suitable dusting powders for this purpose are zinc oxide, starch, talcum, or stearate of zinc. A useful addition to these powders is boric acid in the proportion of one-half to one drachm to the ounce, or salicylic acid, resorcin or thymol in the proportion of five to twenty grains to the ounce. Usually, unless there is a secondary dermatitis, ointments are not desirable. They are mussy and inconvenient and dirty and not more effective than the lotions. Where there is a secondary dermatitis, however, as a result of scratching, ointments are frequently useful not only as vehicles for the active medicament, but as a protection for the abraded surfaces. In such conditions the antipruritic lotions have to be used with some care, as they are more or less irritating. Baths are not contraindicated, but the addition of bran or oatmeal to the baths in sufficient quantities to make them slightly mucilaginous renders them more soothing. *William Allen Pusey.*

URTICARIA PIGMENTOSA.—Urticaria pigmentosa is a rare affection which is characterized by the development of wheals which are followed by peculiar persistent pigmented macules or nodules. It differs in many respects from ordinary urticaria, and, although the disease is accompanied by wheals, it is in all probability not a form of true urticaria. Two forms of the disease exist—the macular and the nodular. These at times occur distinctly, or more frequently the disease presents a combination of the two types. All forms begin in early childhood. The first evidence is the development of erythematous spots, which are followed in a day or two by the development of small reddish wheals. In other cases wheals develop suddenly without any noticeable premonitory erythema. In the macular form, upon the disappearance of the wheals there are left fawn-colored or brownish-yellow pigmented stains. These are level with the skin or perhaps slightly elevated. In the nodular form there is the same sudden eruption of wheals which are succeeded by nodular lesions that remain indefinitely. These are at first reddish, but in time become brownish-red or brownish-yellow. Similar lesions continue to appear and the disease thus goes on for many years. Individual nodules may persist for years; at other times they shrink and disappear, leaving brownish, pigmented, atrophic spots. Usually after several years new lesions no longer develop and the disease gradually disappears. In both the macular and the nodular forms factitious urticaria can be produced by friction, and in the same way wheals may be made to develop at the site of the nodular or macular lesions. Itching in these cases is usually severe, and, continuing as it does for years, is the most serious feature of the disease.

Etiology.—Its cause is practically unknown. It appears usually within the first six months of life, most frequently before the third month, and only a few cases developing after eighteen months have been recorded. Most of the recorded cases have been in boys.

Pathology.—A section from one of the lesions shows no alterations in the epithelial layer except marked increase of pigment in the basal layer and some horizontal stretching of the epithelial cells. The upper part of the corium is œdematous, and there is a peculiarly abundant infiltration with mast cells. Unna was the first to call attention to the marked accumulation of mast cells in the corium, and his observations have been repeatedly confirmed by other observers.

Diagnosis.—The extreme rarity of the disease renders it liable to be overlooked. The presence of factitious wheals and itching suggests urticaria, and when there is added to this the presence of the peculiar brownish-yellow persistent nodules or macules, the diagnosis should readily suggest itself. There is no other disease that closely resembles it. The diagnosis from urticaria is made by the presence of the peculiar persistent lesions. The process might also suggest xanthoma, but the lesions of xanthoma are of a distinctly yellow color, while these are dirty-yellow or brown. Xanthoma does not itch, and has none of the other features suggestive of urticaria.

Prognosis.—The disease usually persists for years, at least until the time of puberty, although some cases have been known to get well after a duration of one or two years.

Treatment.—Treatment has had no effect upon the course of the disease. Relief of digestive disturbances renders the disease less severe, and careful attention to the dietary of the patients has some effect in improving their condition. Crocker reports that the empirical use of Fowler's solution had a marked effect in preventing the development of new lesions in one of his cases. The itching can be in great part controlled by the use of antipruritic applications, such as are used in ordinary urticaria, and the local treatment is along the same lines as in urticaria.

William Allen Pusey.

USTILAGO.—(*Corn-smut, Corn-ergot*, etc.) The fungus *Ustilago Maydis* Leveille, replacing the grain of *Zea Mays* L. This well-known blight of Indian corn grows upon various parts of the plant—stem, leaf, sheaths, tassels, but especially upon the forming ears. It forms early a fleshy, irregular mass of mycelium embedded in a jelly-like substance, and attains upon the ears, which it transforms or destroys, a size equalling that of a cocoanut, more or less irregularly globular. At maturity it develops into a black, dry, crumbly, or powdery mass of spherical, tuberculated spores enclosed in a cellular pouch. It has an unpleasant musty odor and taste. This ripe mass of spores is the portion used, and it is collected in midsummer, simply freed from impurities and dried. As obtained, it is a mass of powder and shreds of membrane, nearly as black and quite as dusty as powdered charcoal.

Little is known of the constituents of ustilago, except that they are, in a general way, similar to those of ergot. Mitchell has found that in frogs it soon acted as a narcotic, destroying consciousness; it then paralyzed the sensory centres in the spinal cord, and afterward, if the dose were toxic, the motor centres and nerves.

Numerous clinical reports have been made to the effect that it acts upon the parturient uterus much like ergot. Its use was considerably urged from 1876 to 1880, and it became official in the United States Pharmacopœia of the latter year, but its use has now almost altogether ceased. It has also been given in menorrhagia, bleeding fibroids, and other troubles which may be relieved by increasing the tension of uterine tissue. Dose, in infusion or fluid extract, from 1 to 3 or 4 gm. (gr. xv. to lx.).

W. P. Bolles.

UTAH HOT SPRINGS.—Box Elder County, Utah.

Post-Office.—Utah Hot Springs. Hotel.

Access.—Viâ Southern Pacific and Union Pacific Railroads. The Utah Hot Springs Company's Steam Motor Line runs in connection with the Ogden City Street Electric Line.

These springs flow from the western base of the Wahsatch Mountains into Salt Lake valley, about nine miles north of the city of Ogden. They are located at an elevation of 4,246 feet above the sea-level. The mountains here are very rugged and picturesque, and attain an elevation of more than 5,000 feet above the location of the springs. As shown by the reports of the United States Signal Service, the climate of the Salt Lake valley is very mild in winter and free from oppressive heat during the summer months. The atmosphere is very invigorating and beneficial to almost all classes of invalids. There are three large springs in the group, and when discovered they resembled three immense wells, twenty to thirty feet in diameter, and eighty to one hundred feet deep. Each of these furnishes a large stream of clear, hot, sparkling water, their combined outflow being about 160,000 gallons in twenty-four hours. The temperature varies from 131° to 144° F. An analysis by Prof. Spencer F. Baird, Smithsonian Institution, Washington, D. C., resulted as follows:

One United States gallon contains (solids): Calcium sulphate, gr. 18.07; calcium chloride, gr. 170.49; potassium chloride, gr. 97.74; sodium chloride, gr. 1,052.47; magnesium chloride, gr. 1.07; magnesium carbonate, gr. 11.77; silica, gr. 2.69; alumina, gr. 0.25. Total, 1,354.55 grains. Carbonic acid gas, 37.18 cubic inches.

The Hot Springs Hotel is a frame structure, about three hundred feet long, the north end of which is used for baths. The resort is very well supplied with bathing facilities, containing, besides many private rooms, a large plunge bath for women and another for men, and an immense swimming pool. The water is quite strongly muriated saline. It contains, in addition to the mineral ingredients, a large amount of organic matter in the form of vegetable growths or algæ. These form rapidly in reservoirs containing the water, and, it is said, they impart a soft, unctuous, or oleaginous effect to the water, which is very pleasing to the skin, and believed to be soothing to the nervous system. The baths are much resorted to by persons suffering from rheumatism, gout, syphilis, chronic bronchial catarrh, obstructive jaundice, disorders of menstruation, etc.

James K. Crook.

UTAH WARM SPRINGS.—Salt Lake County, Utah.

Post-Office.—Salt Lake City.

These springs are situated at the base of the heights of Ensign Peak, in West Second Street, Salt Lake City. The location is about 4,060 feet above the sea-level, or 20 feet above the general level of the Salt Lake valley and 40 feet above the lake itself. The springs are the property of the city, and are leased by the present managers for a period of ten years. An excellent bath-house, easily accessible from all parts of the city by electric cars, is maintained at the springs. The water has a temperature of 112° F. a[illegible]ows. It was analyzed by Dr. Charles T. Jackson, [illegible] Boston, with the following results: One United States gallon contains (solids): Calcium and magnesium carbonate, gr. 10.22; iron peroxide, gr. 1.70; calcium, gr. 23.21; chlorine, gr. 147.14; sodium, gr. 125.66; magnesium, gr. 15.86; sulphuric acid gr. 29.94. Total, 353.73 grains. *James K. Crook.*

UTERUS. See *Sexual Organs, Female*, and *Gestation.*

UTERUS, DISEASES OF: AFFECTIONS OF THE CERVIX.—In considering diseases of the cervix uteri, it must be remembered that the cervix is an integral part of the uterus, and that disease of one part is generally coincident with disease of the whole. The fact remains, however, that disease of the cervix does occur without invasion of the corpus uteri and *vice versa.*

Atrophies.

1. Physiological Atrophies.—*Senile Atrophy.*—Generally with the commencement of the menopause a change in the size and consistence of the cervix takes place in conjunction with changes of a like character which occur at this time throughout the whole genital tract. Instead of at the usual time these changes may appear much earlier in life, and their premature onset, without pre-

vious sickness or known cause, is simply an early physiological ending of the active sexual life.

The cervix becomes reduced in size and assumes a conical shape, the mucous membrane loses its pink color and is pale and anæmic; while the folds of the arbor vitæ atrophy and in some cases almost disappear. The epithelial lining of the cavity undergoes retrograde changes, so that the secretion almost or wholly ceases and the canal may be hardly patent. Oftentimes the cervix nearly disappears, and owing to the atrophy of the vaginal fornices remains only as a dimple in the apex of the cone-shaped vagina.

With the cessation of menstruation we have the well-known general symptoms, be it early or late, but the process in the genitals being a physiological one requires no special treatment.

Under physiological atrophy may also be included the change which takes place after castration; the process and symptoms which follow being analogous to those of senile atrophy.

Atrophy of Lactation.—It has long been a well-recognized fact that the uterus of a woman nursing her child contracts more quickly and firmly, due to a reflex action upon the uterus. This may go so far that the uterus is smaller than normal.

While this process is perfectly physiological, according to those who have made careful observations on this subject, yet it may go so far as to become pathological in women upon whom the strain of nursing is too severe, or who are suffering from debility. Horn, who has investigated this subject very thoroughly, says that with the return of menstruation the uterus regains its former size. He also found that the atrophy was of two distinct kinds. In one class the uterus became pale, anæmic, and small, with the cavity diminished in size. In the other the walls became thin and flabby and the cavity diminished. The cervix was affected in some cases, while in others it took no part in either form of atrophy. When the atrophy is not of the severe type the cervix is little altered, but with the involvement of the whole genital tract it is markedly affected and becomes small and short.

Prognosis in the lactation atrophy, when the process has not been allowed to proceed too far, is good, even when there is some local or bodily ailment.

Treatment is not usually required, as with the return of menstruation and sexual intercourse the uterus regains its former size. In instances in which there seems to be danger of the atrophy proceeding too far, the child should be taken from the breast and the patient given rest and tonics. If more is needed, treatment should be directed to increasing the blood supply of the uterus by passing sounds, by the use of hot douches, by massage after Brandt's method, or by painting the cervix with Churchill's tincture of iodine. Hot sitz and foot baths, as well as scarification, may also be tried.

2. PATHOLOGICAL ATROPHIES.—*Atrophy Following Systemic Diseases.*—This has been reported following tuberculosis, diabetes mellitus and insipidus, myxœdema, nephritis, Addison's and Basedow's diseases. Cases have also been seen after scarlet fever and typhus fever, articular rheumatism, after paralysis of the lower limbs, from the morphine habit, and from psychical derangement.

Atrophy Following Infection of Uterine Adnexa.—The process here is decidedly different from that of the physiological atrophies. Instead of the simple reduction of the individual muscle fibres as regards size, necrosis and degeneration take place, and large pieces of the uterus may be thrown off, with contraction as an ultimate result. Thrombosis of the veins has been shown to take place with loss of muscular structure and mucosa. The connective-tissue formation and its subsequent contraction cause the reduction in size in the last named.

Infection of the ovaries and the destruction of their function lead to the same results as are seen after castration.

Prognosis in puerperal infections, as regards the ultimate recovery of the uterus from its atrophic state, is especially poor, as the tissue changes are far-reaching and usually beyond the hope of regeneration. The outlook is especially grave when there is great atrophy of both cervix and corpus, or when the inflammatory process has extended to the ovaries.

The acute infectious diseases cause as a rule a temporary atrophy, which soon disappears with the restoration of bodily health.

The prognosis of the uterine changes in the chronic systemic disorders is practically that of the associated disease, for in such instances it is only the local manifestation of a general process.

Treatment of all these cases is usually unsatisfactory, as the pathological changes place the tissues beyond a chance of repair.

HYPERTROPHIES.

Hypertrophy of the Cervix.—Chronic metritis is the cause of this rather rare condition, which, as in chronic inflammatory processes elsewhere in the body, brings about a large increase in connective tissue. The muscular structure undergoes fatty degeneration, and bundles of fatty fibres are found enclosed by large bands of connective tissue. Sometimes the blood-vessels are varicose, and sometimes, cut off by these strong connective-tissue bands, their lumen is diminished and the circulation of the part impeded, bringing as a result chronic passive congestion. The entire uterus may be affected and show on section white shining bundles of tough connective tissue with the degenerated muscle fibres between, and small hemorrhages from the walls of the varicose vessels. Occasionally these changes are limited to either the cervix or the body of the uterus; but even when so limited, the remaining part is seldom or never entirely intact. In some instances the hypertrophy of the cervix makes the body appear like a small appendage, and the relations of the body and cervix are as in the child, in whom the cervix forms about two-thirds the entire uterus.

When there is a pre-existing injury of the cervix the lips often spread far apart, become greatly enlarged, and form a knob on the end of the much elongated cervical neck.

Enlargement of the cervix, due to obstruction and retention of the contents of the cervical glands, as the result of endocervicitis, is exceedingly common. It is most often seen after the lacerations and infections of childbirth. The mucous membrane is of a bluish appearance, or at times may appear quite bloodless. The small cysts may give no hint of their presence to the eye, but to the touch they are apparent in all sizes, studding the cervix like small shot or peas under the mucous membrane. They may attain the size of a small marble. At times they stand out like sago grains under the mucous membrane, which is usually hyperæmic, while the so-called erosions are apt to be present, stimulated by the irritating discharges from the cervix. On puncture a clear, cloudy, or even sometimes blood-tinged mucoid substance exudes and the mucous membrane of the gland is seen as the bright, glossy covering of the cyst wall.

As a rule this form of enlargement does not reach the extent of the true hypertrophy, and the cervix usually remains soft and bleeds easily; still it may lead to such contraction and cirrhosis that operations upon such a cervix are practically bloodless. Occasionally, through the increased size of the uterus and cervix, and the relaxed condition of the tissues of the pelvis which generally accompanies the increase in size, the cervix may appear at the vulva. The acid discharges from the cervical canal are irritating to the vagina and external genitals, and are probably the cause of sterility in such cases.

Hypertrophic Elongation of the Infravaginal Cervix.—This is generally a congenital affair, but the form which is considered here is the result of metritis, and so belongs properly to the hypertrophies. The process is the same as previously described. It is accompanied by the general symptoms common to most uterine displacements, and may be the means of furthering a procidentia, as the increased weight of the uterus drags it downward with the long cervix to guide it through the vagina.

Hypertrophic Elongation of the Supravaginal Cervix.—Elongation of the upper segment of the cervix is fairly common and is a mechanical process. The body of the uterus remains fixed in the pelvis either by adhesions or by the strength of its utero-sacral ligaments, the corpus being often retroverted. As this form seems to occur in women who are physically reduced and whose tissues are relaxed, or in cases of subinvolution of the tissues of the pelvis after pregnancy, it seems due to a loss of the normal resiliency of the tissues. The uterine neck is dragged upon by the vaginal wall and so stretched that the cervix may reach the vulva. The bladder wall is always said to descend first and then the posterior wall of the vagina. Coupled with this stretching there is always a certain amount of hypertrophy; but more frequently the neck of the uterus can be felt as a long thin cord stretching up to the body. It is evident that tensile elongation is present; for if the woman lies upon the back, the uterus returns to nearly its normal size, and will undergo still further reduction in size if the patient remains in bed for a few days. For this reason it is always best to examine patients complaining of this trouble in a standing position. There is always apt to be great swelling of the vaginal portion of the cervix with ectropon of the mucous membrane.

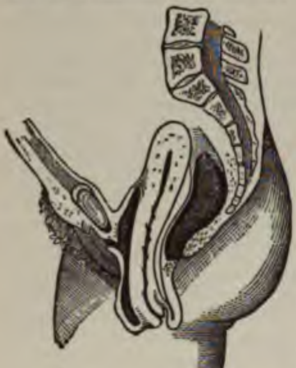

FIG. 4870.—Hypertrophy of Supravaginal Portion of Cervix, showing obliteration of vaginal fornices and descent of vaginal walls. (Schroeder.)

Occasionally cases are seen in which the uterine body feels like a small protuberance on the front of the elongated cervix as it lies in the cavity of the pelvis. This condition may also occur at the time of the climacteric.

Treatment of hypertrophy of the infravaginal cervix is usually rather unsatisfactory, as it is seen as a rule in the later stages when the harm has been done and its effacement is impossible. If the disease comes under observation early in its course considerable can be done, by first removing all the diseased mucous membrane with the sharp curette, and then using tampons of glycerite of tannin, or of ichthyol, or hot douches, with now and then an application of strong tincture of iodine to the cervix. Astringents may be used in the douches as well. By these means the venous congestion is relieved and absorption stimulated. At times puncture of the cervix seems to aid in the reduction in size, after the principle of the old-time leech, which now in the days of asepsis has almost disappeared. As the sufferers from these affections are generally in poor health, tonics suited to the general requirements of the case are indicated. Most important of all is proper hygiene, both as regards the body and as regards the sexual relations; the patient should be enabled to secure proper and sufficient food coupled with rest, freedom from care, and plenty of fresh air.

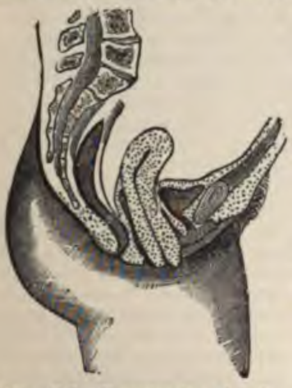

FIG. 4871.—Hypertrophy of Infravaginal Portion of Cervix, showing vaginal fornices in normal position and no descent of vaginal walls. (Schoeder.)

The bowels should be freely moved daily, and the use of calomel in small doses, extending over a period of some months, is said to have a very beneficial action in some cases. Ergotin has also been given in doses of from three to ten grains daily, but the patient must be watched for symptoms of ergotism where the remedy is continued for some time. Puncture with the galvano-cautery and the application of electricity have both been recommended: but the cautery only aids the process which is being combated, while the application of electricity is fraught with more or less danger, and the writers consider it of very doubtful efficacy. In some hypertrophies of moderate size a retroversion pessary may give relief when the conditions are favorable. By this means the feeling of weight is relieved and the tendency to procidentia prevented.

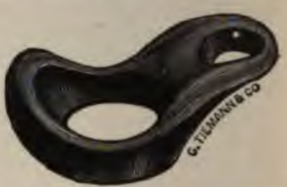

FIG. 4872.—Fowler's Pessary.

Whenever the more simple methods fail, the only aid lies in reducing the size of the cervix by some surgical operation. A wedge-shaped piece may be excised from each side, and the new anterior and posterior lips so formed should then be brought together as in bilateral lacerations of the cervix; or one of the various means of amputation may be tried. If a laceration of any extent already exists, the excision can be made during the repair of the cervix. This treatment always seems to have a very favorable effect upon the metritis which usually exists in the body, and of which the enlargement of the cervix is but a part.

The treatment of the hypertrophy of the cervix due to excessive glandular formation and retention cysts of the Nabothian follicles, must be primarily based upon the cure of the coexisting endocervicitis and endometritis. In the mild cases the small cysts may be punctured and the lining membrane destroyed with strong iodine, or carbolic acid, or nitrate of silver fused on the end of a probe. An elliptical piece may be snipped from the wall of the larger cysts, to prevent closure, and the inside curetted, or they may be treated in the same manner as the smaller cysts.

In the severer types of the disease many small cysts will be felt deeply embedded in the tissues. As a part of the treatment depletion and the hot astringent douches will be found useful.

For the milder grades of endocervicitis and endometritis applications of tincture of iodine and carbolic acid, or of forty-per-cent. formalin, may be tried; but it is the opinion of the writers that the danger is much less in the more severe cases if a curetting with aseptic technique is carried out. When the mucous membrane is extensively diseased, as is often the case in considerable lacerations, and if the lips are filled with cysts, the simplest and best method is to dissect away the diseased membrane as far as may be necessary, after the operation of Schroeder. If a bilateral tear exists it often is possible to remove the diseased tissue in the process of repairing the cervix. Should it seem best, a light packing of iodoform gauze may be placed against the cervix after Schroeder's operation, to prevent effusion between the raw surfaces.

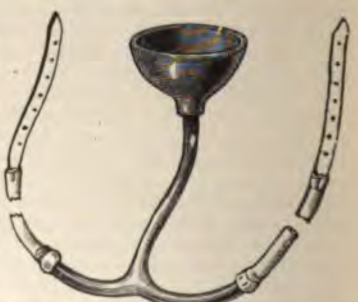

FIG. 4873.—Cup Pessary, with Inflexible Stem and Bands for Attachment to Waist Belt.

Hypertrophic elongation of the cervix when moderate in degree requires treatment only by mechanical means. The indication here is to change the position of the cervix so that its axis does not correspond to that of the vagina. This can be done by means of a retroversion pessary having a bar across to hold the cervix in front, or by the well-known Fowler's pessary, which receives the cervix in a cup at its upper end (Fig. 4872). Of course this treatment is suitable only in cases in which the inflammation has subsided and the perineum is capable of supporting a pessary. The cup pessary can be tried when the vaginal method fails; but it has the great disadvantage that even with skilful and careful use it is apt to cause excoriation, and when the parts are not carefully watched, the pessary may give rise to the development of both recto-vaginal and vesico-vaginal fistulæ. This instrument is made like the cup of the old game of cup and ball. The cervix rests in the cup, while through the lower end of the stem pass the rubber tubes, which form the perineal bands and are attached to a waist band. This is at the best a clumsy appliance, and worthy of use only in cases in which for some reason the operative treatment is refused or contraindicated.

Amputation of the cervix constitutes the surest method of affording relief. This takes away the weight which drags down the uterus and at the same time removes the guide, which, if there is a tendency to procidentia, steers it through the vaginal canal. This may be all that is required; but if there is a ruptured or relaxed perineum it should be repaired at the same time. In case this does not suffice, ventral suspension to maintain the uterus in its proper axis still remains, or total extirpation.

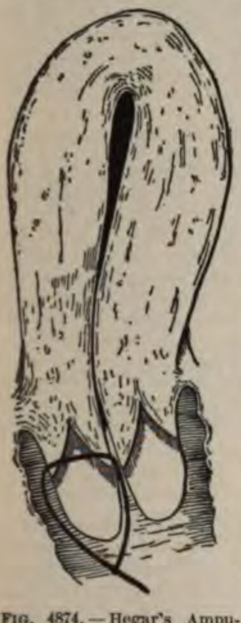

FIG. 4874.—Hegar's Amputation of the Cervix Uteri.

Amputation of the cervix has been performed with the écraseur and also with the cautery; but the knife has taken the place of these methods which are prone to cause stenosis. To Hegar is due the credit of having invented the first really practical operation for amputation of the cervix—one which with slight variations is applicable to most cases. The cervix is split on both sides as far as to the vaginal junction, and a cone-shaped piece is then removed from each lip, according to the need of the individual case. The sutures are passed under the whole denuded surface from the cervical mucous membrane to that of the vagina. This may be continued all around, or, after suture of the central portions above and below, the sides may be brought together as in repair of the bilateral tears of the cervix. (See the section on Wounds of the Cervix, farther on.)

Schroeder's Method.—After lateral splitting of the cervix, as in Hegar's operation, the lips are held apart and the diseased tissue is removed, as shown in Figs. 4875 and 4876. The wound is closed by turning the flaps of vaginal membrane on to the denuded areas and stitching them in place. This brings the sutures into the entrance of the canal. The commissures on both sides are then brought together by sutures passing under the whole denuded area. There are some more complicated operations, but these two, with the modifications of which they are capable, will suffice in all cases.

The results of hypertrophic elongation of the supravaginal cervix are hard to combat by non-operative procedures. The relaxed condition of the vagina and its outlet, and the frequent presence of laceration of the perineum and of a retroverted adherent uterus, render the mechanical treatment of this condition exceedingly difficult.

In young women rest, astringent douches and tampons, and building up of the general health will usually bring about a cure. As the uterus in these cases, which occur after childbirth, is generally retroverted, its support, after replacement, by some form of retroversion pessary is indicated.

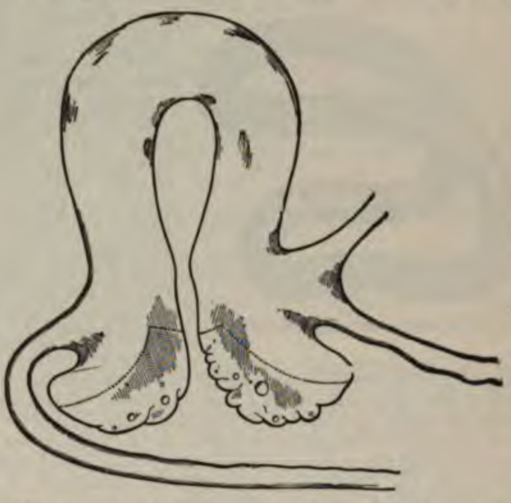

FIG. 4875.—Schroeder's Operation. Dotted lines show the extent to which the cervix should be denuded.

The Hodge pessary may fulfil all the requirements if the lower end is made of such a width that it cannot escape from the grasp of the muscles of the outlet. If this is impossible on account of relaxed outlet, torn perineum, or adherent uterus, which resists well-applied packing in the knee-chest position, operation for repair of the pelvic floor and suspension of the uterus offer the best chance of permanent relief. Pregnancy with the involution which follows it has been known to effect a cure.

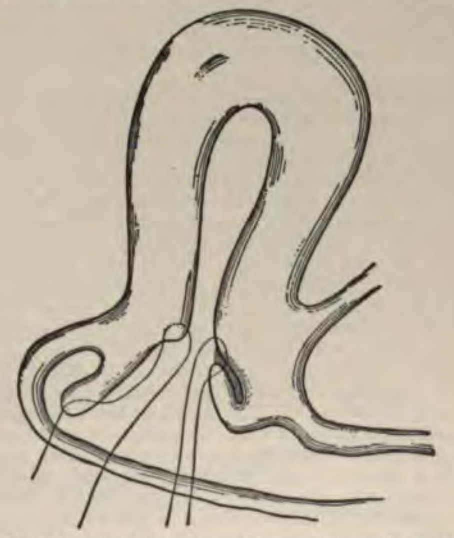

FIG. 4876.—Schroeder's Operation. Diagram shows the manner in which the sutures are to be applied.

At the time of the menopause or subsequently, the chance of effecting a cure except by some operative procedure is slight; but at the same time certain cases may be made comfortable for years. In the case of an ad-

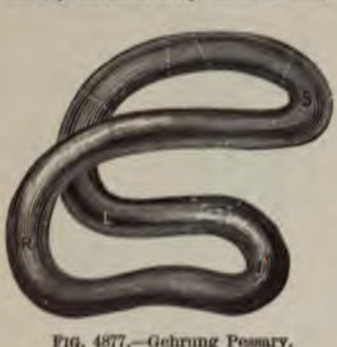

FIG. 4877.—Gehrung Pessary.

herent uterus it may be possible to hold up the prolapsing vaginal wall by the inflated rubber rings; but this, of course, is open to the objection that the walls are slowly stretched by their action, and that they are hard to keep clean. Gehrung's pessary (Fig. 4877) has been successfully used by some practitioners in retaining the vaginal wall in place; but a good pelvic floor is necessary for its retention. Generally speaking, the retroversion pessaries of all forms are not successful at this time of life, as the infravaginal cervix is atrophied and the vagina cone-shaped, while the perineum itself is too relaxed to retain them. As a last resort the cup pessary may be tried, but the many disadvantages, the care necessary to prevent excoriation and possibly worse consequences, may well make the gynecologist loath to use them in the majority of cases.

Should the discomfort and general condition of the patient warrant operation, the same principles will apply as when the disease occurs in early years. Furthermore, at the age when the sexual life is past, hysterectomy and a complete closure of the vagina by denuding its walls and uniting them with catgut thoughrout their length may be used as a last resort in obstinate cases. As we cannot expect the same involution of the tissues in older as in younger patients, operative interference is earlier indicated.

ULCERATION OF THE CERVIX.

True ulceration of the cervix occurs as the result of trauma or of systemic or local disease, and is very infrequent.

Chancroid of the cervix is occasionally seen and has the usual appearance of such lesions on mucous surfaces, except that, from the structure of the cervix, there is little œdema.

Owing to the moisture of the parts treatment is difficult. The cardinal points are cleanliness and dryness. If attention is carefully paid to these the lesion soon disappears, although to prevent further infection it is at times best to apply ninety-five-per-cent. carbolic acid or fuming nitric acid to the sore. The thermo- and the electro-cautery have also been recommended. These applications should be carefully and sparingly made; this is especially true of nitric acid, which may produce bad sloughs and possible stenosis of the os externum. The vagina can be kept dry by a powder composed of equal parts of powdered starch and boric acid, or of compound stearate of zinc with boric acid or acetanilid.

Iodoform is strongly recommended by many, but its odor is very offensive, and it has no particular value over the odorless powders. The powders are best applied in the knee-chest position with the perineum retracted by a Sims speculum. The vagina is cleansed with pledgets of cotton dipped in borax water or a weak solution of bicarbonate of soda, by which means the mucus is easily removed. After cauterizing and drying the ulcer and vaginal walls, one or two teaspoonfuls of the powder are thrown on to and about the cervix, and the vagina is lightly packed with strips of gauze covered with the drying powder. These should be removed every twenty-four hours and fresh powder applied after wiping out any of the previous application which has become moist. The vagina is then to be packed as before. Indolent ulcerations may be touched with nitrate of silver, twenty to forty grains to the ounce of water.

Chancre of the cervix is comparatively rare, but more common than chancroidal ulcer. Rassenone found 117 cases among 1,375 cases of venereal sores of the genitals. Chancres occur more often on the anterior lip and may be multiple; occasionally they extend into the canal. They may be recognized by their well-defined border surrounding a depressed area covered by a grayish membrane. Beginning as mere erosions, they soon become deep ulcers, and instances have been reported of perforation into the rectum or into the bladder. They have been mistaken for cancer, and have been known to undergo cancerous degeneration after healing. Mucous patches are also seen among the secondary symptoms.

Constitutional treatment in a doubtful case will soon settle the diagnosis. As to local measures, douches of corrosive sublimate, 1 in 3,000 to 1 in 5,000, or treatment after the manner of the chancroidal ulcers with a powder of calomel and starch, will be found useful. Cauterizing is useless and may do much harm.

Tuberculous ulceration is very rarely seen, and is usually associated with the disease elsewhere, but may be primary. It may take the form of a simple ulceration or of lupus hypertrophicus, and is easily mistaken for cancer—a point which the microscope alone can decide in many cases.

The best treatment is probably the removal of the uterus and appendages, as they are generally infected. If this seems unnecessary, the cautery or amputation of the cervix may be tried. When the disease is too far advanced for operation the parts must be kept clean with douches of potassium permanganate or chlorinated soda in strengths suited to the comfort of the particular patient.

ATRESIA OF THE CERVICAL CANAL (ACQUIRED).

This is generally the result of lacerations due to delivery or to the action of caustics. It may result from contraction after amputation of the cervix, or after an operation for repair. Occasionally it results from the contraction of an old ulcer, from new growths within the uterus, or from old age. After the menopause this has no detrimental effect, unless, as occasionally happens, some infection takes place and pus is retained in the old uterine cavity. Previous to the menopause hæmatometra may be expected. Under such circumstances, if the atresia is at the internal os, the shape of the cervix is well preserved; but if it is at the external os, the cervix is carried up to a higher level and the entrance appears as a dimple in the vaginal vault.

STENOSIS OF THE CERVICAL CANAL (ACQUIRED).

The causes are the same as for the preceding, and it occurs more often at the external than at the internal os. The cavity of the cervix may be contracted throughout its length, or, when the restriction at the external os keeps back the secretion, the cavity may be rather fusiform in shape.

Diagnosis of the condition may be made by inspection or by passing a sound or probe. As the tip of a small probe is often caught in the folds of the arbor vitæ, care must be exercised in introducing the instrument. Dragging down the cervix with the double hooks or tenaculum will sometimes obviate this difficulty by straightening the canal. Usually there is a slight spasm of the internal os, which gives way after a few moments of steady pressure. This must not be mistaken for stenosis.

Dysmenorrhœa is usually present and there is also sterility, but the first does not follow in every case, as women with a tight internal os often complain of no pain with the menses.

Pain is probably due to the fact that more blood is poured out from the uterine mucous membrane than can be taken care of by the narrowed canal of the cervix, while the distention of the uterus causes painful contractions of a paroxysmal nature. These are often relieved by the passage of a clot or a quantity of mucus. The pains may be so severe that vomiting, fainting, and various nervous manifestations take place.

The sterility is said to be due to the failure of the cervix to expel the mucus from its canal during the orgasm. It is probably also due to the endocervicitis which is present in these cases, and to an altered cervical secretion.

Treatment of stenosis is surgical, and what is said concerning this applies to atresia coming on before the menopause.

Electricity has been tried in the past, and while it may relieve for the time, the ultimate effect, as in the case of the caustics of the earlier days, is to leave the cervix in a worse state than that for which the treatment was undertaken. To-day four methods are in common vogue: gradual dilatation, discission, divulsion, and plastic operations,—all of which are necessarily contraindicated in any acute inflammatory disturbance of the uterus or adnexa.

Gradual dilatation is performed with Hanks' dilators, with the patient on the back or in Sims' position. The vagina is cleansed with soap and water, and wiped out with a solution of corrosive sublimate, lysol, or carbolic acid. The anterior lip is seized with the tenaculum and pulled gently downward. After the direction of the canal has been ascertained by means of a sound, the dilators are inserted in increasing sizes, each one being allowed to remain a few moments in the canal. For a lubricant lubrichondrin or glycerin may be used. The dilatation should not be carried so far as to cause fissures of the os, and one treatment a week is sufficient. Finally the canal is swabbed out with ninety-five-per-cent. carbolic acid or with tincture of iodine, and a tampon of ichthyol and glycerin is inserted. The latter should be removed the next day. Patients had best remain quiet for a time after the operation, as uterine cramps sometimes come on. No permanent results can be expected of this treatment, and it is advocated as a measure to be adopted only when pregnancy is desired. Probably the favorable results which follow are often quite as much due to the cure of the uterine catarrh as to the increase in the calibre of the canal.

Discission of the cervix with the various metrotomes, once practised so widely, has disappeared owing to the hemorrhage, sepsis, and contraction which followed too often in its wake.

Discission as practised to-day consists of splitting the cervix on each side as high as the junction of the vaginal wall and nicking the internal os on each side. The hemorrhage may be quite free, but is easily controlled by packing gauze between the lips. This operation is resorted to principally for the relief of stenosis and atresia of the internal os.

Divulsion or rapid dilatation under ether or chloroform narcosis and with aseptic precautions is almost devoid of danger, and is perhaps the most generally applicable method when the canal is patent. This is performed with any of the well-known cervical dilators, of which Goodell's modification of Ellinger's dilator is perhaps the best (Fig. 4878). The external genitals and vagina having been rendered surgically clean, the cervix is seized with the vulsellum forceps; and if the canal does not admit the tip of the special form of dilator used, it may be expanded with the Hanks dilators to the necessary extent. The blades of the dilator are then inserted under steady, gentle traction upon the cervix with the vulsellum forceps, and spread in all directions until the canal is dilated to from one-half to three-quarters of an inch. This may be followed by curettage, if necessary, and the uterus and cervix packed with iodoform gauze for from twenty-four to forty-eight hours. Curettage is necessary in most instances, as the stenosis may be due to the existing inflammatory condition of the mucous membrane, which is so common in these cases. Some operators prefer to insert a glass plug after operation in place of the packing, but with this there is increased danger of sepsis. Another advantage of the gauze is that it usually brings with it on removal any small pieces of the mucous membrane which have been skipped by the curette. It is also well to wipe out the uterine cavity before putting in the final packing.

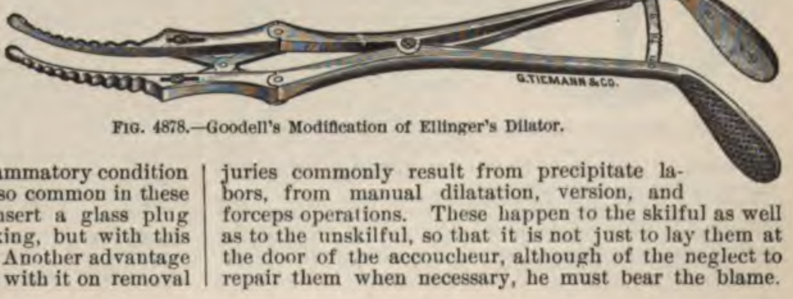

FIG. 4878.—Goodell's Modification of Ellinger's Dilator.

The patient should remain in bed for ten days, and after the first two or three days the use of an antiseptic douche of creolin or lysol, 1 in 100, adds much to her comfort and cleanliness.

Plastic operations are used to relieve contraction or atresia of the external os when the cervical canal is dilated above. The principle of the many operations devised, which accomplish their purpose in the end results, is that involved in amputation of the cervix; and each case must be treated upon these principles, according to its needs.

TRAUMATIC AFFECTIONS OF THE CERVIX UTERI.

The position of the cervix deep in the pelvis affords little chance of injury except as the result of parturition, ill-fitting and neglected pessaries, inflammatory disease or the contraction caused by the indiscriminate use of caustics in the early days.

Abrasions.—Women wearing a pessary for the first time are liable to slight abrasions of the mucous membrane, even with the best of care. These are of no especial importance if taken in time; but, as often happens, the patient, feeling relieved, fails to appear for months, and the pessary becoming encrusted with salts causes not only excoriations, but ulcerations which may extend into the rectum or into the bladder. The external and internal combined pessaries are prone to cause these ill results, as they are generally bought of some instrument maker, often without any measurements being made, and are adjusted by the patient.

Also the support of the pessary from the outside by the elastic bands does not allow it to move freely with the excursions of the pelvic diaphragm without increasing the pressure. With the cup pessary, unless in the proper axis, the lips press against the cervix and cause sloughs.

The removal of the pessary and simple cleanliness suffice for the cure of the small abrasions. When the surface involved includes the vaginal wall as well, it is best after cleansing the vagina to apply some antiseptic powder and lay gauze between the abraded surfaces to prevent their adhering. Indolent or granulating ulcers may need stimulating or astringent applications.

Wounds of the Cervix.—Practically all lacerations of the cervix arise as the direct or indirect result of parturition, and are equally unavoidable. Broadly speaking, at least one-third of all labor cases have lacerations worthy of repair. Tears may occur from miscarriages in the early months, while delivery at full term may leave not the slightest trace of rupture. Portions of the anterior lip may slough from pressure, and large defects are sometimes caused in this way. Pregnancy occurring late in life for the first time, or after inflammatory disease, is apt, on account of the more resistant cervix, to leave its marks. Cases have been reported in which the resistance of the cervix to dilatation has been so great that it has been torn from the uterus by the force of the advancing head. The most severe injuries commonly result from precipitate labors, from manual dilatation, version, and forceps operations. These happen to the skilful as well as to the unskilful, so that it is not just to lay them at the door of the accoucheur, although of the neglect to repair them when necessary, he must bear the blame.

Finally, lacerations may occur from the tearing out of tenacula, double hooks, etc.

The fact that childbirth leaves its mark upon the cervix in so many cases makes it one of the surest guides as to the existence of previous pregnancy; but the fact must not be lost sight of that operative procedures may sometimes leave marks which simulate those of parturition.

PATHOLOGY.—Lacerations may be partial or complete.

A partial laceration is a tear of the mucous membrane and muscular substance which does not extend to the vaginal surface except at the external os.

A complete laceration is a tear through the whole substance of the cervix, laying open the canal for a greater or less extent; sometimes so far as the internal os.

These injuries in turn are designated by the terms unilateral, bilateral, stellate, according to the nature of the injury.

Unilateral lacerations are seen in all parts of the cervix, but are said to be more frequent in the left and posterior portions.

Bilateral laceration is the most common form, where the cervix is divided to a greater or less degree into an anterior and a posterior lip. After forceps delivery this is especially common from the pressure of the forceps exerted at these points.

Stellate lacerations, even when not deep, may cause gaping of the external os, and open the mucous membrane to the influences which cause the unpleasant symptoms of cervical laceration. Following manual dilatation multiple tears are quite common, and the ruptures may be so numerous that after labor the cervix has the feeling of a tassel.

As being the most frequent, bilateral laceration and its treatment will be considered, as what is said concerning it will be equally applicable to the other forms.

Following in the train of these injuries come certain pathological changes as a rule, the end results of which have a far-reaching effect upon the health of the patient unless the operation for repair is undertaken in time. Healing of the cervix after labor may take place; but for the most part the tendency of the lips to separate in the bilateral form keeps the torn surfaces apart, while the process of repair here, as in the other forms, is hindered by the constant flow of lochia over their surfaces.

The danger of infection of the parametrium is considerable when the tear reaches into the vaginal vault. The rolling out of the damaged mucous membrane from the gaping lips favors a state of constant irritation, and the opening up of the connective tissue of the pelvis presents the opportunity for infection. As a result of these conditions there is a constant hyperæmia, which ends in the formation of fibrous tissue and eventually renders the affected parts as hard as cartilage. Exactly as in cervical catarrh the inflammation may proceed so far that the cylindrical epithelium of the cervical mucosa oversteps its boundaries and extends on to the mucous membrane of the vaginal surface of the cervix, displacing the squamous epithelium. This is the "erosion of the cervix."

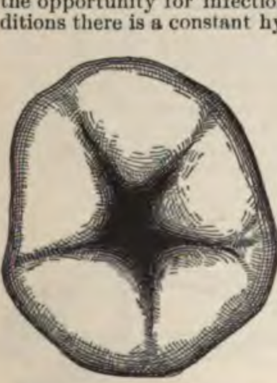

FIG. 4879.—Stellate Lacerations.

With the glandular hyperplasia comes increased secretion, while gradual occlusion of the glands by the new-forming connective tissue causes the Nabothian cysts.

The masses of cicatricial tissue so often felt about the uterus owe their origin primarily to these tears of the vaginal vault, and secondarily to the changes which take place in them as a result of infection; and in consequence of the contraction which subsequently takes place in these areas of new-formed tissue, displacements of the uterus in different directions are sure to follow. Subinvolution is very frequently seen after extensive injuries to the cervix.

In addition to the pathological changes which are found in the pelvis itself, various disturbances may take place, due not to the lacerations themselves, but to the irritation of the chronic metritis and endometritis with which they are so often combined. Furthermore, the increased weight of the subinvoluted uterus, when coupled with relaxed ligaments and a torn perineum, causes the organ to sag downward and adds to the effect of the diseased organs upon the system, the discomforts which arise from the loss of mechanical support. The unhealthy state of the mucous membrane is the cause of frequent abortions, and there is no doubt that cancer of the cervix is more common in cases which have suffered for years from these chronic inflammatory processes, of which the untreated injuries caused by childbirth were but the beginnings.

SYMPTOMS.—The symptoms of fresh laceration of the cervix would be bleeding after the birth of the child, which could not be accounted for by a relaxed condition of the uterus or by a vaginal tear. Slight tears are always present, and it is only seldom that it is necessary to search for the point of hemorrhage at the time of labor.

Symptoms of cervix lacerations, as they are seen at more or less remote periods from the time of their occurrence, are quite variable. Sometimes there is pain on coitus, or, if a displacement is present in addition, the symptoms may refer more to the altered position of the uterus than to the injury itself. The extent of the injury is also no guide as to the seriousness of the symptoms. At times there is bleeding without apparent cause, and the menstrual periods are apt to be painful and accompanied by excessive flow. Leucorrhœa, often blood-tinged, is almost constant, and there is a feeling of general malaise. Reflex symptoms, neuroses of the stomach, eyes, bowels, and even hysteria may be present, while pain over the sacrum or in the lower abdomen is a frequent complaint.

DIAGNOSIS.—The sense of touch enables one to form the best opinion as to the extent of a cervical laceration; for the introduction of a speculum, except in the knee-chest position, is apt to roll apart the lips and so obscure the exact condition. This is especially true in the bilateral tears. However, by seizing the upper and lower lips with tenacula and pulling them together, a good idea of the extent of the damage may be obtained.

When cysts are present in great numbers the feeling may be that of cancer, but inspection generally reveals the true state: the presence of small bead-like cysts, and of an inflamed, bulging mucous membrane, sometimes showing the plicæ palmatæ. Occasionally the condition presented may simulate hypertrophy, but by the drawing together of the lips the true state of affairs at once becomes apparent.

PALLIATIVE TREATMENT.—In the past, immediate repair of the cervix after labor has been recommended by some writers; but the consensus of opinion to-day is that operative procedure is not best until after the puerperium. The reasons for this are plain. After labor the cervix is bruised and some portions may slough. Also the tissue is so stretched and œdematous that correct coaptation of the parts is next to impossible, and with the rearrangement of the muscle fibres and subsequent contraction the sutures would become too tight and cut out. It is surprising to see how what appear like considerable lacerations at the time of delivery almost disappear when involution has taken place. Occasionally it may be necessary to insert a suture to control bleeding from the circular artery, but, as a general thing, a firm packing of the uterus and vagina, or even of the vagina alone, will cause the hemorrhage promptly to cease.

The larger number of patients with lacerations present themselves for treatment months or years after the injury has occurred. For this oftentimes the patients themselves are at fault more than their physician, as they defer the examination after the labor and wait until discomfort, pain, or repeated miscarriages force them to seek relief.

Not every case of cervical tear demands operation. For the severe lacerations and their unpleasant symptoms operation offers the only lasting cure. For the slighter injuries, the writers believe that the degree of the existing endometritis and the density of cicatrix must be the guides.

When operation is contraindicated or refused, it may be possible to relieve the discomforts to a certain degree. The subinvolution and endometritis may be relieved by hot douches and by depletion with glyceride of tannin, ichthyol, and glycerin and boroglyceride. The patients should be carefully instructed in using the douche, both as to quantity and as to temperature. It should be taken while the patient is lying on her back, with the hips elevated, and at least twice daily. Not less than eight quarts of water should be used at a temperature as hot as can be borne. To this may be added disinfectants, or astringents, as alum or tannin. The reservoir should be just high enough above the patient for the water to flow very slowly, and at the end the reclining position should be maintained for from twenty to thirty minutes.

Cysts if present should be punctured and the exuberant mucous membrane painted with tincture of iodine, carbolic acid, or silver nitrate as often as may be demanded.

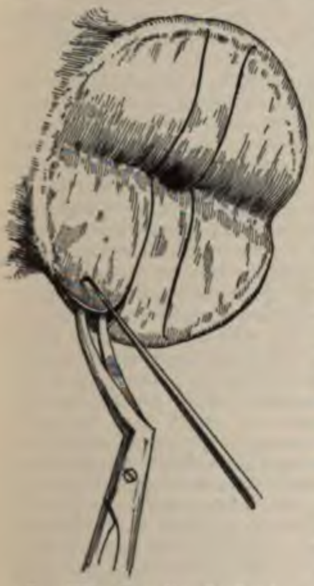

FIG. 4880.—Denuding the Cervix.

Considerable relief is often obtained by these measures, and they often prove a valuable preparatory treatment for many operative cases.

Unfortunately the price of this relief is constant treatment, and with its cessation the old symptoms soon return.

OPERATIVE TREATMENT. — In considering the subject of operative treatment, the first question is to decide in what cases to advise operation. Every deep laceration is not in need of repair, and many comparatively slight ones demand more than palliative treatment. Generally speaking, it is the condition of the cervix and uterine body more than the extent of the tear which decides the treatment; but, as has been said, the more extensive the laceration, the greater likelihood of endometritis, ectropion, and the widely known "erosion." Instances are seen of widely gaping lips, which are soft and without the slightest sign of inflammatory disturbance. Such as these do not need operative interference. For the small laceration with much uterine catarrh and enlarged tender cervix, showing the effect of the irritating discharges, curetting of the uterus and depletion may prove sufficient. If the cervix is much hypertrophied and studded with cysts, curetting, the excision of a wedge from each side and uniting by the method of Emmet, or Schroeder's operation is to be advised. (See Amputation of Cervix, in the section on Hypertrophies.) Where very extensive disease is present, amputation is the best procedure.

As the climacteric approaches, repair is more necessary than in younger women, for it is well known that the lacerated cervix seems to be the starting-point for malignant disease.

Operation.—Emmet was the first to put the operation for the repair of the cervix before the medical profession, and his operation, with a few modifications, has stood the test of time and is applicable to most cases, although in atypical lacerations modifications must be introduced to suit the requirements.

The operation is performed either in the Sims' or in the lithotomy position. The bowels should be thoroughly moved the day before, and on the morning of the operation an enema should be given at least two hours before the time set for operation. The patient is given a hot douche of borax water, which clears away the mucus, and the hair on the genitals is clipped close. Under ether the external genitals are scrubbed with green soap and gauze, and douched with sublimate solution, 1 in 3,000. In case of very foul uterine discharges, it may seem best to curette the uterus and wait for a few days before operating upon the cervix.

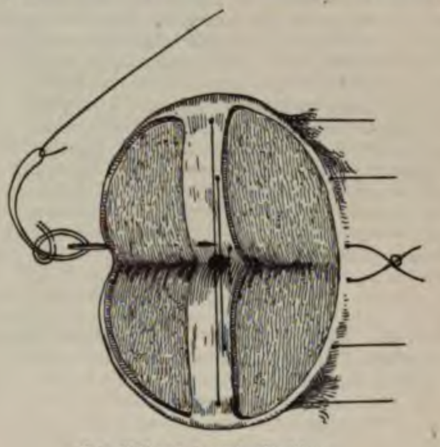

FIG. 4881.—Sutures in Position.

The vagina is held open with specula, the cervix is seized with the double hooks, and the direction of the canal and the extent of laceration are determined with the sound. The cavity of the uterus is then curetted as a preliminary step.

With the tenaculum the posterior lip is seized in the centre and denuded, as shown in Fig. 4880. All the diseased mucous membrane and the cicatricial tissue which always forms in the apex of the tear, must be removed, only the mucous membrane in the line of the cervical canal—a strip from one-fourth to three-eighths of an inch wide—being left. The anterior lip is treated in the same way. If the hemorrhage is considerable, it can be readily stopped by packing a sponge against the cervix for a few moments.

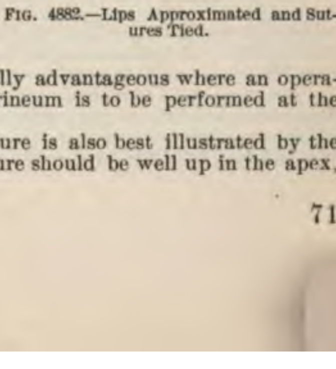

FIG. 4882.—Lips Approximated and Sutures Tied.

For the denudation the scalpel is best, as it causes less trauma. Scissors can be used and the hawk-billed scissors of Skene are often useful in clearing away scar tissue at the apex of the wedge.

Suture material of chromicized catgut, silkworm gut, or silver wire may be used. Chromicized catgut has the advantage that it is unnecessary to remove the sutures. This is especially advantageous where an operation for lacerated perineum is to be performed at the same time.

The manner of suture is also best illustrated by the figure. The first suture should be well up in the apex, and each should pass from the vaginal surface under the whole denuded area and through the edge of the mucosa which has been left to form the new canal. Usually from three to five sutures on each side are sufficient. Sometimes, on account of the large amount of scar which has to be removed, it will be found necessary to cut away one strip of the mucous membrane which was left to form the new canal. This can be done without fear of atresia. It is generally better in operations upon the cervix not to pack the uterine cavity, as the removal of the gauze may tear out the sutures. Stellate and atypical lacerations must be repaired in a manner suited to each case. Where small tabs exist, they are often advantageously removed, especially if the cervix is enlarged, and the two adjoining edges denuded and sutured.

George Haven.
Ernest Boyen Young.

UTERUS, DISEASES OF: CONGENITAL MALFORMATIONS.

— Development. — The uterus is formed by the approximation and fusion of the middle portions of the Müllerian ducts. The upper portions remain distinct, constituting the Fallopian tubes, while the lower unite and form the vagina. A vertical partition separates at first those parts of the ducts of Müller which go to make up the uterus and vagina, but this subsequently disappears, and the two canals become one. At a later period in the course of development, at the lower end of the middle third of the tube thus formed, the cervix appears, dividing the genital canal into uterus and vagina. The tissues at the summit of the middle third and between the points of origin of the Fallopian tubes likewise thicken, and the fundus uteri comes into existence. The insertion of the round ligament separates the upper from the middle third.

It is interesting to note that in the lower animals development regularly stops short at various points in the scale of progression, which ultimately ends in the formation of that which in the human female is a perfected genital canal, so that what in the latter are termed abnormalities, in the lower animals are the normal characteristics. At birth the cervix is longer and thicker than the uterine body, and this state of affairs persists throughout childhood. At puberty rapid growth occurs, and this condition is reversed, the cervix then appearing as an appendage to the body. By the twentieth year the genitalia have reached their full measure of development.

General Etiology.—Congenital malformations of the uterus are owing to a non-appearance of the elements which go to make up this body, to an arrest in their development, or to their complete destruction by nutritive disturbances, pressure changes, etc.

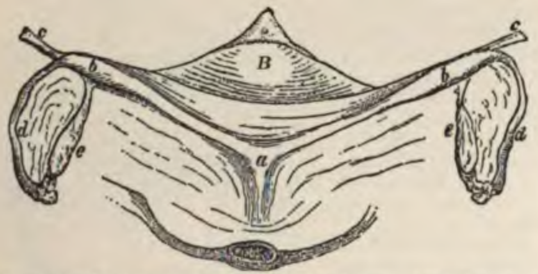

FIG. 4883.—Rudimentary Uterus, Posterior View. (After Veit.) *a*, Fused but solid portion of the uterus; *b*, *b*, uterine horns; *c*, *c*, round ligaments; *d*, *d*, tubes; *e*, *e*, ovaries; *B*, bladder.

Classification and Nomenclature of Varieties.—The whole subject of congenital malformations of the sexual passages has been thrown into much confusion by the varying methods of arrangement and classification adopted by different authors, and still more so by the complicated and pedantic terminology that has been employed. The same name has been given to different conditions, and the same condition has received different designations. The classification and nomenclature which follows is that of Müller; it is at once the simplest and the most comprehensive.

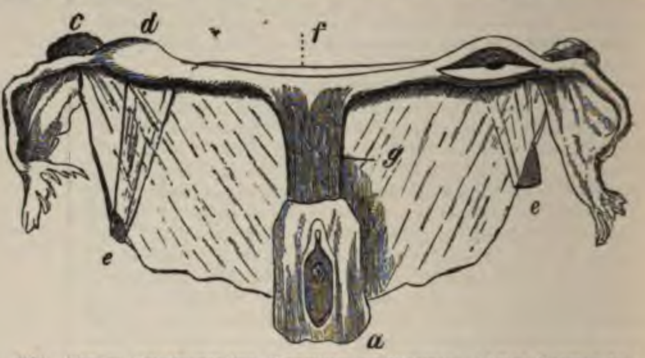

FIG. 4884.—Uterus Rudimentarius Bipartitus or Bicornis. (After Rokitansky.) *a*, Vagina; *b*, tubes; *c*, ovaries; *d*, enlargement of the horn; *e*, round ligaments; *f*, point of union of the two horns; *g*, cellular tissue traversed by muscle fibres which simulate the uterus in form.

I. Complete Absence of the Uterus: Defectus Uteri.—*Anatomy.*—Complete absence of the uterus, a condition rarely met with in viable subjects, is by no means uncommon in monstrosities incapable of life. Whenever encountered, other evidences of a serious blow to the progress of development are almost always present in some portion of the genital apparatus. The individual, in voice, habit, and general conformation adheres to the female type, but the organs which characterize the woman may, alone or in combination, be entirely wanting, or else may exhibit all grades of rudimentary development. Thus, with absence of the uterus it may be impossible to discover any trace of ovaries, tubes, vagina, or mammary glands; yet these structures may be present, though in a sufficiently undeveloped condition to render the proper performance of the functions severally peculiar to them a matter of doubt or of impracticability. Still, though this is true only of those in whom life is possible, the remaining organs characteristic of the female may be nearly perfect in their construction, and some, though rarely all, may correspond entirely with the normal type. The external genitals have been observed to be either normal or poorly developed, and in adults occasional absence of the pubic hair has been noted.

Etiology.—Defectus uteri is dependent either upon an entire absence or upon a complete destruction of the median portions of Müller's ducts.

Diagnosis.—The recognition of the abnormality under discussion is surrounded with the utmost difficulty, and it is never warrantable to assume positively in a given case, even after negative results have been obtained from careful abdomino-rectal palpation, assisted by a sound in the bladder, that no traces of a uterus exist; for even upon the post-mortem table errors have arisen, and the rudiments of a bilobed uterus have been mistaken for the Fallopian tubes, or a hollow rudimentary uterus for the vagina.

Treatment.—No treatment will, of course, be of any avail.

II. Rudimentary Uterus: Uterus Rudimentarius.—*Anatomy.*—Between defectus uteri and uterus rudimentarius there is often no very great hiatus in the scale of development, for the more decided forms of the latter malformation may be almost indistinguishable from complete absence of the womb. Thus the presence of a slight indefinable thickening on the posterior surface of the bladder, or at the junction of the imperfectly developed broad ligaments, or again, of a solid, fibrous mass, the size of a hazelnut, located at the point normally occupied by the womb, may be all that there is to indicate an attempt at uterine formation.

If development has proceeded a step farther, a solid, narrow, flat, laterally extended band composed of muscular tissue, with the tubes ascending and the round ligaments descending from it, may be encountered; or a fibrous mass without a neck, and solid, but still having the general conformation of the uterine body, has been observed, from the upper angles of which the round ligaments originate and extend downward into the inguinal canal.

In the uterus bipartitus, which exemplifies the next stage in progression toward the typical organ, two separate, round, solid, vertically placed bodies, composed of muscular and connective tissue, lie between the bladder and the rectum. Occasionally these two bodies unite toward their lower extremities, forming a mass not unlike the cervix in shape, which is in immediate relation below with a rudimentary vagina, while above they still remain independent, like two diverging horns, and are usually solid, but may present a slight hollow enlargement lined by mucous membrane at or near the point of origin of the round ligaments. To this latter abnormality the name uterus rudimentarius bicornis has been given, although some prefer the term uterus rudimentarius bipartitus.

With uterus rudimentarius, which is not confined to monstrosities, but occurs also in viable subjects, the external genitals, vagina, tubes, ovaries, and mammæ may exhibit the same variations in structure which have been alluded to in speaking of defectus uteri.

Etiology.—The cause which produces the rudimentary conditions just described operates during the very earliest stages of fœtal development, and as the exact time of its appearance and the degree of its activity vary, so a variation in results, though always within certain limits, will be observed.

In defectus uteri the elements from which the uterine body is to be formed are wanting or have been obliterated, but in the present instance they have appeared, but have been more or less destroyed, at divers periods of their development, by nutritive disturbances of differing intensities. It should not be forgotten, however, that there may be growth of even the lowest rudimentary forms.

Physiology and Symptoms.—Although in absence of the uterus and in atrophy of the organ the general conformation peculiar to the female and her desire for the opposite sex are preserved, yet there is such an imperfect development of other organs that the functions characteristic of woman do not come into play at all. The condition of the ovaries will determine the existence of ovulation. Menstrual molimina may, but menstruation cannot, occur, and vicarious hemorrhages are rare. Sexual intercourse is possible when the vagina is not too seriously involved, and even then the urethra may be utilized for this purpose. Conception is, of course, impossible.

Diagnosis.—It is not difficult to confound absence of the uterus with atrophy of the organ, when development has been arrested at a very early stage. Even on the most careful examination mistakes have been made by the most skilful among diagnosticians. In any doubtful case, to determine the presence or exact condition of the womb, the patient should be thoroughly anæsthetized, and the bladder and rectum should be empty. A sound or a silver catheter is introduced into the bladder, the finger of one hand is passed into the rectum, and the other hand is placed upon the abdomen; the entire length of the catheter or sound can now be felt between the hands if no uterus, or only an extremely rudimentary one, is present. Any solid mass lying in the median line between the rectum and the bladder is probably a rudimentary uterus. The tubes usually occupy a somewhat lateral position, but may be mistaken for uterine cornua. The ovaries, by their sharply defined boundaries, size, shape, mobility, and situation can be more or less easily recognized.

The more advanced forms of atrophic uterus are not difficult to map out, and, in any event, examination is often facilitated by palpation through the posterior bladder wall, if the urethra has been dilated by previous attempts at cohabitation.

Treatment.—If menstrual molimina occasion severe suffering, castration is a justifiable procedure. The rudimentary uterus has also been extirpated.

III. ABSENCE OR ATROPHY OF THE CERVIX UTERI: DEFECTUS CERVICIS UTERI ET CERVIX UTERI RUDIMENTARIA.—*Anatomy.*—Numerous grades of this deformity may be encountered. The entire cervix is absent, or a solid fibrous mass or band replaces the normal structure. When its formation is more perfect the internal os is alone closed, or the external os may be thus affected, or both may be occluded, while the cervical canal between is partially or entirely patent. Atresia of the external os only, marks the slightest degree of this maldevelopment. The uterus above may be perfect in structure or rudimentary. The vagina is normally developed, though occasionally the upper part of the canal may participate in the cervical atresia.

Since obstruction is the essential accompaniment of absence or atrophy of the cervix, hæmatometra is the natural pathological sequence when menstruation occurs.

Etiology.—In the more pronounced types of the deformity under discussion, and especially if other portions of the genital canal participate in the existing maldevelopment, it is probable that there has been at best only an abortive attempt at cervical formation. But when the uterus, vagina, etc., are normal in structure and the cervix presents no very aggravated form of atresia, we must regard as the important etiological factor some nutritive disturbance originating late in embryonal life, after differentiation of the genital canal has been effected by the appearance of the cervix.

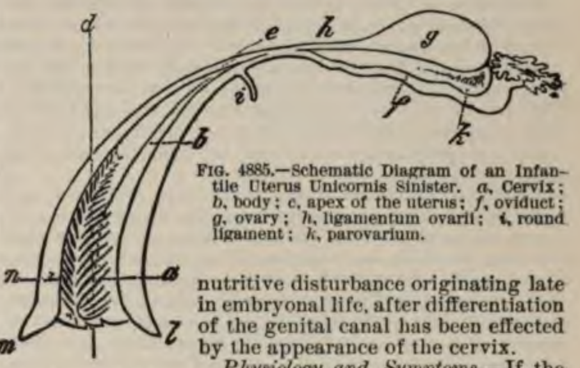

FIG. 4885.—Schematic Diagram of an Infantile Uterus Unicornis Sinister. *a*, Cervix; *b*, body; *c*, apex of the uterus; *f*, oviduct; *g*, ovary; *h*, ligamentum ovarii; *i*, round ligament; *k*, parovarium.

Physiology and Symptoms.—If the ovaries and uterus are not arrested in development, menstruation will occur when puberty has been reached and hæmatometra appears, accompanied at first with menstrual molimina, and later by almost continuous pain, by pressure symptoms, and by threatened rupture of the Fallopian tubes. If the uterus and ovaries are rudimentary, there will be no menstruation, and therefore no blood stasis. Sterility is an invariable accompaniment of any form of cervical atresia.

Diagnosis.—Careful combined manipulation, performed as described in speaking of atrophy of the uterus, will reveal an absence or marked rudimentary condition of the cervix, while the failure to pass a sound or probe, or to find an opening in a neck apparently of normal structure, will at once denote the existence of one of the less marked forms of cervical atresia.

If hæmatometra exists, fluctuation can be detected through the rectum, and perhaps through the obstructing membrane, if it be not excessively thick and resistant, as is likely to be the case when the upper part of the vagina is involved in the atresia.

IV. THE ONE-HORNED UTERUS: UTERUS UNICORNIS: UTERUS UNICORNIS SINE ULLO RUDIMENTO CORNU ALTERIUS.—*Anatomy.*—When the uterus is one-horned the cervical is larger than the corporeal portion, and the latter consists of a long, tapering, arched, or bow-shaped cone, situated laterally or lying obliquely in the pelvis, from the apex of which spring a Fallopian tube, a round ligament, and an ovarian ligament supporting an ovary.

In the purest form of this anomaly no trace of the other horn, or of the tube, round ligament, ovarian ligament, ovary, or broad ligament of the corresponding side is to be found.

Occasionally the one-horned uterus is solid.

Although uterus unicornis may be the only rudimentary condition discoverable in a given case, yet the vagina is often narrow, and in the more pronounced types of this anomaly one-half of the whole genito-urinary apparatus is occasionally found to have suffered in its development.

Etiology.—In uterus unicornis without a rudimentary second horn, it is probable that only one Müllerian duct has ever been formed.

Physiology and Symptoms.—Although the one-horned uterus differs in shape, size, and position from the normal uterus, yet when hollow it possesses such anatomical essentials as enable it to perform all the functions which pertain to that organ. Menstruation, conception, and pregnancy occur without hindrance, and even twins have been delivered from a one-horned womb. On account of somewhat deficient muscular development, it might be surmised that rupture of the uterus would be readily induced during the throes of labor. Such is not usually the case, although, if the muscular structure of the organ be weakened and displaced by the growth of placental vessels, such an accident during parturition is not improbable.

The muscular hypertrophy accompanying the first pregnancy assists the uterus unicornis in the part it has to play in those occurring subsequently.

Diagnosis.—Uterus unicornis is easily recognized on careful examination, a sound being introduced into the uterus and one examining finger into the rectum. Even when impregnated its shape and oblique position may be preserved; but the normal organ is not uncommonly deflected to the side at this period, and the one-horned uterus may be so broadened by the physiological hypertrophy of pregnancy as to lead to some confusion in diagnosis.

Treatment.—It is not unlikely that appropriate treatment will produce an enlargement and strengthening of the muscular structure of the one-horned uterus, and this is a very desirable end to be achieved when we consider the possible danger of rupture during parturition. When rupture at this period is threatened, labor should be expedited by artificial means, if necessary, and at the same time the risk of post-partum hemorrhage should be held in mind and proper contraction of the organ secured.

V. THE ONE-HORNED UTERUS WITH ATROPHIED SECOND HORN: UTERUS UNICORNIS CUM CORNU RUDIMENTARIO; UTERUS UNICORNIS EXCAVATUS CUM RUDIMENTO CORNU ALTERIUS SOLIDO S. EXCAVATO.—*Anatomy.*—On the convex side of an obliquely inclined uterus unicornis there may be found a rudimentary second horn, which exhibits in different cases various degrees of imperfect development. A solid muscular cord, or band, unconnected with the ovary above or the other horn below, is sometimes observed, but occasionally this is expanded at the upper extremity, is hollow, and communicates with the tube alone, or with the better developed cornu below, or with both, although it may be closed at each extremity.

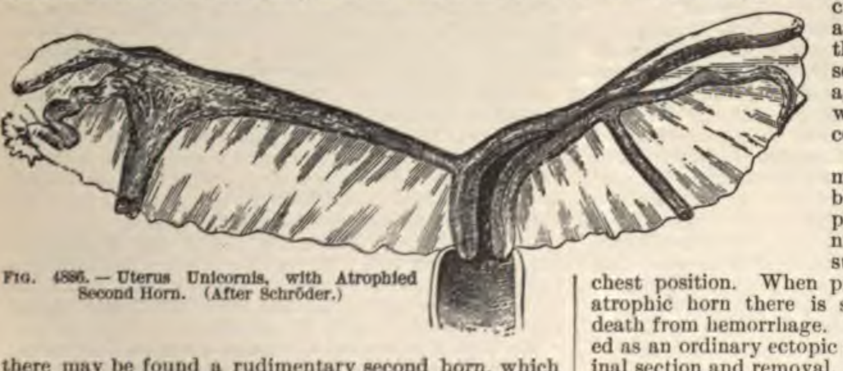

FIG. 4896. — Uterus Unicornis, with Atrophied Second Horn. (After Schröder.)

Etiology.—In this condition both Müllerian ducts have appeared, but one has been more affected in its development than the other by causes, of a nature already described, operating early in embryonal existence.

Physiology and Symptoms.—The functions which a rudimentary cornu attached to a one-horned uterus is capable of performing depend, of course, upon the degree of its development. If it is hollow and its inferior extremity is patent, menstruation may occur, though not so early nor in so great quantity as from the more perfect horn. But if there is no opening below, a slowly developing hæmatometra will result, and perhaps a hæmatosalpinx as well.

When pregnancy occurs, it is usually in the more typically formed cornu, and utero-gestation is quite normal, and parturition also, except when, as sometimes happens, the rudimentary horn offers a mechanical obstacle to its accomplishment.

It is quite possible, however, for the product of conception to be implanted in the rudimentary horn, especially if a communication exists between it and the vagina through the normal cornu. When there is no such communication, a like result may be accomplished by the processes known respectively as transmigratio ovuli externa and transmigratio seminis externa.

When pregnancy does take place in the atrophic horn, this enlarges up to a certain point and then ruptures, as a rule between the second and fifth months of utero-gestation, death usually ensuing, although encapsulation of the fœtus may occur and recovery take place. Still, pregnancy may go on to full term without interruption.

The normal horn participates to a certain extent in the changes incident to pregnancy, and a decidual membrane forms within its cavity.

Diagnosis.—The existence of a conical arched body, with a mass more or less like itself springing from its convex surface, will convince the examiner that he has to do with a one-horned uterus with a rudimentary second horn, although a pedunculated subperitoneal fibroid may closely resemble the atrophic cornu and be mistaken for it.

When pregnancy occurs in the poorly developed horn the symptoms will all be those of extra-uterine fœtation, and as the round ligament cannot be mapped out with any certainty, it will remain a matter of doubt whether the ovum has been implanted in the Fallopian tube or in the rudimentary horn.

Treatment.—In this condition active interference is indicated only when there has been considerable blood stasis in the rudimentary horn and rupture or other dangers threaten, or when the horn offers a mechanical impediment to delivery, or is itself the seat of pregnancy. Accumulated blood may be evacuated by trocar puncture through the vaginal vault, although in some cases laparotomy and drainage, or entire removal of the sac, will be the more judicious procedure.

The rudimentary cornu, which makes labor tedious or impossible, may be elevated above the parturient canal by vaginal manipulation combined with the assumption of the Sims or knee-chest position. When pregnancy occurs in a markedly atrophic horn there is serious danger of rupture and death from hemorrhage. The condition should be treated as an ordinary ectopic gestation should be, by abdominal section and removal.

VI. THE TWO-HORNED UTERUS: UTERUS BICORNIS.—*Anatomy.*—Next above the uterus unicornis with a rudimentary subsidiary cornu, is placed, in the scale of development, the uterus bicornis. Various degrees of this latter rudimentary condition are described. In the lowest and most imperfect forms there are two separate and distinct hollow uterine bodies, projecting laterally like horns, which unite below in a common cervix, deeply furrowed before and behind. Again, the union is more complete and a sulcus is found only on the external aspect of the fundus, indicating the point of coalescence of the two cornua, while the rest of the body and the cervix, though unusually broad, show no furrowing of their outer surfaces. This condition has been variously termed uterus arcuatus, uterus introrsum arcuatus, and saddle-shaped uterus. When the fundus shows no furrow, but is flat—the next step in advance—the designations uterus triangularis, uterus incudiformis, and uterus planifundalis have been employed. In all forms of the two-horned uterus one side of the organ is apt to be larger than the other, and the left horn—that is, the normally developed organ—lies a little farther forward than the right. A partition wall more or less complete may divide the cavity of the uterus bicornis. The entire womb may be thus separated into two parts (uterus bicornis septus), or the body is divided while the horns remain distinct (uterus bicornis unicorporeus), or the body is double and the cervix single (uterus bicornis unicollis). Still, in many cases no pronounced partition is discoverable, though bands of tissue may run from the anterior to the posterior uterine wall, or a prominent ridge on the interior of the uterus may show an attempt at division. With uterus bicornis, although the vagina is often found divided, the remaining elements of the genital system are usually perfect in development. Sometimes, very curious to say, the face, thorax, and pelvis are broadened, as if to correspond with the unnatural width of the uterus. When one-half of a two-horned uterus is conspicuously behind its fellow in development, it is not unusually occluded: this is more frequent on the right than on the left side, and the atresia may be seated in the cervix or at the external os uteri.

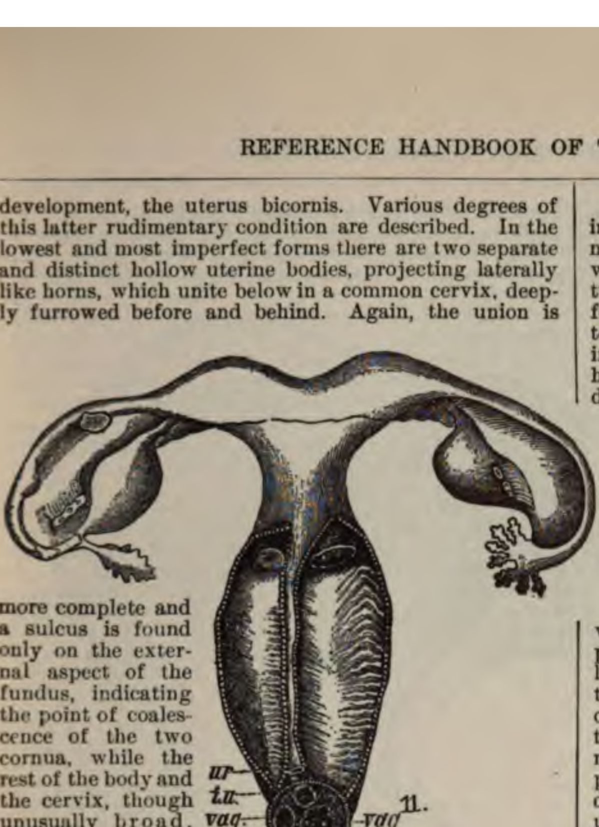

FIG. 4887.—Uterus Bicornis. (After Hunkemöller.) *ur*, Urethra; *i.u*, entrance to the urethra; *vag* and *vag*[11], entrances to vagina. The anterior wall of both vaginæ has been removed.

Etiology.—When coalescence of the middle portions of the Müllerian ducts is only partial, uterus bicornis will result, and the degree of deformity will depend upon the extent of fusion. The recto-vesical ligament undoubtedly plays an important part in the genesis of this rudimentary condition. This ligament, as its name implies, stretches from the anterior surface of the rectum to the posterior surface of the bladder, and lies in the furrow on the fundus uteri. Its origin is somewhat doubtful. Winckel suggests, from a study of a case of his own, that its formation is due to an unfolding of the peritoneum before the upward-growing uterus. He examined the tissues of the ligament microscopically, but could find no muscular fibres.

Physiology and Symptoms.—The uterus bicornis may, in the performance of the functions pertaining to the normal womb, act like two independent organs. Thus, while menstruation may occur simultaneously from the two cornua, it is not unusual to see them alternately performing this function, and a periodical flow may continue to escape from one cavity after pregnancy has occurred in its fellow. If one side is occluded (bilateral atresia has never been observed), hydrometra or hæmatometra develops slowly, and here, as also with pyometra, rupture of the sac may take place and its contents be discharged into the vagina, into the better developed cornu, or into the abdominal cavity. Hæmatosalpinx is a frequent and early source of danger.

A considerable number of patients with two-horned uterus never conceive, but this is not due to the condition of the uterus, but rather to the fact that intercourse is carried on in the larger and occluded half of the accompanying divided vagina. Either half of a two-horned uterus may become gravid, the other horn participating in the subsequent hypertrophic and decidual changes. The fœtus may lie largely in one cornu while the placenta is adherent to the inner surface of the other. Sometimes pregnancy occurs first in one and then in the other horn, and in twin pregnancies, which are not uncommon, both ova may occupy the same or each a different cornu. The presentation varies largely with the grade of the rudimentary condition: in uterus bicornis septus and uterus bicornis unicollis, the vertex; with a common uterine cavity, the breech; in uterus arcuatus unicorporeus, transverse presentations are common. During labor, contractions may occur simultaneously in both horns of the uterus, or the empty horn may play an entirely passive part in the process of delivery. In twin births contractions of the two horns alternate, and delivery from one may be accomplished much earlier than from the other. Independence of action between the two cornua is observed most characteristically when independence of structure is most marked.

The course of utero-gestation and of the puerperium in individuals with uterus bicornis is usually uneventful, but labor is apt to be tedious, difficult, or dangerous. The non-gravid horn, the recto-vesical ligament, or the septum dividing uterus or vagina, may oppose barriers to the exit of the child which are difficult to surmount. Death from exhaustion is apt to ensue, and rupture of the lower uterine segment has been observed. In nearly every case some operative interference is called for to insure safe and rapid delivery. Placenta prævia is by no means uncommon, and post-partum hemorrhage is to be feared when the placenta is attached to the uterine septum.

Diagnosis.—When, from great breadth of the uterus or the presence of a divided vagina, uterus bicornis is suspected, a correct diagnosis is often arrived at by the introduction of two sounds into the womb. When their points cannot be approximated low down in the uterine cavity a partition is usually present, and if after further introduction they diverge markedly toward the respective sides of the pelvis, they have probably entered the independent cornua of a two-horned uterus. Diagnosis is facilitated also by the various combined methods of examination, and is especially easy when, after labor, the finger can be introduced through the dilated cervical canal.

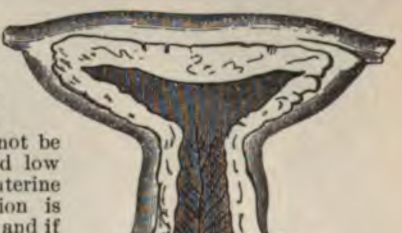

FIG. 4888.—Anvil-shaped Uterus. (After Oldham.)

Treatment.—The same rules governing the operation for the evacuation of fluid retained in the rudimentary cornu attached to a one-horned uterus, apply when a like result has followed unilateral atresia of a two-horned uterus, and the same complications originating in imperfect drainage and rupture of a tubal blood sac are to be feared. Puncture of the sac is best made at its most dependent part. Müller observes that when the head during delivery is impeded by the recto-vesical ligament, the correction of the obliquity of the pregnant horn, or placing the patient on the side corresponding to the non-pregnant half of the womb may suffice; but if not, podalic version and extraction should be attempted. Obstructing septa or bands may be pushed to one side or divided.

VII. THE TWO-CHAMBERED UTERUS: UTERUS BILOCULARIS; UTERUS SEPTUS, SUBSEPTUS, OR UTERUS SEPTUS DUPLEX. —*Anatomy.*—The two-chambered uterus is an organ rather broader than normal, but of perfect outward form except that there is usually some disparity in size between the two sides. A partition more or less perfect divides its cavity into two lateral portions. If this dividing wall extends from the fundus downward only for a short distance into the body of the womb, we have the sub-variety of uterus bilocularis known as uterus bilocularis unicorporeus or uterus subseptus unicorporeus; if to the level of the internal os, the designation uterus bilocularis unicollis, or uterus subseptus unicollis is employed; if to the external os, uterus bilocularis septus sive completus; when the partition extends only so far into the cervical canal that there is but one external opening (os) common to both chambers, the condition is termed uterus subseptus uniforis. The name uterus biforis supra simplex indicates that a septum is situated only in the neighborhood of the external os and that the cavity above is single. Occasionally the uterine partition is continuous with a septum dividing the vagina into two lateral chambers. As in other varieties of duplex uterus, the dividing wall is not always perfect in its structure, but may contain one or more perforations. Atresia of one chamber has been observed but rarely.

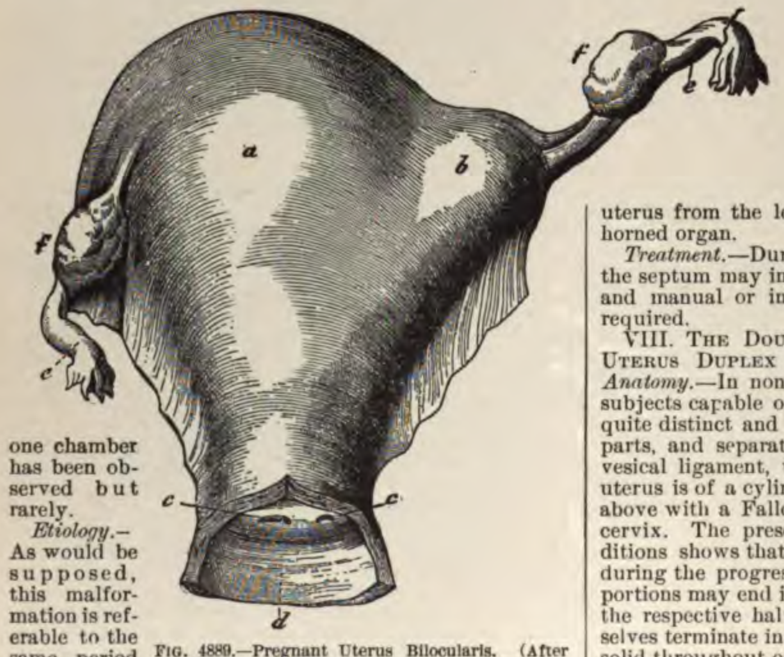

FIG. 4889.—Pregnant Uterus Bilocularis. (After Cruveilhier.) *a*, Right horn; *b*, left horn; *c*, external os; *d*, vagina; *e*, tubes; *f*, ovaries.

Etiology.—As would be supposed, this malformation is referable to the same period of intra-uterine life as uterus bicornis, or perhaps, better, to a slightly later time in the same period. The causes of the two anomalies are the same. The fusion of the Müllerian ducts has been complete, but the partition wall has only partially disappeared, or else persists throughout.

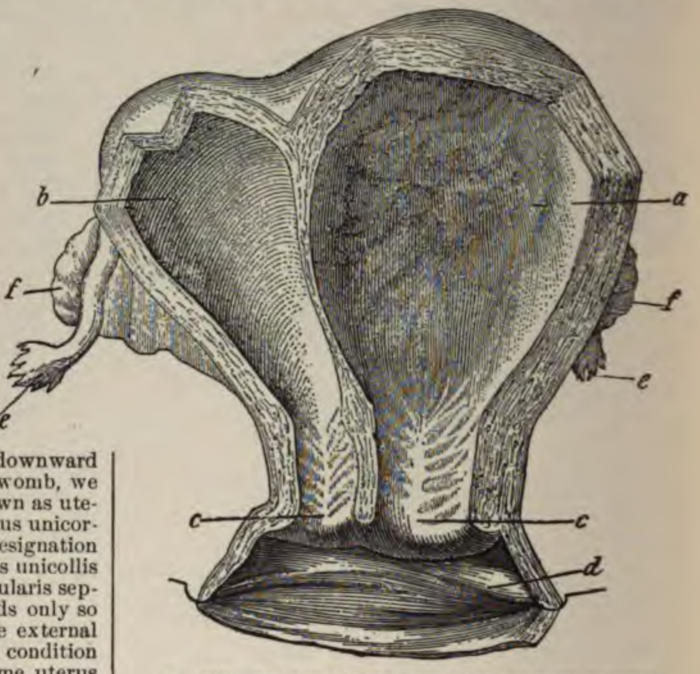

FIG. 4890.—The Same, Front View. Anterior walls removed.

Physiology and Symptoms.—The two-chambered uterus, in so far as menstruation, conception, pregnancy, and delivery are concerned, in no way differs from the two-horned uterus.

Diagnosis.—On bimanual examination the uterus is found to consist of a single, somewhat broadened body, while two sounds introduced into its interior are prevented from touching by the dividing wall. With all the facilities at our command it is safe to say that, in the living subject, it is not possible to differentiate the two-chambered uterus from the least rudimentary forms of the two-horned organ.

Treatment.—During labor, as in the uterus bicornis, the septum may interfere with the process of expulsion, and manual or instrumental assistance is occasionally required.

VIII. THE DOUBLE UTERUS: UTERUS DIDELPHYS: UTERUS DUPLEX SEPARATUS: UTERUS DIDUCTUS.—*Anatomy.*—In non-viable monsters, and occasionally in subjects capable of life, two uteri are sometimes found quite distinct and independent of each other in all their parts, and separated, sometimes widely, by the recto-vesical ligament, urachus, bladder, and rectum. Each uterus is of a cylindrical or conical shape, is continuous above with a Fallopian tube, and terminates below in a cervix. The presence of other grave anomalous conditions shows that quite a severe blow has been struck during the progress of development. Thus the cervical portions may end in the bladder, rectum, or cloaca, or in the respective halves of a septate vagina, which themselves terminate in these cavities. The uteri also may be solid throughout or a limited atresia of either organ may be present.

Etiology.—Before the eighth week of embryonal life, when as yet there has been no approximation or fusion of the Müllerian ducts, certain of the abdominal or pelvic organs, among which are the bladder and intestine, force their way between the ducts and prevent their union. The recto-vesical ligament is also, no doubt, an important etiological factor. As a result of this interposition the formation of a single uterine body is rendered impossible.

Physiology and Symptoms.—In double uterus the menstrual discharge does not seem to alternate between the two cavities. Either may be occluded, and either organ or both simultaneously may become gravid.

Diagnosis.—In the recognition of the rudimentary condition under discussion, it has been truly said that the presence of two vaginal portions are of the utmost diagnostic value; for since the tubes which coalesce to form the middle portion of the genital tract unite from below upward, two cervices predicate two independent uterine bodies. If a sound is introduced into each uterine cavity, a finger inserted in the rectum can be pressed forward in a straight line without coming in contact with either uterus.

Treatment.—Retained menstrual blood is to be evacuated, and any obstacle offered to delivery is to be overcome by methods which have already been described.

IX. Faulty or Deficient Development of the Uterus: Hypoplasia Uteri.—*Anatomy.*—Under this head are grouped a large number of associated conditions, in all of which the uterus is fairly well developed, but has not quite reached the type of structure usually found in adults. Thus it may retain in later life the characteristics of the organ as found at the time of birth (uterus fœtalis), when the cervix is large and the body small, the whole possessing the shape of an anvil, while often an extreme degree of cervico-corporeal anteflexion exists. Again, it may be developed yet a little further, and though still unnaturally small, with thin walls, the body and cervix are of equal size, or the former is somewhat larger than the latter (uterus pubescens; congenital atrophy or hypoplasia of the uterus). The walls are occasionally excessively thin and membranous (uterus membranaceus). The body and cervix may exhibit the same relative proportion to each other as in the perfectly developed uterus, but the whole organ perhaps is still deficient in size and possesses walls of abnormal thinness, while the plicæ palmatæ pass well up into the cavity of the corpus (uterus infantilis). All these forms are closely allied with one another, and with the least pronounced types of congenital malformation on the one hand and the normal adult uterus on the other. The term hypoplasia uteri may be used to include them all. As a rule, some of the remaining elements of the genital system show slight errors in development, and the ovaries are not infrequently rudimentary, or are sometimes entirely absent. The heart and the rest of the vascular apparatus may likewise be undeveloped.

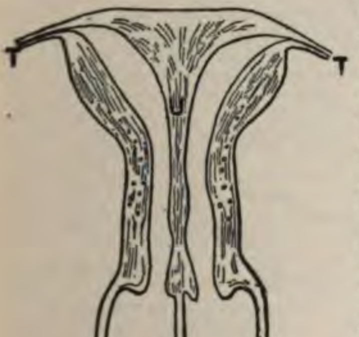

FIG. 4891.—Bilocular Uterus and Vaginal Septum: Vertical Section. (Kussman.) *U*, Partition which divides the uterus into two halves; *T*, tubes; *V*, vagina divided by the uterine septum prolonged.

Etiology.—Hypoplasia uteri cannot with justice be called a purely congenital condition. It is true that during the final months of embryonal life injurious influences, such as constricting peritoneal adhesions, may prevent a uterus almost completely formed from attaining anatomical perfection. But unhealthy systemic states (associated with disease of the vascular or nervous system) during infancy or childhood, and lack of ovarian stimulation when these glands are absent or rudimentary, may bring about a like result.

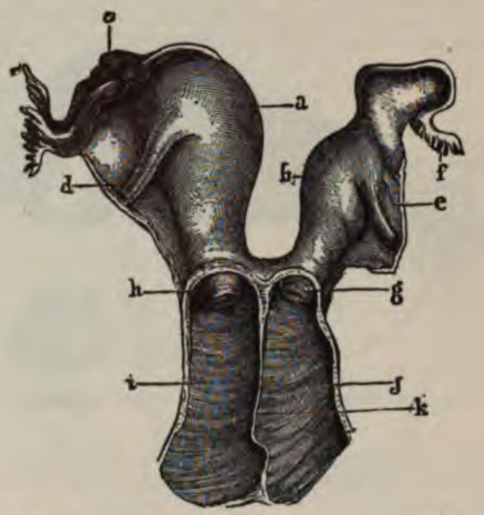

FIG. 4892.—Didelphic Uterus and Divided Vagina. (Olivier.) *a*, Right segment; *b*, left segment; *c*, *d*, right ovary and round ligament; *f*, *e*, left ovary and round ligament; *g*, *j*, left cervix and vagina; *k*, vaginal septum; *h*, *i*, right cervix and vagina.

Physiology and Symptoms.—It is the condition of the ovaries rather than that of the uterus which determines largely the nature and degree of the disturbances which accompany hypoplasia uteri. Menstruation may not appear at all, or may be scanty, irregular, and painful; and pregnancy, when it takes place, is not unlikely to end in abortion.

Diagnosis.—If, upon examination, the uterus is found to be less than two inches in length; if the cervix is larger than the body; and if the uterine walls are thin and membranous, even with a cavity which measures a little over two inches, the condition is one of hypoplasia; though we should be careful to exclude uterus unicornis before expressing a final opinion.

Prognosis.—In many cases a hypoplastic uterus will of itself, or in consequence of appropriate treatment, or of pregnancy, take on further growth, and ultimately attain normal proportions.

Treatment.—When the general condition is good; when the ovaries are present and are not excessively atrophic, and when the uterus is not too small, much can be done for the relief of amenorrhœa, or dysmenorrhœa with scanty menstruation, by the employment of the well-known local uterine irritants, and if these fail and suffering is excessive, castration in suitable cases should be resorted to.

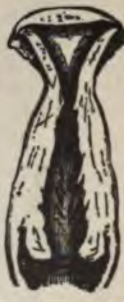

FIG. 4893.—Infantile Uterus. (Schröder.)

X. Slighter Developmental Anomalies of the Uterus.—1. *Obliquity of the Uterus; Obliquitas Uteri quoad Formam.*—From deficient development of one Müllerian duct, and from the traction exerted by a broad ligament shortened by fœtal inflammation, one side of the uterus may be somewhat smaller than the other, and the organ is thus made to occupy an oblique position in the pelvis (Fig. 4894).

Dysmenorrhœa and sterility usually accompany this condition.

2. *Congenital Ante-, Retro-, and Lateropositions of the Uterus.*—The uterus, although normally formed, may be situated too near the anterior, posterior, or lateral wall of the pelvis. If displaced laterally, it is usually toward the left side. Contraction of one or the other broad ligament, and unusual size of neighboring organs, may bring about this result.

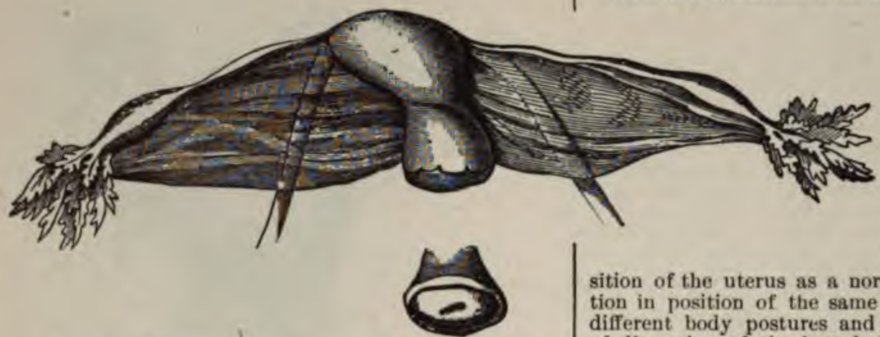

FIG. 4894.—Obliquity of the Uterus. (After Tiedemann.)

3. *The Double-mouthed Uterus: Uterus Biforis.*—An antero-posterior partition may divide the external os into two lateral halves, the cervix and uterus being otherwise normal in every particular. As in other forms of septate uterus, of which this represents the least pronounced type, the dividing band may offer an obstacle to the passage of the presenting fœtal extremity, and may, when ruptured, either cause considerable hemorrhage or form a starting-point for septic infection. If the septum during labor cannot be pushed aside, it can with safety be ligated in two portions and divided.

4. *Abnormal Plication of the Cervical Cavity.*—In this condition a fold of tissue, not unlike a second portio vaginalis, projects into the cervical canal, causing hemorrhages occasionally, and leading also to tedious labor. Incision or ablation is sometimes indicated.

5. *Abnormal Communications with the Uterus.*—The uterus may either open into the cloaca, or have faulty communications with different portions of the urinary system, or with the rectum. A case is on record in which one side of a uterus bipartitus opened upon the external surface of the body.

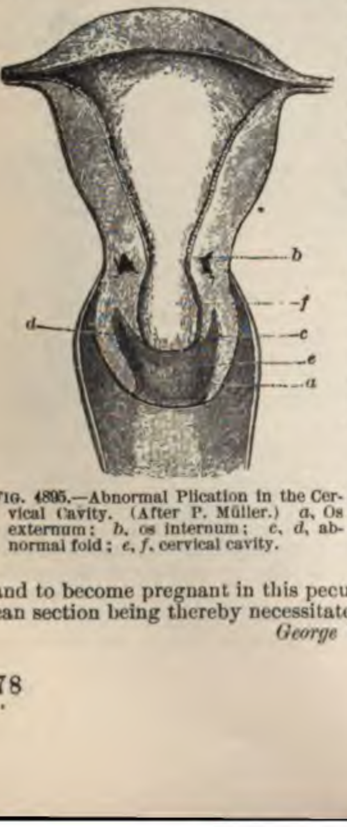

FIG. 4895.—Abnormal Plication in the Cervical Cavity. (After P. Müller.) *a*, Os externum; *b*, os internum; *c*, *d*, abnormal fold; *e*, *f*, cervical cavity.

6. *Premature Uterine Development.*—Along with the breasts and the organs peculiar to the female, the uterus is occasionally found precociously developed, and menstruation occurs prematurely.

7. *Hernia Uteri.*—The uterus, along with a prolapsed ovary, has been known to descend into a congenital inguinal hernial sac, and to become pregnant in this peculiar situation, Cæsarean section being thereby necessitated.

George Woodruff Johnston.

UTERUS, DISEASES OF: DISPLACEMENTS.

—A displacement of the uterus may be defined as a permanent departure from a normal position, and is therefore to be sharply distinguished from a temporary normal deviation. One reason for the slowness of investigators in the past to agree upon any position of the uterus as a normal one has been the variation in position of the same uterus when examined in different body postures and under different conditions of distention of the bowels by gas or fæces, or of the bladder by urine. In the perfectly normal pelvis the range of mobility is great, the condition being one of delicate poise maintained by the resultant of various forces, while the supporting structures are elastic, and some of them (round ligaments) are contractile.

Several structures more or less yielding and elastic serve to maintain the uterus in position. The upper portions of the broad ligaments at the sides and the round ligaments forward and laterally serve chiefly as stays or guys. Connective tissue in the lower portions of the broad ligaments, together with the so-called utero-sacral ligaments and bladder attachments in front, serves as a kind of sling attached low down on the organ, and gives support to its weight. The most important supporting structures are the muscles and fascia of the pelvic floor, chiefly the levator ani and coccygeus muscles, and the internal pelvic fascia with the perineal fascia (Fig. 4896). Another supporting influence may be likened to hydrostatic pressure. When the pelvic floor is intact, the tonicity of its muscles and of those of the abdominal wall serves to some extent to float, as it were, all movable bodies in the abdomen. This support is greatly reduced when the abdominal parietes have lost their normal tone. The uterus moves with the whole pelvic diaphragm in the acts of vomiting, violent coughing, or straining in defecation. As it is attached to the bladder by a comparatively broad surface, the constantly varying distention of that organ swings the upper part of the uterus forward and backward. A range of normal mobility of several inches can be demonstrated without instrumental traction by contrasting the position of the cervix when the patient is in the standing position, with its position in the knee-chest posture after air distends the vagina. Under anæsthesia the cervix may with a tenaculum be drawn to the vaginal outlet without injury.

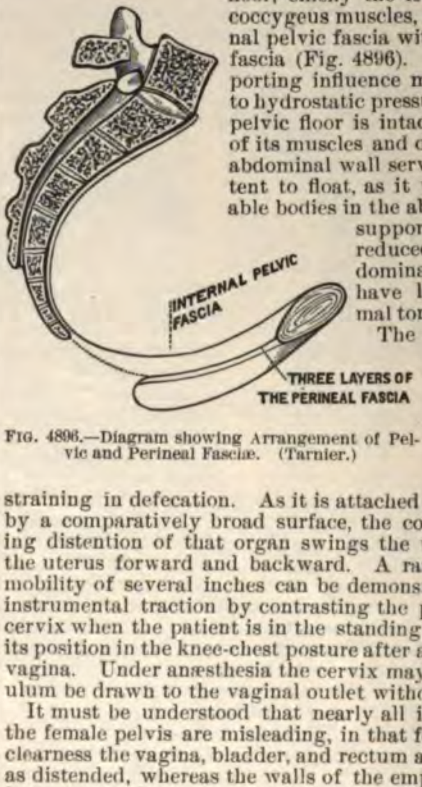

FIG. 4896.—Diagram showing Arrangement of Pelvic and Perineal Fasciæ. (Tarnier.)

It must be understood that nearly all illustrations of the female pelvis are misleading, in that for the sake of clearness the vagina, bladder, and rectum are represented as distended, whereas the walls of the empty organs are in contact and occupy very little space.

The normal uterus is poised in the pelvis, the organs being empty, the cervical portion almost central and as high as the top of the symphysis pubis, the fundus inclined forward almost horizontally and at times a little to the right or left to accommodate the rectum. The fundus is readily felt by the examining hand near the pubic bone, behind and below a line joining the promontory of the sacrum with the top of the symphysis (Fig. 4897).

Causes of Displacement.—Congenital defects of development result in some changes of position, chiefly backward deviation of the axis or a curving of the axis of the organ forward upon itself. These congenital alterations are usually accompanied by an imperfect development of ovaries and tubes, as well as of the uterus, though the external genitalia may be normal. The accompanying dysmenorrhœa and sterility are usually difficult to overcome.

Acquired displacements may be due to sudden strains, especially downward strains, to the slow action of tumor pressure, of gravity, of intra-abdominal pressure, or of contraction of inflammatory adhesions, while among contributing causes are laceration of the pelvic floor, subinvolution after labor, hyperplasia, œdema, passive congestion, general loss of muscular tone, faulty dress, constipation, infrequent emptying of bowel and bladder.

Sudden or acute displacements are usually backward and downward. They occur in persons who have sustained laceration or overdistention of the pelvic floor, though a few cases have been reported in which the cervix has appeared through the vulva in the virgin as the result of strain, and it is not very uncommon to have the fundus forced backward into acute retroversion in the unmarried. The history of the case usually shows that strain had been applied while the person was in an extreme stooping posture, as in lifting a heavy weight from the floor, or it may result from a fall upon the nates. One of the writer's patients, when a girl of fifteen years, previously perfectly well and totally unconscious of her anatomy, while lifting the corner of a heavy cook stove and trying to put a block under it, felt something "give way." Great pain in the lower pelvis and back followed, confining her to bed for a few days. There was soreness in walking, lasting months. The uterus remained in retroversion, and was an element in a disability which had continued for years until completely relieved by operation. Another patient, with a rather fat abdomen and an impaired pelvic floor, suffered acute retroversion while stooping and lifting the tray of a trunk. There were acute pain in the pelvis and back, frequent urination, and pain down the thighs. The uterus was caught below the promontory of the sacrum. Immediate relief followed the reduction of the displacement. In the extreme flexion of the thighs or the abdomen, not only is the muscular support of the perineum relaxed, but considerable pressure is made by the thighs upon the abdomen. The relief obtained in the squatting position, naturally assumed by some persons in extreme cases of difficult defecation, illustrates the mechanical principles involved. The uterus when suddenly forced down and back is most likely to be caught below the sacral promontory when the organ is somewhat enlarged by an early pregnancy or when the promontory projects well forward.

Laceration of the pelvic floor and imperfect involution after labor are the two chief elements in the production of *gradually acquired* displacements. The lacerations which occur during labor are not to be regarded as involving only the perineal body and the outlet of the vagina. A very complicated series of changes has taken place in the whole pelvic diaphragm. Planes of fascia are torn, and they slide one upon the other. Their attachments are pulled away, especially from the central areas. Great muscle planes are relaxed and torn apart, so that the levator ani, the coccygeus, and co-ordinating structures act less perfectly as a sling for the support of the pelvic viscera. If the upright position is resumed too early after confinement, and if the patient takes too little rest, not only the uterus but all the pelvic tissues fail to regain their normal tone. The uterus remains soft, large, and flaccid, and under the mechanical influence of gravity and imperfect support an exceedingly complicated change of relation of parts follows, infinitely varied according to the integrity of the holding power of untorn parts; but the uterus tends slowly to descend, tilting backward as an early step; the vaginal walls, becoming lax and redundant, are protruded before the descending bladder and rectum, until in extreme cases a true hernia of pelvic contents and even small intestine takes place through the pelvic outlet.

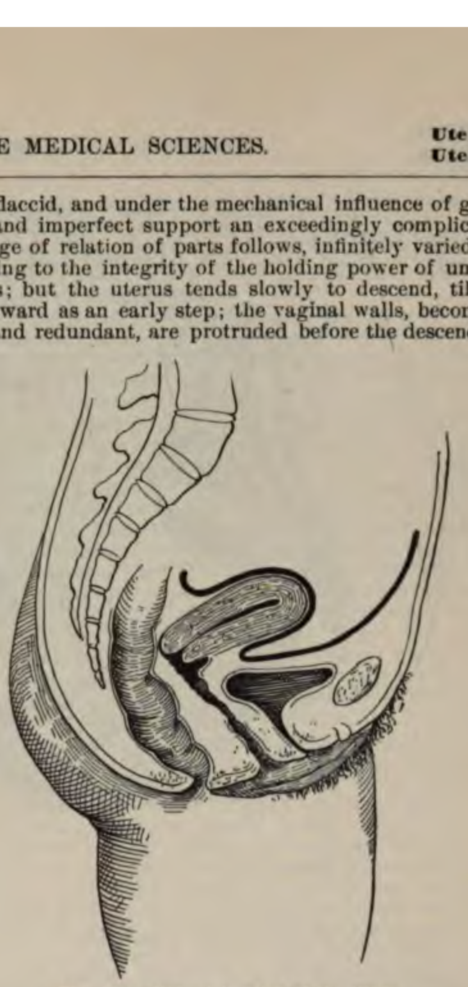

Fig. 4897.—Normal Position of the Uterus.

The *contraction of adhesions* which result from inflammatory disease in the abdomen, is responsible for some well-marked uterine displacements, especially those in a backward and those in a lateral direction. When, for example, a collection of pus, two or three inches in diameter, forms behind the uterus and broad ligaments, a heavy wall of plastic exudate unites the uterus and upper edges of the broad ligaments to the large intestine behind or to both large and small intestines, the omentum still further covering in the mass. Should this pus escape into the bowel or bladder or by the slow process of absorption disappear, the limiting wall of adhesions, following the shrinkage, slowly contracts around the remains of the mass. This contraction will in some cases fix the uterus and tubes, pulling the former slowly back over the disappearing pus sac. The influence of other causes which have been mentioned is obvious without detailed description.

Varieties.—The varieties to be described are: Upward, lateral, forward, backward, and downward; the organ may also occupy various hernial sacs, or may be completely turned inside out, the so-called inversion.

Upward displacement of the uterus is seen only as the result of the growth of tumors. A dermoid cyst of the ovary for example, or a nodule of a fibroma of the uterus, may become adherent in the pelvis behind the uterus, and by its growth push that organ out of the pelvic cavity entirely. Uterine fibromas which completely surround the uterus, grow too large for the pelvic cavity, and drag the uterus and bladder upward, stretching the vagina, so that on examination the os uteri is found to be completely beyond the reach of the finger. The treatment is determined by ordinary surgical principles in the removal of the growths, should that be called for.

Lateral displacement may follow contraction of plastic exudate or adhesions about an obliterated pelvic abscess.

especially in the broad ligament or peri-uterine connective tissue. The writer has seen the uterine cornu attached hard and fast to the bony pelvis at the side from such a cause. The abscess had been drained above Poupart's ligament several years before. Broad-ligament cysts and intraligamentary uterine fibromata crowd the uterus to one side. No symptoms are directly caused by these forms of displacement.

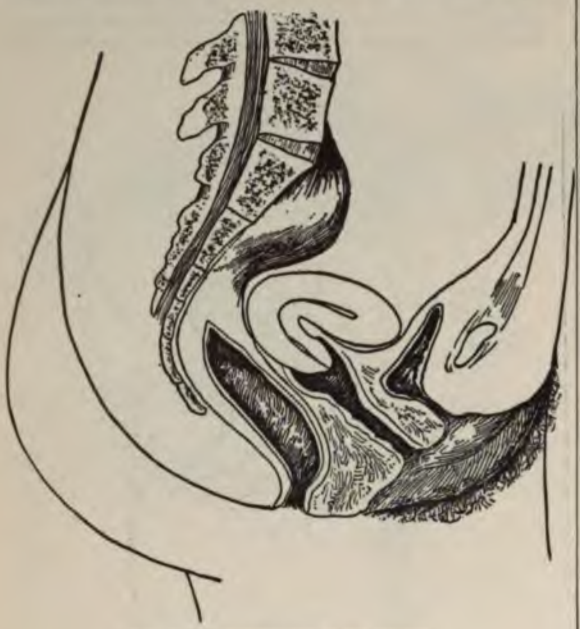

FIG. 4898.—Anteflexion of the Uterus.

Displacement Forward; Anteversion. — Twenty-five years ago the inclination of the axis of the uterus well forward (anteversion) was considered to be pathological by many gynecologists, and much ingenuity was expended upon the mechanical correction of the supposed resulting disabilities, including sterility, frequent urination, and dysmenorrhœa, by pessaries or by operations on the cervix or vagina. As the result of further observation opinion has changed, so that treatment is now no longer directed to this condition, and the object of the numerous operations is to induce the uterus to stay forward in what is now considered the normal position.

Anteflexion, however, when of extreme degree is recognized as pathological. This involves a bending or curving forward of the uterine axis. It is frequently found in an infantile or undeveloped uterus, associated with scanty, painful menstruation and sterility in persons of neurotic tendencies (Fig. 4898). Much discussion has arisen as to the rôle played by the flexion in the production of pains and sterility. It is claimed with truth that there is no real obstacle presented to the passage of menstrual blood or of spermatozoa unless the uterine canal is sharply bent at an angle. A gradual curve, no matter how short its radius, does not affect the lumen of the uterine canal. Above a sharp angle, however, clots may form, and as they enlarge they produce a valve-like closure at the point of flexion. A point of great tenderness may at times be detected by the sound at the angle. One theory is that increased vascular tension induces painful pressure at this point. Where the endometrium is swollen or diseased, as evidenced by tenderness and abnormal discharges, benefit in a few cases may be obtained by a cautious dilatation and curetting of the uterine cavity, followed by packing of the canal, for twenty-four or forty-eight hours, with sterile or iodoformized gauze to maintain the dilatation; or, according to a few authorities, a stem pessary may be introduced to secure the healing of the parts in a more normal direction. Such methods require care and good judgment, as salpingitis or endometritis may be readily caused. Prevailing opinion is against the protracted wearing of stem pessaries, because of their dangerous pressure or irritation as foreign bodies. If the ovaries and tubes, as well as the uterus, are of sufficient development to allow pregnancy to occur, the conditions are usually greatly improved after labor and the subsequent involution of the parts. In many cases of undersized flexed uterus, the only benefit to be secured is through general tonic and roborant treatment directed to the improvement of the impaired nutrition of the nervous system, which is apt to be present. When the uterus is quite small, it does not develop under physiological stimuli and the sterility is permanent.

COMBINATION OF VARIETIES.—An abnormal curvature may accompany an abnormal position. For example, anteflexion may be combined with retroversion (Fig. 4899).

When the uterine canal remains straight, the backward change of direction of the whole organ beyond the perpendicular line of the body constitutes a *retroversion* (Fig. 4900). When the canal is curved backward by a bend in the body of the organ, the condition is known as *retroflexion* (Fig. 4901). The two conditions are very commonly combined, constituting the most important of the series of displacements, except downward displacements. The degrees of malposition are sometimes divided into groups, called first, second, and third, though their limits are arbitrary and of little practical value.

Retroversion and retroflexion may be considered together, as clinically their symptomatology and treatment are much the same.

Retroversion of a small healthy uterus which has not descended, occurring in a woman who has an intact pelvic floor and healthy ovaries and uterine tubes, may not cause any symptoms. Such a state of affairs would not call for treatment were it discovered. In almost all cases, however, the backward uterine displacement appears as a feature in a more or less complicated situation, which includes lacerated pelvic floor, prolapse of ovaries and tubes, possibly with adhesions, uterine descent, engorgement of pelvic vessels, subinvolution, endometritis, pelvic peritonitis.

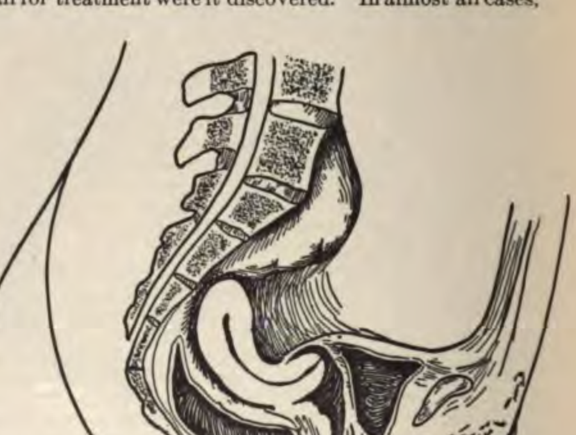

FIG. 4899.—Anteflexion with Retroversion.

Symptoms.—The symptoms of backache, bearing down, irritable bladder, increased duration and quantity with lessened interval of menstrual flow, are frequent. Occasionally patients complain of interference with defecation, and while lack of expulsive force, due to laxity of the pelvic floor, is most apt to cause the symptom, there seem to be a few cases in which the retroposed fundus does act as a partial obstruction to the onward passage of the contents of the rectum. Not all of these symptoms may be due to the retroversion, but the condition cannot be cured if this is not corrected. Indeed it must be constantly borne in mind, in considering all forms of uterine displacement, that it is frequently the conditions which accompany these disorders which give rise to symptoms and not the change in position or of curvature considered by itself.

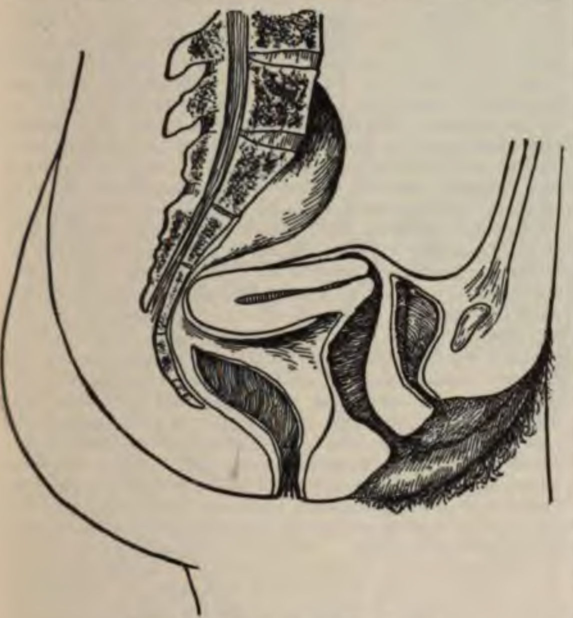

FIG. 4900.—Retroversion of the Uterus.

Diagnosis.—The diagnosis is made by locating the relative position of the uterine fundus and of the cervix by means of the two hands, one pressing down the lower abdominal walls, while one or two fingers of the other are introduced into the vagina with firm backward and inward pressure. When the abdominal walls are rigid or the parts small, an anæsthetic may be required. It may be necessary to draw the whole uterine body downward by a tenaculum hooked into the cervix. It is unnecessary and often dangerous to introduce the uterine sound for purposes of diagnosis.

Replacement.—The use of a uterine sound or a jointed rod repositor within the uterus is to be condemned as likely to work mechanical injury, especially where peritoneal adhesions exist, and because a very early pregnancy cannot be excluded. By drawing down the cervix with a tenaculum, and carefully picking up the fundus with the hand applied to the abdomen, at the same time that the cervix is swung backward and inward, any non-adherent retroverted uterus can, with a little patience, be brought forward, although the manipulation may require some skill and practice. Until this replacement has been carried out, it is difficult and frequently impossible to determine with accuracy the condition of the prolapsed ovaries and tubes. When there are no peritoneal adhesions binding down the fundus, or when the median portions of the tubes and broad ligaments are free, the replacement of the uterus can be completely effected. Attention must then be turned to the problem, frequently a complicated one, of maintaining the organ permanently in a forward position. Lacerations of the pelvic floor must be repaired as a preliminary step, whether the mechanical support of a pessary is to be used or not. If it be decided not to use a pessary, various operations may be considered.

Prognosis.—Permanent cure may in a small percentage of cases be secured by repeated reduction and systematic massage, but the method is uncertain and open to objection. After the correction of constipation by laxatives, of uterine hyperplasia and pelvic congestion by hot douches, rest, medicated tampons containing especially ichthyol and boroglyceride, the use of some form of pessary may be considered. This instrument is far less frequently used than formerly, and there are many gynecologists who seldom or never make use of a pessary. Nevertheless, in the hands of a careful physician, of good mechanical judgment, this instrument may be made to give much comfort to a certain number of patients; it may even effect a cure in a few cases, especially those suffering from subinvolution after childbirth when only a few months have intervened since the labor.

The prognosis is good in all pathological forms of uterine displacement, if treatment is extended to the removal of causes, to the correction of concurrent conditions like endometritis and uterine hyperplasia, and if operations be carried out upon sound mechanical principles. Very many operations have, however, proved disappointing in their ultimate results, or they have, by interfering with pregnancy or with the normal mobility of the parts or by inducing a hernia, proved worse than the conditions which they were designed to correct. Moreover, a perfectly aseptic technique in operating is essential, for an operation correctly designed may fail to cure because of infection of the wound. This applies particularly to operations for shortening the round ligaments and to that which is designed to effect a suspension of the uterus, to be hereafter described. In both these instances infection may be followed by disastrous results, which leave the patient in a worse state than before.

Pessaries for the correction of anteversion are seldom required, and have gone almost entirely out of use. For posterior displacements the most useful form of pessary belongs to the type represented by that known as the Smith-Hodge, which consists of a hard-rubber ring, flattened at the sides and with a double curve, the upper and posterior extremities being designed to hold the fun-

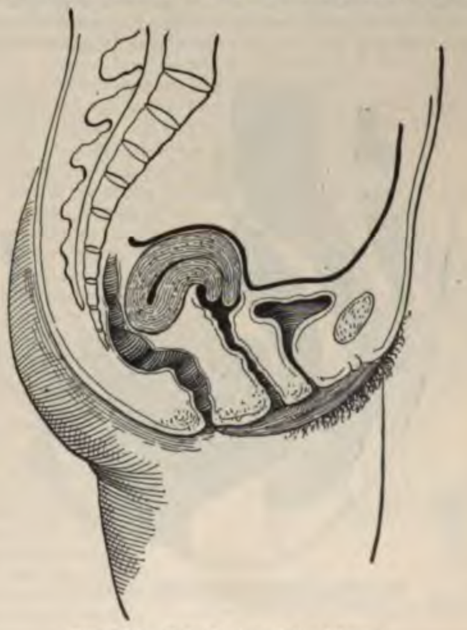

FIG. 4901.—Retroflexion of the Uterus.

dus forward and at the same time draw the cervix backward (Fig. 4902). The anterior end is curved downward slightly so as to avoid pressure on the urethra. In conditions of great relaxation of the parts, a plain ring of soft rubber is occasionally used, but much greater irritation is produced by it than by the hard-rubber instrument. Much ingenuity has been expended upon the mechanical support of the uterus, and the number of instruments suggested is very great. Very few of them, however, have acquired a permanent place in the treatment of the conditions for which they were designed, and a description of the numerous varieties will not be here attempted. When the causes which produced the original displacement can be removed by operation, the results are usually much more satisfactory, as the wearing of any instrument is a continual source of irritation, and more or less constant supervision by the physician is required. In particular, all forms of instrument which obtain the necessary support from external straps are unsatisfactory and in many cases injurious.

Stem Pessaries.—Many attempts have been made, by the use of an intra-uterine stem having the curve of a normal uterine canal, to correct flexions of the uterus. While it is possible, after complete dilatation and under aseptic conditions, for the uterus to tolerate such a foreign body, the dangers of endometritis, salpingitis, or other results from irritation have led to the abandonment of the instrument by the majority of gynecologists. The theoretical advantages are more than offset by the injurious results which have followed its use in some cases. If they are used at all, abundant provision must be made for the drainage of the normal secretions of the part. When any form of pessary is worn, a daily cleansing douche is required, and at least once a month the instrument must be removed by the physician and the effects of injurious pressure looked for.

Among the chief *causes of failure* in the use of instruments for the correction of uterine displacements, the greatest is the presence of inflammatory adhesions, either of the uterus itself, which may be thus confined in its abnormal position, or of the ovaries, broad ligaments, and Fallopian tubes. Retroversion especially is very commonly accompanied by salpingitis, metritis, or endometritis; and salpingitis is usually the more important disorder of the two. After the acute stages of tubal inflammation have entirely passed, and after all exudates have been absorbed or organized, the resulting adhesions of previously smooth peritoneal surfaces are often firmly established and remain as a permanent condition. Strong fibrous bands and layers of newly formed tissue of great strength surround the parts in their new position, interfere with the return circulation, and prevent the normal change of position which is required as the rectum or bladder fills and empties, or as the person moves about, coughs, sneezes, and the like. The appendix may be caught and pinned down within this area of chronic peritoneal inflammation, and at the same time small masses of cheesy pus in the tubes or lower peritoneal cavity serve as a focus for succeeding attacks, which continue indefinitely the disability. Expert knowledge and skill are required to recognize and properly appreciate many of the conditions referred to, while even under an anæsthetic adhesions of the pelvic viscera, if in the form of long bands, will often escape detection. It may be regarded as axiomatic that the replacement of the uterus, even if possible, will not produce relief of symptoms in the presence of adhesions or inflammation of tubes, ovaries, and broad ligaments. Inasmuch as the uterus has a tendency, when its position is altered by a force from without, to return to its original position, the elastic pressure exerted upon the pessary used will be likely to produce injurious results. And then, on the other hand, if the normal position be maintained, pressure and traction upon the diseased tissues near by will ultimately increase the distress of the patient. An uncomplicated backward displacement of the uterus, for example, is a comparatively rare condition, and, like other displacements, were it not accompanied by increase in the size of the organ, endometritis, salpingitis, chronic peritonitis, pelvic congestion, varicose veins of the broad ligament, and imperfect circulation in lymph channels, it would produce comparatively little disability. While, therefore, a displacement of the uterus may be the most easily demonstrated feature in a given case, it cannot be too strongly urged that attention must first be given to the correction of complicating conditions, and especially to the removal of all adhesions, before the replacement of the uterus by any form of support is to be undertaken. This preparatory treatment may occupy weeks, and may consist of hot douches, of elastic packing in the knee-chest position, of the application of absorbifacients on carefully placed vaginal tampons, as well as of the correction of unhygienic conditions of all sorts. In the event of failure of these efforts abdominal or vaginal section may even be required, especially where destructive tubal inflammation has occurred. Rapid replacement of the uterus under anæsthesia has been advocated in some cases, for example by Schultze. This should be attempted only in simple cases, and by one familiar with intra-abdominal operating, as it is easy to rekindle a slumbering pelvic peritonitis, produce hemorrhage by laceration, or distribute the infected contents of a tube. If undertaken, the operation should be done only by the hands, *i.e.*, by using bimanual manipulations, while the cervix may be steadied or moved in the proper direction with a tenaculum. Replacement by means of an intra-uterine instrument with a mechanical arrangement for changing the direction of its outer extremity is open to the objection that it may perforate the uterus or otherwise injure it, and that, when a difficulty of one kind or another is encountered, cautious intelligent action is impossible.

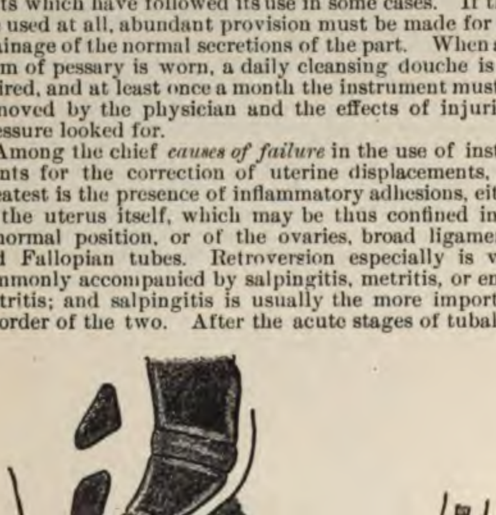

FIG. 4902.—Smith-Hodge Pessary in Position.

Downward Displacements.—The downward are usually combined with the backward displacements, and are those which carry in their train the greatest amount of physical discomfort, disability, and in some cases secondary disease. The degree may vary from a trifling descent of all the structures in the pelvic canal, including the uterus, to the complete extrusion of the organ from the body (Fig. 4903). The uterus in its descent is usually accompanied by the bladder and the anterior wall of the rectum, which undergo stretching, the walls of the vagina are also stretched, as are the connective tissues and the fascial supports of the pelvic floor. In the greater degrees of downward displacement, known as procidentia uteri, very elaborate changes of structure and of anatomical relations have taken place, and cases vary greatly in the individual changes of relation which have occurred. Sometimes the uterine body escapes from the pelvic outlet and the fundus may be defined in the upper portion of the protruding mass, while no great change has occurred in the size or shape of the uterus or of its cervical segment. In these rare cases the protruding mass forms a true hernia. A considerable portion of the bladder, all of its base, all of the vaginal walls and urethra, the lower portions of the broad ligaments, part of the uterine tubes, several inches of rectal wall, the ovaries, with some small intestine or omentum, may be found in the mass. More frequently the fundus of the uterus remains in the lower portion of the pelvic outlet together with the tubes and the ovaries, while the central and cervical portions of the uterine body elongate downward and undergo hypertrophy (Fig. 4904). The result is a very great increase in the size and weight of the uterus, its canal measuring six or eight inches in length, and the cervical segment may be two or three inches in breadth. Hypertrophy of the vaginal mucous membrane and underlying connective tissue and passive congestion and œdema unite in the production of an external mass which may be five inches in diameter. In some instances urination can take place only after the protrusion has been manually replaced and the urethral canal thereby unbent. Secondary changes due to chafing and passive congestion may produce superficial inflammation and ulceration, so that more or less bleeding is quite common, even in cases which are seen in old age and which have not undergone cancerous degeneration. The imperfect emptying of the bladder may result in decomposition of residual urine and secondary bladder or kidney changes. Defecation is more or less interfered with and frequently requires manual assistance; impairment of the return flow of blood favors the development of hemorrhoidal conditions and other disorders of the rectum. Notwithstanding the enormous amount of displacement and distortion of the parts, patients, especially working women of the phlegmatic type, will sometimes complain of surprisingly little discomfort, and many women, supporting the parts with a tight napkin, will perform heavy manual labor and entirely refuse operative relief. In the extreme degrees of downward displacement, no form of instrument or apparatus proves satisfactory, as anything which gives sufficient support is more than likely to produce irritation or ulceration from direct pressure It appears impossible to secure in the greatly widened and straightened pelvic outlet a proper point of support for any instrument. In the minor degrees of this condition relief may be obtained sometimes for long periods by the use of the plain ring pessary, though each case requires an adaptation of the support to its peculiar conditions.

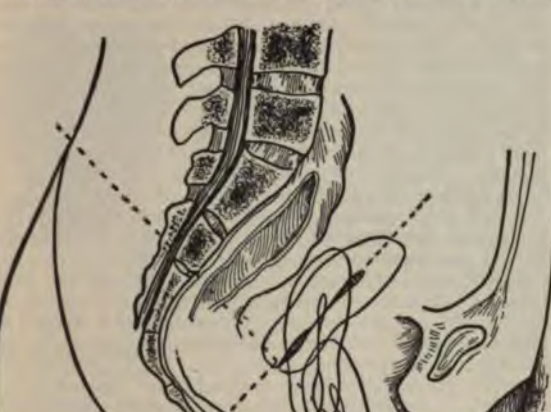

FIG. 4903.—Prolapse of Uterus. Diagram represents the degrees of prolapse, but not the usual distortion of the organ.

The operative relief of downward displacement has received much study, and many procedures have on protracted trial proved unsatisfactory. Removal of the uterus, occasionally advocated, does not restore the accompanying displacement of bladder, rectum, and vagina, and in well-marked cases of procidentia it has proved entirely unsatisfactory, unless followed by extensive plastic operations for the correction of the other elements in the condition and for the support of the other organs of the pelvis. Those procedures ultimately fail which do not succeed in restoring, to a large extent, the mechanical arrangement of supporting structures which originally maintained the uterus in position. All operations should aim at a restoration of the integrity of the pelvic floor, and particularly at repair of the torn fasciæ and separated fibres of the levator ani muscle. In addition to this the increased weight of the uterus must be corrected, its cervical segment, if elongated, must be shortened, and the utero-sacral attachments must be in effect restored in order to draw the cervix backward; and at the same time some operation must be carried out which will not only restore the normal forward position of the fundus, but will also, if possible, contribute to its support. In long-standing cases of procidentia the endometrium is usually diseased and hypertrophic glandular endometritis is commonly present. The first procedure to be undertaken, therefore, is curetting of the uterine cavity, and next the cervix is to be repaired if lacerated, or, if it is greatly elongated, the bladder and rectum are to be dissected off, the lateral blood supply of the uterus is to be ligated as in the early steps of a vaginal hysterectomy, and the lower portion of the uterus is to be amputated at such a point as will leave the organ approximately normal in length. This lessens the blood supply of the organ and tends to produce involution. When now the anterior and posterior flaps of the vagina are united to the flaps of the cervix by deeply placed radiating sutures, the deficient utero-sacral support is in effect supplied posteriorly, and the vagina and bladder are attached at a higher point on the anterior face of the uterus. An operation must now be performed that will diminish the cystocele. According to some methods a horseshoe-shaped denudation is made on the anterior vaginal wall and the edges of the denuded areas are united by rows of interrupted sutures. A preferable method includes free dissection of the anterior vaginal wall and its underlying connective tissue from the bladder over a triangular area whose base is directed toward the cervix, and whose width is determined by the degree of relaxation of the parts. The triangular flaps thus formed to the right and left of a median longitudinal incision on the most prominent portion of the cystocele are freely cut away; after which a series of buried superimposed catgut sutures is introduced to close the wound, and a superficial layer of continuous silk suture unites the cut edges of the mucous membrane and of the fascia beneath. This operation restores, better than can be accomplished in any other way, the integrity of the structures which normally support the bladder and anterior wall of the vagina.

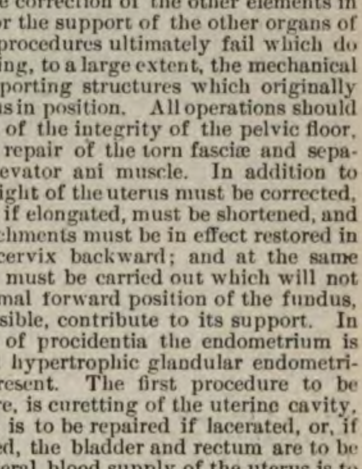

FIG. 4904.—Procidentia Uteri. Hypertrophy of supravaginal portion of cervix.

Attention is now turned to the defective posterior wall, which should be widely denuded, the upper edge of the denuded area being continued at the sides higher than in the median line, as in the operation for restoration of the pelvic floor designed by Dr. Thomas Addis Emmet. The sutures are so introduced as not only to approximate the sides of the denuded area, but also to draw upward the prolapsed tissues. They take their point of support in untorn fascia at the sides of the pelvis. Another excellent plan of perineal repair is that of Hegar.

Any existing hemorrhoids should be removed by ligation or by cauterization. Extreme degrees of uterine descent will not be permanently cured unless, in addition to the procedures described, some operation be undertaken above the pubic bone to support the uterus and secure for it a permanent anterior direction. The operations that are most favored at the present time for securing these objects are either shortening of the round ligaments of the uterus, or an attachment of the fundus to the anterior abdominal wall.

Shortening of the Round Ligaments; also known as *Alexander's Operation.*—These cords of unstriped muscular fibre take their origin near the uterine cornu, pass forward and outward through a fold in the broad ligament, and entering the inguinal canal are attached at the external abdominal ring to its pillars and to neighboring tendinous structures immediately about the pubic spine. The ligaments may be pulled outward through the inguinal canal after their outer ends have been reached through a small incision over the external abdominal ring. The redundant portion having been cut away or attached by various methods to neighboring structures, the remaining portion of the ligament is sutured in the lower end of the canal. By some operators the round ligament is reached after an extensive opening of the inguinal canal, afterward shortened, and its remaining end attached. Other methods involve the opening of the abdomen in the median line, the folding and suturing of the round ligaments upon themselves, or to the uterine body, after the manner described by Matthew D. Mann, W. Gill Wylie, Palmer Dudley, and others (Fig. 4905). A plan has also been proposed for carrying a loop of round ligament, or the cut end back through a perforation made in the broad ligament to a point behind the uterus where it is to be sutured. The methods of intra-abdominal shortening of the round ligament have not been so extensively practised as those in which it is approached by way of the inguinal canal.

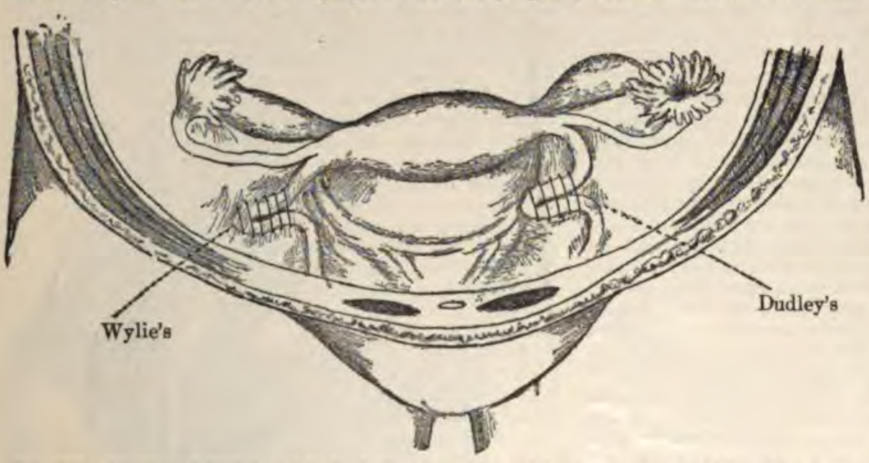

FIG. 4905.—Diagram of Wylie's and Dudley's Methods of Intra-abdominal Shortening of Round Ligaments.

Suspension of the Uterus.—In retroversion of marked degree, after adhesions or disease of tubes and ovaries have been appropriately treated, and after the problem of the support of the uterus from below has been met, the operation of uterine suspension, as devised by Howard Kelly, may be carried out. The object is not to hang up the uterus by a strong supporting band, but to form a light attachment of the fundus to the anterior abdominal wall, which elongates under subsequent traction and forms a delicate cord. This serves to maintain the uterus in the normal position of anteversion, so that the weight of the abdominal contents is received on the posterior instead of the anterior surface of the organ, and the mechanical forces of the normal uterine support are again put in play. The attachment is made by two or more sutures of fine silk entering the uterine substance a short distance posteriorly to the line of the tubes, emerging at a distance of about one-half inch, being again introduced on the peritoneal surface of the anterior abdominal wall, passing through the properitoneal fat, grasping a few fibres of the rectus muscle, crossing the wound and penetrating in turn rectus fibres, properitoneal fat, and fascia, again appearing through the peritoneum, when they may be tied within the peritoneal cavity and remain buried. The abdominal wound is closed separately in layers or by methods usual in the practice of the operator.

Objection is frequently made to this operation on account of its supposed interference with subsequent pregnancy. There have been reported a number of cases in which this operation had been performed, and in which formidable complications were met during labor. Such complications may usually be traced to a too great amount of fixation of the uterus at the original operation, or to inflammatory adhesions which have produced a firm attachment of the uterus to the abdominal wall. Such an attachment is not contemplated in the operation of uterine suspension, and should never be carried out in women who are liable to bear children. In the operations for the cure of procidentia in elderly women a firm attachment may, however, be made by an operation known as uterine fixation.

Fixation of the Uterus.—Through an abdominal incision in the median line just above the pubis, Olshausen secured the indirect support of the uterus by uniting the round ligaments and the broad ligaments to the parietal peritoneum on either side. He secured this union by means of buried sutures. Theoretically the operation provides an opportunity for hernia of the intestine between the fundus and the abdominal wall, and consequently it has never been widely practised. Leopold directly fixed the uterus by its anterior surface to the abdominal parietes after scarification. He passed three of the sutures which were destined to close the abdominal incision though the uterine tissue, one penetrating the uterus in the line of the tubes, another opposite the origins of the round ligaments, and a third still farther down the anterior wall. The result of this procedure was, as a rule, a very firm attachment of the uterus forward and above the bladder, especially when any appreciable degree of inflammatory reaction followed the operation. So firm is the attachment secured by this operation that pregnancy, should it occur, is likely to be followed by dangerous complications. In a number of instances complications of this nature have compelled a resort to the operation of Cæsarean section. It has been found, in these cases, that the anterior wall of the uterus develops as a thick compact mass, confined by adhesions to the brim of the pelvis, while the posterior wall of the uterus, stretching upward, becomes greatly thinned; in consequence of which conditions the normal presentation of the child is rendered impossible, the engagement of the head does not occur, and even version or the high application of the forceps may fail to effect delivery.

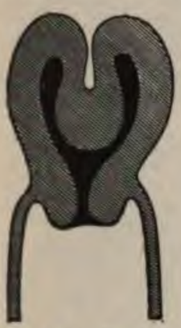

FIG. 4906.—Partial Inversion. (Thomas.)

Vaginal Fixation of the Uterus.—One of the three chief methods of securing the uterus in a forward position and of counteracting its abnormal descent is the operation known as vaginal fixation, which was elaborated by Mackenrodt, who described it in 1892, and by Dührssen, who worked along similar lines. In these operations an attempt is made to overcome the relaxation of the anterior attachments of the uterus, to attach the over-stretched vaginal supports at a higher point on the anterior surface of the uterus, and to overcome the downward displacement of the bladder. In performing the operation the lower limit of the bladder in front of the uterine cervix is first established, and then the surgeon proceeds to take the following steps: a transverse incision is made (just below the point fixed as representing the lower limit of the bladder) down to the bladder wall, and a longitudinal incision from the centre of this transverse line is carried forward nearly to the external urethral orifice; triangular flaps are made on either side and the bladder is separated from the vaginal wall and the anterior face of the uterus. The utero-vesical pouch of peritoneum is opened, any existing adhesions are separated, and the uterus is brought forward to its normal position and sutured to the cut edges of the vaginal wall. In order to overcome the objection that the changes effected by this operation interfere too seriously with pregnancy, it has been later advised to suture the anterior uterine wall to the peritoneum covering the bladder. While the immediate mortality following this operation was small, the effect upon subsequent pregnancy proved in many cases to be unfortunate. Abortion followed in many instances; in others the uterus was unable to rise in the pelvis, the anterior and posterior walls did not develop symmetrically, and complicated operative treatment became necessary to effect delivery. Several deaths have thus been traced indirectly to the operation of vaginal fixation, and it has not secured for itself a permanent place in surgery. It is seldom performed in America.

The choice between these operations for maintaining the normal forward position of the uterus will depend upon conditions present in different patients and also upon the experience and preference of the operator. Some gynæcologists perform a large number of operations upon the round ligament and seldom suspend the uterus; with others the practice is exactly the reverse. The objection that the round-ligament operation, as suggested by Alexander, does not permit of the inspection and treatment of intra-abdominal disease is obviated, as claimed by certain operators, by the adoption of the radical method. These surgeons virtually perform a cœliotomy upon each side of the abdomen, lay open the entire inguinal canal, open the peritoneum at the internal ring, and, after performing any necessary intra-abdominal operation, they shorten the round ligament and restore the inguinal canal in a manner allied to that adopted for the radical cure of inguinal hernia. This radical method, however, should not be considered in discussing the relative merits of uterine suspension as compared with an external round-ligament operation. The latter gives excellent results when performed by a surgeon who has had abundant experience with it, and is especially adapted to those cases in which the uterus is small and not diseased, in which the element of descent is not important, in which pregnancy is likely to follow later, and in which there are no complicating disorders of the tubes and ovaries. Suspension of the uterus on the other hand may be chosen in those cases in which it is desirable to open the abdomen for other reasons, such as the removal of an irritable but not greatly diseased appendix vermiformis, the separation of peritoneal adhesions, resection of diseased tubes and ovaries, or the removal of the same. While the band of attachment is drawn out into a thin cord and a certain amount of mobility of the uterus is ultimately secured, and while pregnancy in many cases is followed by no complication, the operation is best adapted to those patients who are not liable to become pregnant.

The intra-abdominal operation of shortening the round ligaments may be applied in the same class of cases as those for which the extra-abdominal is usually chosen.

Shortening of the Utero-sacral Ligaments.—This has been done as a direct procedure by several operators who reach the ligaments either through an incision in the posterior vaginal cul-de-sac or from above after opening the abdomen. The object is to draw the cervix backward and somewhat upward, thereby restoring the tendency of the uterus to incline forward as in the normal pelvis, since it is in this position that the uterus best resists the influences which tend to displace it.

Bishop describes (*Lancet*, March 14th, 1903) an operation which aims to reproduce utero-sacral ligaments for the cure of prolapse of the uterus. The abdomen is opened and, with the patient in the Trendelenburg posture, the uterus is drawn up and by a vaginal instrument the posterior vaginal fornix is thrust upward. A stout suture on either side is introduced well into this prominent vaginal tissue from within the abdomen and then attached firmly and deeply to the sacrum, a point being chosen, on either side of the rectum, which is free from vessels and nerves.

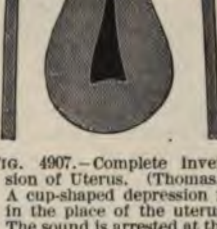

FIG. 4907.—Complete Inversion of Uterus. (Thomas.) A cup-shaped depression is in the place of the uterus. The sound is arrested at the angle of flexion.

Hernia of the Uterus.—The true hernia through the pelvic outlet has been described, but among the curiosities of medicine appear a few cases in which the uterine body has formed a part of the contents of a hernial sac in other regions of the body. Gould and Pyle in their work on "Anomalies and Curiosities of Medicine" quote nineteen cases of hernia of the uterus (C. Debierre: "Les Vices de Conformation des Organes Génitaux et Urinaires de la Femme," Paris, 1892). Thirteen of these cases occurred in inguinal, two in femoral, one in obturator, and three in umbilical hernia.

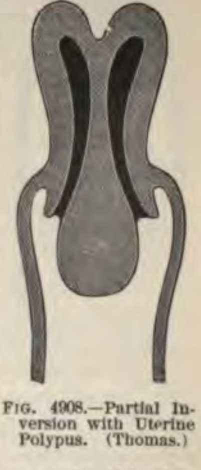

FIG. 4908.—Partial Inversion with Uterine Polypus. (Thomas.)

Manning Simons (*Amer. Jour. of Obst.*, January, 1903, p. 70) describes a case in which both ovaries, both tubes, the bladder and rectum were in a sac formed by the prolapsed vagina, whose anterior and posterior walls had adhered below the cervix uteri. The whole mass protruded from the pelvic outlet.

Inversion of the Uterus.—The uterine body may be turned inside out or inverted in two principal ways: First, immediately following labor, and as a result of pressure from above, or through traction on the placenta and membranes from below, the fundus of the uterus may become indented (Fig. 4906) and irregular contractions may result in a complete inversion of the organ, so that the endometrium appears in the vagina and the uterus presents itself in that passage as a pear-shaped body (Fig. 4907). As the second cause may be mentioned the contractions produced by an intra-uterine tumor, especially a fibroid tumor, which is attached by a pedicle somewhere in the upper portion of the uterine canal, and whose body is within the grasp of the uterine muscle. Long-continued contractions of the uterus in the effort to expel the tumor may drag down the uterine wall where the pedicle is attached, first producing an indentation (Fig. 4908) and finally, as the tumor is extruded, complete inversion of the organ. This process may require several months, while the accident following labor occurs in a very few minutes.

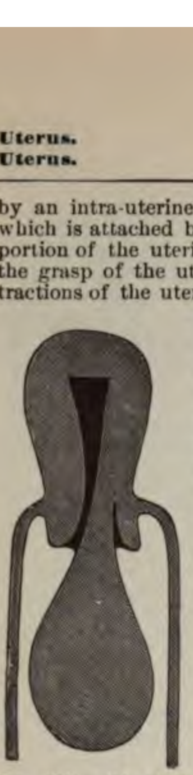

FIG. 4909.—Uterine Polypus. (Thomas.) The uterus is in its normal position. The sound passes into its cavity.

Symptoms.—The chief symptom is hemorrhage, which is persistent and often excessive in both varieties. Dragging, bearing down, irritability of the bladder and rectum, and a sense of fulness may be complained of in the chronic variety, while pain and collapse often accompany the hemorrhage of acute inversion.

Diagnosis.—In acute cases little difficulty will be found in recognizing a depression at the former site of the uterine body in the abdomen, and in the vagina a smooth regular tumor with a freely bleeding surface. In some complete cases it will be found that the uterine cervix and the cervical canal have entirely disappeared. In chronic cases in which the inversion is incomplete, a sound entering the cervical canal will serve to define the limits of the protruding body and its relation to the remainder of the uterine structure as felt above the pubis. When a polyp is present without inversion (Fig. 4909) it will be possible to demonstrate the fundus in its normal position. Obscurity is occasionally increased by inflammatory adhesions of the thick stem of a uterine polypoid tumor to the inner surfaces of the uterine canal (Fig. 4910).

Prognosis.—Reduction of the inversion is very seldom spontaneously accomplished. In recent cases the prognosis is good under well-directed efforts at replacement, although in chronic cases very great difficulty may be encountered.

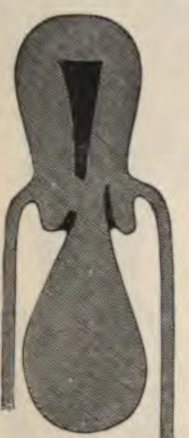

FIG. 4910.—Uterine Polypus. Adhesions around neck of polypus obliterate cervical canal.

Treatment.—In acute cases, under anæsthesia, efforts are made to dilate with the thumbs of the operator the contracted cervical ring, while at the same time the presenting fundus is indented and an effort is made to press it through the ring, one portion at a time. A variety of instruments have been devised, in the hope that by means of them the inverted organ may be restored to its normal relations. The end, which is cup-shaped, is designed to fit the fundus and to receive pressure transmitted through a stem which rests against the operator's body or is held in the hand of an assistant. Manual dexterity, however, combined with patience, will usually succeed in effecting the desired reduction, although the process is frequently a difficult one. In long-standing cases the dilatation of the cervical ring is a matter of much greater difficulty. Some device must be used which will make a slow and constant pressure upon the inverted fundus, after the tumor which produced the condition has been removed. In a few cases the reduction has been effected by opening the abdomen and drawing upon the uterine tubes and the upper portion of the fundus, while at the same time pressure was made from below. In this way more ready access is obtained to the contracted cervical ring for the purpose of dilatation; but reduction can usually be accomplished after repeated efforts without opening the peritoneal cavity. Finally, in some cases the wall of the uterus has been split longitudinally from within the vagina, and then, after reduction had been accomplished, the lips of the incision were united by sutures.

George Erety Shoemaker.

UTERUS, DISEASES OF: MALIGNANT TUMORS.—

DEFINITION.—The malignant tumors here referred to, include the various forms of cancer and sarcoma, and deciduoma malignum. The general pathology of the several forms is given elsewhere in this HANDBOOK.

FREQUENCY.—According to the registrar-general of Great Britain in 1900, in England and Wales, 0.975 woman per one thousand of inhabitants died from cancer; and of all female deaths cancer of the uterus caused 1.3 per cent. In 1890 but 0.830 woman per one thousand of inhabitants died from cancer. In New York in 1890 the deaths from cancer in women were 0.37 per thousand of inhabitants, and in 1900 they were 0.43. These figures show the ratio of increase of cancer in women, most of the increase being in cancer of the uterus. It is needless to multiply the statistics.

And of all cases of cancer which occur in the body, William H. Welch found that the uterus was involved in 29.5 per cent. There is no means of accurately determining the ratio between true cancer, sarcoma, and deciduoma malignum.

Sarcoma and deciduoma malignum are very rare. The one fact which is impressively evident is the steady increase in cancer of the uterus. As the disease has been recognized for many years, this increase is real and not "apparent and due to more precise diagnosis."

AGE.—In New York in 1890 fifty-seven per cent. of all deaths from cancer were below forty-five years of age. In 1900 fifty-two per cent. were below forty-five years of age. The statement that the disease occurs more frequently than formerly in young women is not correct. The apparent greater frequency is due to the fact that a diagnosis of the disease is now made earlier than it formerly was. The youngest woman having cancer of the uterus in the author's service was twenty-six years of age. The maximum number of cases occur above forty-five years of age. It is exceedingly rare before twenty-five years.

RACE.—No race is exempt. It is probable that savage races have it less frequently. The observation used to be made that the negress was exempt. Cullen has proven this not to be the case at the present time. Whether more mulattoes are now found than formerly, and that the pure-blooded negress is less liable, I cannot state.

CAUSES.—These are actual and contributing. The supposed actual causes of cancer are described elsewhere. The contributing causes are many.

(*a*) *Irritation and Trauma.*—The fact is undoubted that cancer of the cervix is rarely seen in the nulliparous woman, and in a number of instances in which it has occurred in them a trauma, such as dilatation, has preceded its appearance. It appears that nulliparæ have adeno-carcinoma of the body of the uterus about as often as mothers, but that squamous-cell epithelioma is seen most frequently after childbearing or other trauma.

(*b*) *Heredity.*—This is not now believed to be as potent a factor as it was formerly held to be. However, in about twenty per cent. of uterine cancers, another member of the family has had some form of cancer.

(*c*) *Locality.*—In an attempt to find the true cause for cancer all the circumstances under which it occurs have been sought. In these investigations it has been found that certain localities, and even certain houses, have an unusual number of cases. This has given rise to the expression "cancer zones." Those who seek to show the contagiousness of cancer point to these facts as corroborative of their views, but thus far most authorities believe that the unusual prevalence of cancer in certain localities is merely accidental.

Cancer of the Cervix Uteri.—This occurs in two forms: as a squamous-cell epithelioma and as an adenocarcinoma. Furthermore, either the vaginal part of the cervix or the cervical canal may be involved.

Squamous-cell epithelioma of the cervix is the most frequent form. Squamous epithelium multiplies upon the surface and invades the stroma. Occasionally the epithelial cells are found grouped together so as to form "epithelial pearls." One of the earliest changes in the epithelial cells is the increase in chromatin. The ingrowth of the epithelium precedes the outgrowth, but after a time the epithelium produces delicate filiform projections on the surface of the cervix. The papillary growths consist of branching stroma and epithelium, and are exceedingly vascular. After a time necrosis of the projections takes place and ultimately an ulcer occurs where formerly an outcropping was present.

At first the cervix is nodular and hard, and new vessels may be seen coursing across the nodules. The nodules are of deep color and unequal in size. It is in this state that the disease is seldom recognized. In the state of papillary excrescence the outcroppings appear as delicate papillæ, red in color, bleeding upon the slightest touch, and always pedunculate. They may be so numerous as to form, when massed together, what is appropriately described as a "cauliflower growth." The least touching of such a growth causes bleeding. The excrescence is generally covered by a foul-smelling pus, the result of necrotic changes, and at points minute blood clots may be seen. Without difficulty the finger can be made to penetrate the growth. As ulceration proceeds all traces of the cervix become lost. There is then present at the vaginal vault a cup-shaped ulceration surrounded by raised edges, the surface of the cavity being covered by pus, and the ulcer bleeding easily. The adjoining vaginal wall may be involved, or cancerous foci, the result of secondary "inoculation," may be seen upon the vagina, even at some distance from the cervix.

Extension.—Cancer of the cervix tends to extend bilaterally along the lymphatics in the broad ligament, downward into the vagina, anteriorly toward the bladder, and posteriorly toward the rectum. There is but little tendency for it to grow upward above the internal os, the body of the uterus being usually free even in those who have died from cancer of the cervix.

As the disease extends toward the broad ligaments, the glands lying over the obturator foramina, then those along the iliac arteries, and later the inguinal glands become involved. This glandular involvement is at first due to saprophytic and septic invasion, but later to the presence of cancer elements. It is also true that the epithelia occasionally appear in masses along the veins (Fig. 4911). Cancer of the cervix has little tendency to leave the pelvis. Not only is it at first localized in one part of the uterus, but even to the end it remains as a rule localized in the pelvis. After general pelvic involvement has occurred, all the various phases of pelvic suppuration may be presented: ovarian abscess, pyosalpinx, broad-ligament suppuration, suppurating glands, and peritonitis. The paths along which the cancer extends become ulcerated, and as a result fistulous openings into the bladder, less frequently into the rectum, may be seen. The ureters, for some strange reason, although surrounded by cancer, rarely become corroded.

As the broad ligaments become involved, which involvement takes place, as a rule, more rapidly upon one side, the ureters become obstructed and hydro-ureter results. The rectum may be pressed upon and constipation result. When the rectum or bladder is invaded, the lesions of inflammation of these viscera may be present. The cervical growth may be so large as to block the cervical canal, causing retention of the uterine discharges and pyometra.

Symptoms.—The writer believes that he has discovered a first early symptom of cancer of the cervix which has been furnished by all his patients who were intelligent and cleanly enough to observe such a symptom. Inasmuch as epithelioma of the cervix is characterized by a multiplication of epithelial elements and by increased vascular supply to the cervix, the earliest functional evidence of the disease *is a marked increase in the woman's habitual leucorrhœa, or the occurrence of a whitish leucorrhœa in those who have not previously had it.* In drawing out this symptom, the questioner should first determine the exact amount of discharge which is normal and usual to the individual. In refined women the toilet embraces a certain amount of and frequency in douching, every day or every few days. Without assignable cause such a woman will notice that her habitual leucorrhœa has become markedly increased, and that more frequent douches are needed to keep her tidy. In the case of an old woman whose glandular structures have shrunken with the menopause, a return of her forgotten leucorrhœa will be observed. Old women are apt to look upon this as an evidence of rejuvenation, a pathetically mistaken interpretation. The writer has given such prominence to this symptom in order that the attention of readers may be fixed upon it, and that more extended observations by other physicians may either corroborate or correct him. In his cases this symptom has preceded all others by from three to six months, months most valuable to the surgeon and to the woman. But as a rule women, accustomed as they are to vaginal discharges, seldom pay attention to an increase in leucorrhœa. The next symptom is a *change in the type* of the vaginal discharge. From being mucous and odorless, it now becomes watery and often has a putrid odor; or there may be an occasional muddy stain due to the admixture of blood. The menstruations are not altered in periodicity or in character. The presence of a putrid odor is always an indication of molecular death of tissue. Upon coitus, douching, straining, and lifting weights, or even after ordinary exercise, this muddy spotting of the underclothing may be noticed. The putrescence of the discharges and the intermenstrual bleedings become so marked that the attention of even the most indifferent woman is attracted to them. Up to this time the general health of the patient has not suffered. As the broad-ligament lymphatics become infiltrated, there is produced some pain, particularly if the obturator glands enlarge and press upon the obturator nerve. The pain is usually referred to a sacro-iliac joint or to the hip. Should the bladder be invaded, symptoms of cystitis supervene. As the pelvis

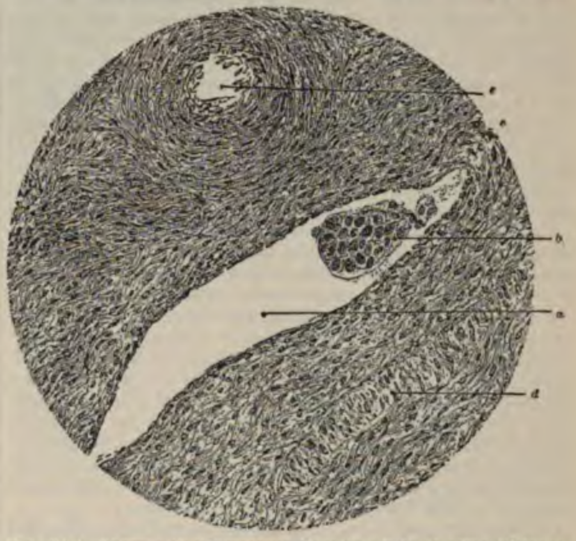

Fig. 4911.—Shows a Carcinomatous Mass in a Vein at some Distance from the Original Seat of the Disease. *a*, A vein containing a carcinomatous mass; *b*, isolated mass of carcinomatous tissue; *c*, transverse section of an artery; *d*, section through a vessel; *e*, muscular tissue. (Abel.)

becomes generally involved, the symptoms of peritonitis appear. It is remarkable how extensive the uterine degeneration may be without pain being produced. About the time the putrescence of the discharges becomes marked most patients become anæmic or "cachectic." They are usually in good flesh, but the tissues assume a waxen hue The patient is easily fatigued and avoids physical activity. After a time the pelvic pain becomes so great that she lies down a great deal. The consciousness of emitting a disagreeable odor makes of her a recluse. The anæmia is progressive; the severe pains necessitate the use of opiates, and these induce intestinal disturbances; possibly rectal or vesical symptoms supervene, and the physical prostration becomes extreme. In about two years after the onset of the disease the patient dies, either from sheer exhaustion or from some complication.

PHYSICAL SIGNS.—In the stage of infiltration the cervix is nodular, the nodules being of irregular size, deeply colored and evidently vascular. They feel hard, but upon thrusting a probe against them, or seizing them with a bullet forceps, it is seen that they readily break down, exposing bleeding and granular-looking surfaces. The appearance of a nodular and large cervix in a woman past the menopause is significant of cancer, for at that age the cervix should be shrunken. If papillary projections are present, they will be found pedunculate and bleeding upon the slightest touch. They can be scraped off by the nail. The cervical tissue underlying them has the same friability as in the first stage. If the disease has progressed to the formation of a cauliflower growth, this presents itself as a granular outcropping from the cervix, exceedingly friable and bleeding easily. It is always pedunculate and lobulated. After the papillomatous projections have necrosed, there is left an excavated, foul ulcer. The cervix can no longer be detected as a separate structure, but in its place, at the vaginal vault, will be seen the ulcerated excavation; or in its place, particularly in elderly women, the production of connective tissue may predominate, and the place of the cervix be taken up by a puckered, scar-like tissue, "scirrhous cancer." This latter is a very rare condition.

Pain.—As stated, some patients have little pain, but in the later stages of the disease pain of some sort is usual. It may be limited to the pelvis or may radiate to the distribution of the obturator or sciatic nerves

Strength.—Little outward sign of cancer is present until the new growth begins to break down Then the patient loses flesh, owing to the excessive elimination of nitrogenous material. The muscles fade first, and the fat more slowly. The cachexia is due to absorption of poisonous toxins from the cancer, and to the progressive loss of appetite. Slight leucocytosis is present and the percentage of hæmoglobin lowered.

Pulse and Temperature.—As the patient weakens, the pulse quickens upon the least exertion. In the latter stages of the disease there are irregular rises of temperature

DIAGNOSIS.—In the earliest stage this is to be made from the nodular condition of the cervix, due to cystic degeneration and stellate lacerations; in the papillomatous stage, from condylomata, sloughing polypi, exaggerated conditions of "erosion," and hypertrophy of the cervical glands; and in the stage of ulceration, from tuberculous and chancroidal ulcers, or those due to pressure. Cancerous nodules are exceedingly friable; and if a bullet forceps is hooked into one, it tears its way through upon the exhibition of even a slight traction. The same thing will occur with cystic degeneration of the cervix if much force be used; but when the cystic cervix tears, the gelatinous contents of the cysts are evacuated, whereas a bleeding granular surface is left if the nodule be cancerous. It is interesting to note that cystic degeneration to a marked degree and cancer rarely coexist. The elevations produced by stellate lacerations of the cervix are firm, and have the same consistence as the rest of the cervix

Upon superficial examination, "erosions" of the cervix (cervical folliculitis), particularly if this part of the uterus be torn and everted, resemble cancer in the first of the papillary stage. The surface of the "erosion" is raised, as is that of the cancer; but in cancer each papilla exists as a separate structure, always pedunculate, bleeding upon the least touch, and easily scraped off with the finger nail. None of these features of cancer is present in erosion Furthermore, beneath carcinomatous papillæ the infiltrated cervix is brittle, while the stroma beneath an "erosion" is increased and the tissues are more firm than normally. Parenthetically, a criticism of the term "erosion" may be uttered. It is an absolute misnomer, for not only is there no erosion or loss of substance, but, on the contrary, there is hypertrophy of the glands. Condylomata of the cervix are firm, covered by epithelium, and, unless ulcerated, do not readily bleed. Sloughing polypi present themselves as single pedunculate growths, exceedingly soft, and as a rule very much larger than the single papillary excrescences of cancer. They often present ulcerated surfaces, but are usually covered by a firm epithelium, giving them a glistening appearance, entirely unlike cancer. Polypi arise from the lining membrane of the cervix, and the cervical stroma is not involved.

Syphilis of the cervix is exceedingly rare, as is chancroid. In a suspected case of syphilis, antisyphilitic treatment gives prompt results, and chancroid is usually accompanied by similar ulcers in other parts of the genitals. In all doubtful cases a portion of the suspected tissue should be excised and submitted to a competent pathologist. Tuberculosis of the cervix is usually secondary to tuberculosis of the vagina or of the body of the uterus.

Old scirrhous cancer of the cervix strongly simulates the cicatrization found about lacerated cervices, but here again the tenaculum shows the disintegration of the cancerous cervix.

In removing tissue for examination, as much of the cervix should be amputated as possible; in any event, the pathologist should be furnished with a section which includes all the elements of the cervix, basement membrane as well as glands.

TREATMENT.—If the uterus be movable and the disease limited to the cervix, the uterus, ovaries, tubes, and parametric tissue should be removed, either by way of the vagina or by way of the abdomen. In some cases there are distinct contraindications to a radical operation. In such the high amputation of Sims, accompanied by the use of the galvano-cautery, may effect a cure. No internal medication is of avail, except the continuous ingestion of thyroid extract. This, taken in doses of five grains, t.i.d., p.c., not only tends to hold the disease in abeyance for months, but also may cause it to disappear *for a time.*

ADENO-CARCINOMA.—The cylindrical epithelium of the cervical canal often extends downward upon the face of the cervix, and this form of cancer may appear upon any portion of the cervix having cylindrical epithelium; but as a rule it occurs within the external os. The disease begins as a submucous, nodular accumulation of cellular elements, proceeds to the production of papillæ, and ulcerates. Or the ulceration may begin before papillæ make their appearance. Not only are the epithelial cells enormously multiplied, but there is also great increase in the glands of the cervix. The papillary excrescences may block the cervix and produce pyometra, but ulceration usually begins before this occurs. The entire supravaginal cervix may be riddled with sinuses, and yet the os externum appear normal. Sloughing and necrosis begin early, and altogether the progress of adeno-carcinoma is more rapid than that of squamous-cell epithelioma. Peritonitis and adnexal lesions also occur more frequently, owing to blocking of the cervical canal, followed by septic endometritis; and cancerous involvement of the bladder occurs more frequently and earlier. The disease is more frequent before the menopause.

Symptoms.—As a rule the first symptom is an increase in the woman's habitual leucorrhœa and in the amount of cervical mucus secreted. As in the case of squamous-cell epithelioma, the indifference of women to any discharge from the vagina causes them to pay no attention to this important first symptom. Therefore the usual symptom which brings these patients to us is an offensive discharge Blood-staining of the clothing, occurring between menses, is not seen so early as in squamous-cell epithelioma, because the involved field is within the cervical canal and protected against trauma. Therefore patients with adeno-carcinoma first present themselves with the disease far advanced. The menses are unaffected by the cancer. Women with cancer of the cervix, particularly this type, have been most prolific. The disease is rare in the nulliparous. Pain is not present until the disease has extended outside the uterus.

Upon examining a patient with adeno-carcinoma of the cervix the disease may be seen upon the surface. If it is not visible upon the surface, the introduction of the sound produces sharp bleeding. In fact, so dense is the normal cervical mucosa that it will tolerate a marked degree of trauma without hemorrhage.

Diagnosis.—Tuberculosis of the cervical canal presents all the local signs of adeno-carcinoma. As a primary affection it is exceedingly rare, but must be borne in mind as a possibility. Sloughing polypi present themselves in the form of ulcerated projections, while adeno-carcinoma appears as an excavation when active ulceration is in progress. Small submucous myomata projecting into the cervix may be felt with the finger as hard nodules, not at all resembling cancer. The cervix treats polypi and fibroids projecting into its cavity as foreign bodies, and as a rule it becomes widely gaping.

When the diagnosis is difficult a portion of the cervix may be scraped or cut away and submitted to a pathologist.

Treatment.—If the disease has not extended outside the uterus and there are no contraindications to a radical operation, abdominal ablation of the uterus and adnexa is indicated. Cases are rarely met with early enough to admit of the vaginal operation being successfully performed.

CANCER OF THE UTERINE BODY.—This occurs in from six to ten per cent. of all cases of cancer. It is the form of cancer which nulliparous women usually have. The type is nearly always the adeno-carcinomatous. The disease begins at one point in the endometrium, and from there tends to spread. The lesions are similar to those in the cervix—slender papillary outgrowths from the surface of the endometrium, underlying which is a spot of infiltration. The papillæ may entirely fill the uterus and cause marked enlargement of the organ. The uterus becomes soft and boggy. As the cancer grows and sloughs a septic endometritis occurs, and pelvic lymphangitis and salpingitis are common sequelæ.

Symptoms.—About three-fourths of the women are past the menopause. The first symptom is sometimes bleeding, sometimes a watery discharge. This may appear as a spotting of the clothing, or a rather sharp hemorrhage may occur. If the patient is menstruating, the menses are increased, and shortly she has intermenstrual leaking of blood. The uterus resents the presence of the growth, and irregular uterine cramps are often observed. Some patients complain of lancinating pains shooting through the uterus. Cancer of the uterine body produces early in its course symptoms which attract the patient's attention; therefore the cases are seen early. Furthermore, it is of slower progress than cancer of the cervix; and, as the corpus uteri is free from attachments to other organs, extension outward does not occur so soon as in cancer of the cervix. Cancer of the uterine body extends through the lymphatics and not by progressively invading the tubes and ovaries. About half of the women are sterile.

Diagnosis.—Sloughing uterine polypi, sloughing submucous fibromyoma (particularly if cystic), hypertrophic endometritis, retained bits of placenta, tubal pregnancy, uterine sarcoma, tuberculosis of the endometrium, all produce symptoms similar to those arising from corporeal cancer. I shall not attempt a detailed statement of each of these diseases for the purpose of drawing fine distinctions in the gradations of the symptoms. The sole positive test is the microscopic examination of the scrapings secured by a curette

Treatment.—Unless too firmly fixed in the pelvis by glandular involvement, the uterus should be removed by way of the vagina. Recurrence after three years takes place in only about thirty per cent. of the cases. If all the operations could be done in the first few months, recurrence would be rare. In cases too far progressed to admit of a radical operation, the uterus should be curetted and cauterized by the galvano-cautery.

The Operative Treatment of Carcinoma of the Uterus.—This is of two very distinct and markedly differing kinds: those procedures which may be called radical, and those which are solely palliative.

INDICATIONS FOR THE VARIOUS RADICAL OPERATIONS FOR CANCER OF THE UTERUS.—*Cancer of the Cervix Uteri.*—As a general proposition it may be stated that whenever malignant disease of the cervix is discovered and is limited to the uterine tissue a radical operation is indicated. In certain cases the general condition of the patient may be so poor that to subject her to a grave operation would be fraught with too great danger. Advanced lung disease, nephritis, and mitral disease, as a rule, contraindicate ablation of the cancerous uterus. As a converse proposition, it may be laid down that whenever the cancer has extended beyond the uterine tissue, radical work is out of the question. Such extension reveals itself in a greater or less density in the pericervical tissues, fixity of the cervix, and, remotely, glandular enlargements. But these conditions are also brought about by inflammatory lesions, and these latter must be eliminated as causes for the fixity of the cervix before the propriety of a radical operation can be determined. There is a surgical rule, with its corollary, that all operations for cancer shall proceed through normal tissues, and that no radical operation shall be attempted unless the section of the tissues can pass outside the cancerous field: for the scope of any proposed operation is determined not so much by the fact that this or that fraction of tissue is involved in the cancerous invasion as by the tendency of cancer to recur after removal. And the merits of any operation for the relief of this condition are determined by the ultimate results rather than by the immediate. Good ultimate results are not to be expected when the cancer has extended beyond the uterus. And, furthermore, the less the involvement of the uterus itself, the better the remote results following operation. Therefore cancer which is diagnosticated only by the microscope is less likely to recur than that which is revealed by the symptoms which it produces. So, then, the earlier cancer is diagnosticated the clearer the indications for radical operation and the better the results from such operation, both immediate and remote. Even when bimanual examination demonstrates that the uterus is perfectly movable, cystoscopic examination will often show that the cervico-vesical wall is involved. This involvement will cause rounded elevations beneath the vesical mucosa.

The great problem which confronts the surgeon is the determination of the distance, from the cancer field, to which his section of the tissues must proceed. It may be stated that in epithelioma the tissues may be severed closer to the involved field than in adeno-carcinoma. Whether this clinical observation is due to the lesser virulence and slower progress of epithelioma, or to the fact that as a rule epithelioma is usually, because of the nature of its growth, discovered sooner than adeno-carcinoma, I do not know. But it is my belief that epithelioma of the cervix is far less malignant than adeno-carcinoma. However, the rule in operating is to keep as far away from the cervix as possible. There are two routes for operating upon cancer of the cervix the vaginal and the abdominal. And of all cases of cancer of the uterus which come to us for treatment, scarcely ten per cent. can be subjected to any radical operation.

(*a*) *Indications for the Radical Vaginal Operation.*—These are to be found in the immediate mortality and in the ultimate results.

The death rate from vaginal hysterectomy in cancer of the cervix should not be more than five per cent. It is most difficult to determine precisely the ultimate results because so many patients are lost sight of, and the groups of cases falling into the hands of different operators vary so much in the extent of the involvement. Of all cases operated upon by the vaginal route, about sixty per cent. recur within the first year after operation. Of the remainder, not more than twenty per cent. are free from recurrence after five years. And these results are found by those who are thorough masters of technique.

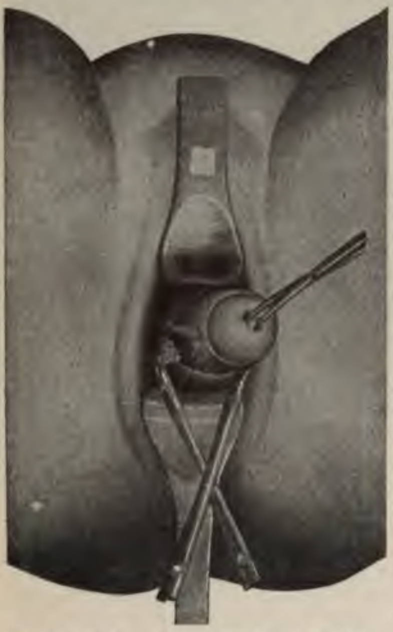

FIG. 4912.—The Forceps Operation for the Removal of a Cancerous Mass through the Vagina. The forceps are shown grasping the bases of the broad ligaments. All the tissues have been cut so as to free the cervix upon all sides. (Pryor.)

Vaginal hysterectomy for cancer of the cervix is an operation which can be rapidly performed and does not necessitate a profound degree of narcosis. It is therefore indicated in those who are aged and who would not for other reasons stand a more severe and prolonged operation. If it is indicated at all, it is in old women, in very stout women, and in those with nephritis or cardiac disease who are suffering from epithelioma. It is the author's belief that a less severe operation gives results equally good remotely and far better immediately. I refer to the high amputation of Dr. John Byrne. And when we reflect that the radical vaginal operation is limited to cervical cancers which have not extended beyond the uterus, while the procedure of Byrne is applicable, and always with benefit, to all cases in which the disease has not actually invaded the bladder or bowel, we can see the greater value of Byrne's operation.

The Operation.—The patient is placed on the back in the lithotomy posture. All necrotic and cancerous tissue about the cervix should be scraped and cut away. The cervix is then closed by a series of heavy silk sutures. These effectually prevent soiling the wound by cancer elements and furnish excellent traction strings. The uterus must be removed *en masse*, and without hemisection and morcellation. The cervix is now entirely circled either by the scissors or by a cautery knife, preferably the latter. The line of incision must be as far away from the cervix as possible; posteriorly at the lowest limit of the pouch of Douglas, laterally near the ureteral lines, and anteriorly at that point beneath the bladder which will just escape entering that viscus. Approximately this cuff of cervical tissue will not be over one-fourth of an inch in depth. The posterior, anterior, and lateral vaginal walls are retracted by assistants, one of whom pulls the cervix down. The operator now carefully dissects up the vaginal cuff by means of toothed forceps and scissors. He next enters the posterior cul-de-sac and extends the lateral margins of this incision by his fingers until the bases of the broad ligaments are reached. Into this posterior opening a gauze pad is introduced to catch fluids and prevent prolapse of the intestines. The operator then turns his attention to separating the bladder from the uterus. This must be accomplished slowly by means of the toothed forceps and scissors; more rapidly by using the index finger to peel up the vesical tissues.

When the vesico-uterine fold of peritoneum has been severed, the lateral borders of the anterior incision are extended by means of the fingers. The uterus now hangs by its lateral supports only. It is important to release the ureters from their associations with the loose tissue about the cervix. This is accomplished by gently shoving the tissues away from the cervix first on one side, then on the other, anteriorly and posteriorly. It may be doubted whether the ureters can be laterally displaced in this manner. I have many times demonstrated it upon the cadaver. This separation of cervix from ureters is still further increased by drawing down the uterus and lifting the bladder with the trowel. While this is being done one index finger is introduced behind the uterus, and the tissues upon one side, then upon the other, are grasped by forceps. The bases of the broad ligaments upon each side are in this manner grasped, together with the uterine arteries. Before the forceps are locked they should be slowly worked outward as close to the ureters as possible and without wounding them. After locking the forceps the tissues are cut close to them up to the points of the forceps (Fig. 4912). These two forceps must also embrace the insertions of the utero-sacral ligaments. The uterus now hangs by the tops of the broad ligaments and by the round ligaments. In order that these may be secured without risk of wounding the gut, the cervix is released and the body of the uterus delivered beneath the bladder (Fig. 4913). The ovaries are drawn out also and held by suitable forceps. A forceps is then applied from above downward upon the right side outside the ovary, with its points lapping the forceps below and internal to it (Fig. 4914). The broad ligament and round ligament are cut and the uterus swings out of the pelvis. It is an easy matter now to grasp the ovarian artery on the left side and remove the uterus (Fig. 4915). If the operator prefers to do so, he may now substitute ligatures of stout tendon for the forceps. These ligatures are passed by the large aneurism needle first to the bases of the broad ligaments and then to the tops. I always ligate the round ligaments separately to guard against their pulling out of the loop of the ligature, thus loosening it and causing secondary hemorrhage. Care must be exercised in removing the forceps lest the stumps slip away from the operator. He should attach a fine artery forceps to the cut end of the artery, and then, as an assistant loosens the large forceps, the operator ties down hard and makes the second knot as rapidly as possible before the elasticity of the stump loosens the first knot. My individual preference is for the use of the forceps exclusively. If this is done, the

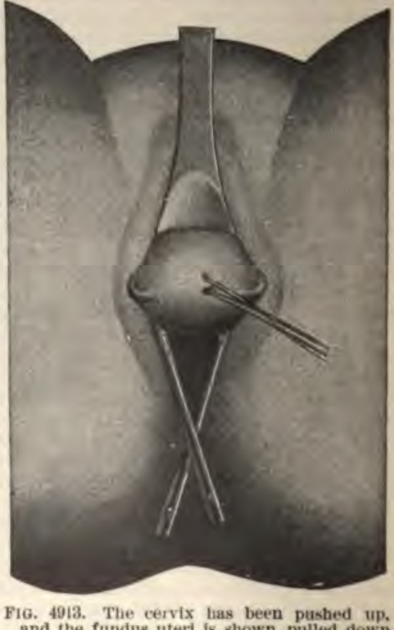

FIG. 4913. The cervix has been pushed up, and the fundus uteri is shown pulled down beneath the bladder. The insertions of the Fallopian tubes into the fundus are shown. (Pryor.)

wound is dressed as in the similar operation for pus. If ligatures are used, these are cut short and the stumps allowed to retract upward. The centre of the wound is then closed by several sutures of tendon, which unite the anterior and posterior cut edges of the vagina.

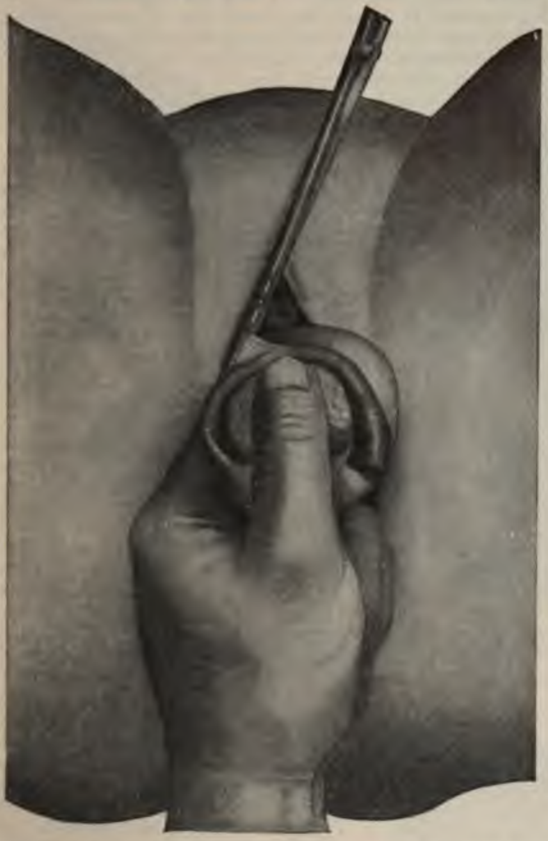

FIG. 4914.—The retractors have been withdrawn and the right ovary and tube are shown grasped by the thumb in front of the fundus uteri. The forceps is grasping the top of the right broad ligament. (Pryor.)

Intra-abdominal pressure will force the peritoneal edges together. A snug drain of iodoform gauze is inserted upon each side up to the stumps of the uterine arteries so as to prevent prolapse of the intestines or omentum, and the vagina is loosely packed with iodoform gauze. If ligatures are used the stumps do not slough, while forceps, if left on, always cause sloughing. It is because of this effect of forceps that I always use them. With ligatures the stumps remain vitalized, while with forceps they come away. Therefore forceps remove more tissue than the ligatures, and broad removal of tissue is what we desire when operating for cancer. The dressings are removed and renewed at the end of seven days.

(*b*) *Indications for Abdominal Ablation of the Cancerous Uterus.*—Inasmuch as the abdominal operation allows the operator to secure the ovarian vessels at the pelvic brim and the uterine arteries outside the ureters; and, further, as by this operation not only the individual lymph glands, but also the lymph channels in the broad ligaments and the greater part of the vagina, if this should be found necessary, can be removed, I always perform this operation for cancer of the cervix if a radical operation is indicated. The operation permits the broadest section of tissue in an uninvolved field with accurate removal of lymphatics, thus complying with the first surgical requisite. It further admits of this being done under a preliminary hæmostasis, and the vessels and lymphatics are severed before the uterus is subjected to any squeezing, thus eliminating the possibility of extrusion of the cancer elements into the absorbents. Furthermore, complications can be better dealt with by this route. The abdominal route permits the surgeon to remove all those structures to which cancer normally extends and in which it has a tendency to recur. In some quarters there is a tendency to apply the vaginal operation to the early cases, reserving for the abdominal operation those in which there are complications, or in which extension of the cancer outside of the cervix has taken place. If cancer were free from the tendency to recur, such a selection might be proper, but by adopting such tactics the operator is neither just to the operation nor to his patient If the abdominal operation is the preferable procedure for accomplishing all that surgery can accomplish for this disease when complications already exist, it is, I believe, still more strongly indicated in the early cases. No one has the right to rob a patient suffering from cancer of even a fraction of a per cent. of immunity from recurrence. In all cases it is the surgeon's duty to do the most radical operation possible, provided this complies with the surgical and anatomical requirements of the case and does not carry a prohibitive mortality. A woman with early cancer has a greater right to a radical operation than one with the disease in a later stage, for her chances of recovery and of acquiring immunity against recurrence are greater.

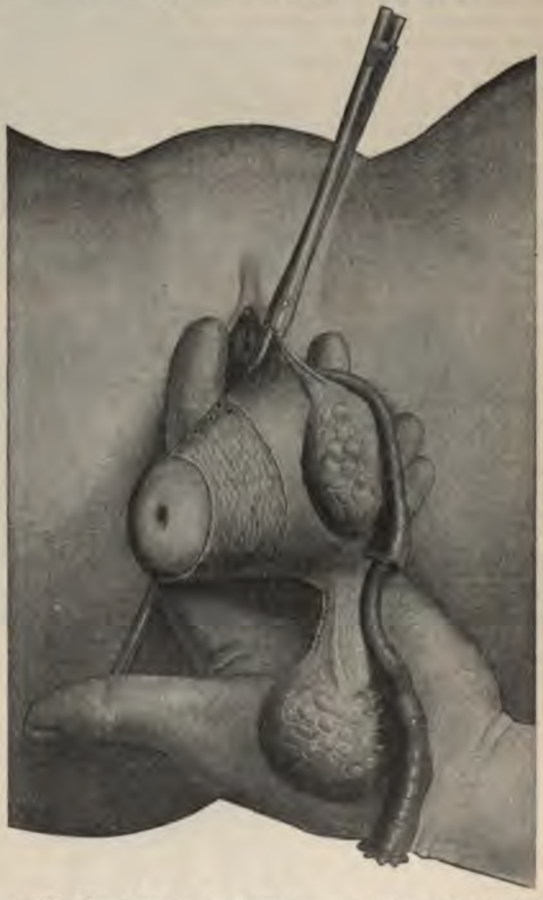

FIG. 4915.—Upon cutting the uterus loose upon the right side, it is made to swing entirely out of the body, so that its posterior surface presents itself, and the forceps is shown grasping the top of the left broad ligament, the last pair of forceps to be applied. (Pryor.)

The operation has been before the profession for too short a time justly to estimate the ultimate results. It has been performed by me thirty-four times with three deaths, 8.8 per cent. mortality. In no case in which the parametrium was not already involved has there been recurrence as early as at the end of one year. The first operation was done five years ago, and the patient is still alive, free from recurrence. In the three fatal cases the causes of death were respectively angina pectoris due to arteriosclerosis, nephritis, and endarteritis obliterans. An extended report will be made at a future date. Enough has been said here to furnish reasons for the procedure.

The Operation. The Vaginal Stage.—The uterus is curetted and all cancerous spots are cut away. The cervix is then thoroughly roasted with the dome-shaped cautery. The vagina is now cleansed, and a self-retaining catheter introduced and left open to drain the bladder. This stage has been conducted by the first assistant, who now resterilizes his hands. The patient is then placed in position for laparotomy.

The Abdominal Stage.—A median incision is made from the pubes to the umbilicus. It is necessary to go through the pyramidalis muscle down to the pubic cartilage. If the woman be fat, the umbilicus is removed and the incision extended above this. Upon entering the abdomen the table is lowered into the exaggerated Trendelenburg position. The intestines and omentum are gently taken from the pelvis and placed in the abdomen, and the sigmoid flexure is straightened out. The curvature of the loins upon each side of the spine above the pelvic brim is carefully and accurately filled with gauze pads, and other pads are used so as to make a complete dam across the body at the upper end of the incision, holding the intestines back. The table is now raised so as to be almost horizontal. A careful survey of the field is made, but rapidly. I then pick up the ovarian vessels of one side at the pelvic brim before they cross the external iliac artery and ligate them. Provisional ligatures are then applied near the ovaries. The same is done on the other side. The broad ligaments between are cut close to the first ligatures, which latter are cut short. The round ligaments are seized by artery forceps, drawn out, ligated close to the internal inguinal rings, and cut short. Beginning upon the right side the peritoneum is split upon a director from the point of the first cut, along the pelvic brim below the internal iliac artery, to the vesico-uterine fold. This having been done on each side and the two cuts united by a third across the bladder at the vesico-uterine fold, the peritoneal covering of the organs to be removed is severed at all points except posteriorly. Using the fingers only, I push (on one side at a time) the lower flap of peritoneum, in which should be the ureter, away from the upper, feeling for the pulsation of the common iliac artery. This blunt dissection proceeds down into the pelvis until the internal iliac is found. At a point over this, about one-half an inch below the bifurcation of the common iliac, the internal iliac is carefully exposed. For this purpose I use toothed forceps and Sims' blunt vesico-vaginal scissors. It will be seen that the artery is accompanied, as a rule, by one vein, which usually lies below it; sometimes it is accompanied by two veins. The aneurism needle is passed unthreaded around the vessel from within out. It should then be threaded with a chromicized tendon one-sixteenth of an inch in diameter, perfectly round and tested. This is drawn around the vessel. The first knot is made with one turn of the strand and tied. It should be tied slowly without lifting the artery, and by a pressure of about two pounds so as to approximate without rupturing the intima walls. The second knot is carefully tied. If pulsation is found below the ligature another is passed and tied. The ligatures are cut short. To one side of the bladder, beneath the horizontal pubic ramus, the loose areolar tissue and fat are spread apart by the fingers so as to expose the white obturator nerve. The needle carrying a fine tendon is passed around the vessels, and they are ligatured. The variations of the obturator artery must be borne in mind at this stage. The dissection described above and the ligations are repeated upon the other side. These eight preliminary ligations have cut off all blood supply through the ovarian, round ligament, uterine, superior vesical, pubic, obturator, gluteal and sciatic arteries, and sometimes through the ilio-lumbar. The field of operation will be bloodless except from severed veins and anastomoses low down in the pelvis. I next dissect out the ureters to the point where they pass beneath the uterine arteries, ligate these arteries at their origins from the internal iliacs as a precaution, and trace the ureters forward well up to their insertion into the bladder. All fat in the obturator foramina about the upper third of the vagina and between the iliac vessels, together with all glands which are visible, are now removed. Particular attention is paid to the bases of the broad ligaments and obturator foramina, to remove all lymphatics and glands. While the ureters are held up, the operator dissects the bladder from the uterus and upper half of the vagina. In freeing the ureters they should be dissected entirely away from the peritoneal flaps, otherwise much fat will be left clinging to them. I usually at this stage ligate, as a precaution, the superior vesical and other anterior branches of the internal iliac close to the main artery. The uterus is now held high up so as to put the vagina and utero-sacral ligaments on the stretch, and the vagina and utero-sacral ligaments, with their peritoneal covering, are circled by the scissors below the upper third of the vagina. Deep down in the pelvis the erectile tissue of the vagina will be found bleeding. This is grasped and ligated. All loose bits

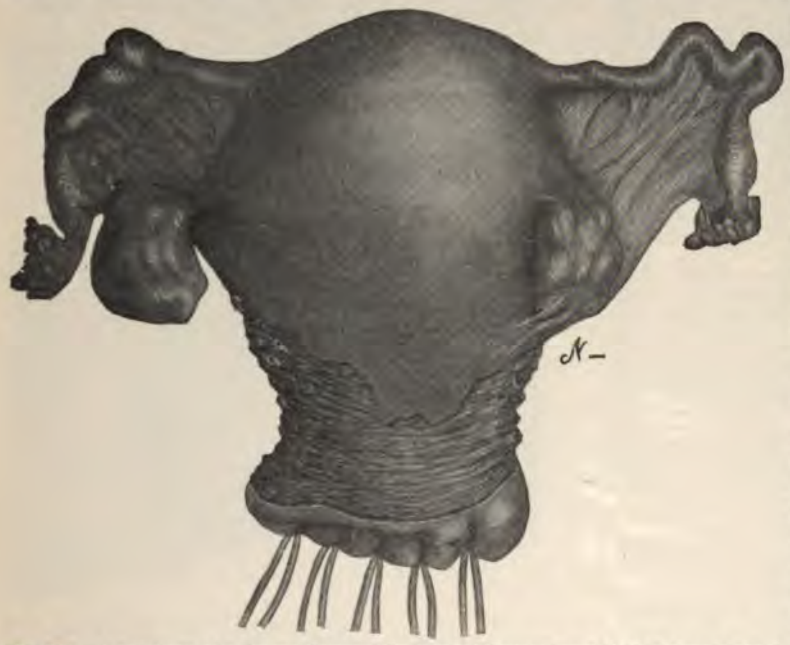

FIG. 4916.—A Specimen of a Uterus Removed by Vaginal Hysterectomy (by the forceps operation). The cervix, which was the seat of a cancerous growth in an early stage, is shown closed by heavy silk sutures, which were employed to prevent soiling of the field of operation by the contents of the uterus. (Pryor.)

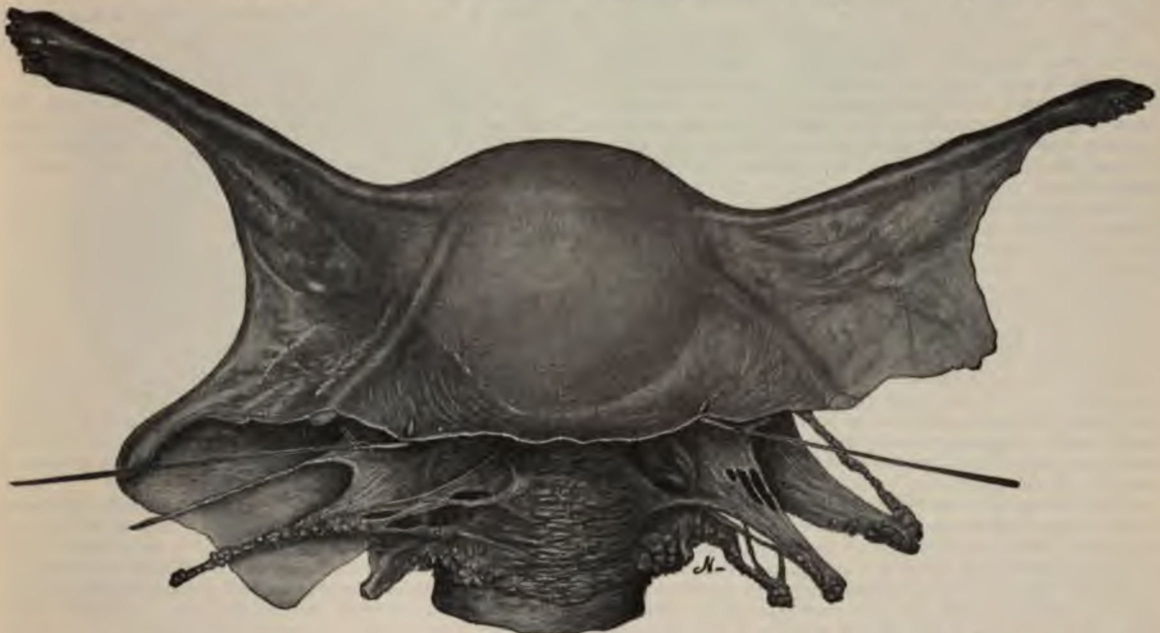

FIG. 4917.—A Second Specimen of a Uterus which was Removed, by the Author's Method of Abdominal Ablation with Preventive Hæmostasis, on account of Cancerous Involvement of the Cervix. The vaginal cuff and the lymphatics surrounded by fat are well shown. The drawing is from life, the specimen having been preserved in alcohol. (Pryor.)

of fat above the bases of the broad ligaments, between the iliac arteries and between the severed utero-sacral ligaments, are picked out. If the venous bleeding is troublesome the patient may be lowered into Trendelenburg's position while the operation is being completed. The vagina is held open by two forceps and several rolls of gauze are introduced, their ends projecting above the vagina. The ureters are returned to their beds and the peritoneal flaps adjusted by interrupted sutures as far as possible. Upon each side a suture should pass through the round ligament, which is stout, and then through the fold of peritoneum at the sides of the rectum. It is unnecessary to suture the rectum to the bladder, as they will fall together (Fig. 4917).

The field of operation having been closed out, the retaining pads are removed, the sigmoid flexure and the omentum are brought down, and the abdominal wound is closed. The wound is dressed and the patient placed in the lithotomy position. The vaginal dressings are examined and adjusted. In doing this the livid hue of the vulva and buttocks, due to the ligation of the internal iliacs, will be noticed. The patient is given a high enema of one quart of warm saline solution containing two ounces of whiskey. This is done by dropping the head of the table and not by inserting a long rectal tube. If shock is present it is to be treated as detailed elsewhere. The vaginal dressings are removed and renewed at the end of ten days.

High Amputation.—Indications.—In the author's opinion, the few cases which cannot stand the strain of the perfected abdominal operation will receive a better ultimate result, with less immediate risk, from the operation now about to be discussed than from vaginal hysterectomy. It has been shown that cancer of the cervix has little tendency to ascend above the internal os. It is, therefore, in operating for cancer of the cervix, not necessary to proceed above the internal os. The true indication is for a removal of the upper third of the vagina and the parametric tissue and glands outside the ureter. This is accomplished only by laparotomy, never by vaginal hysterectomy. Vaginal hysterectomy may then be termed an operation of purely local application, such as is amputation of the mamma without muscular and glandular extirpation. It will be seen how thorough a procedure is the high amputation with cauterization

The Operation.—The patient may be in either the lithotomy or the Sims position. I prefer the former. Wooden retractors are preferable. If metal ones are used they must be frequently cooled by iced water. The uterus is curetted and the cervix amputated by Sims' method. The diverging tenaculum is then introduced into the uterine canal and the excavated stump drawn down. A sharp-pointed knife, curved on the flat, is inserted into the tissues, and a hollow cone of tissue is removed. The tenaculum is again introduced and another cone removed. This is repeated until the uterus is excavated, so that upon digital examination nothing remains of the cervix but a thin shell of tissue. The resulting cavity leads by a broad opening into the uterine cavity, and there should be no constriction at the former site of the internal os. The wound made by the successive applications of the knife should open downward as a cone with a broad base.

The operator now introduces the dome-shaped electrode, cold, as high up as the fundus uteri and turns on the current sufficiently to heat the knife white. It is held in one position until all bleeding stops and the adjacent tissues are charred black. This takes about fifteen minutes. The heat radiates in all directions, and while being applied frequent applications of gauze, wrung out in iced water, are to be made to the vaginal retractors. The staff of the cautery must, of course, not be allowed to touch the retractors. After thus cooking the corpus uteri the current is turned off and the cautery is withdrawn as far down as the cervix. If it is arrested at this point it is because the cervix has not been properly excavated by the knife. The cautery is next held within the cervical excavation and the current turned on. Not only should the heat convert the remains of the cervix into a carbonized mass, but the grayish tint assumed by the adjacent vagina shows that it, too, is destroyed. As the cervical cavity has been thinned out, less time is required to destroy it than in the case of the corpus. In fact, the corpus is so thick that the area of carbonized tissue protects it, and I have never seen it all slough away. The application of the cautery to the cervix must be most thorough. It is more often done incompletely than in an adequately thorough manner. It is almost needless to say that the heat produces a sterilized wound. It must also undoubtedly destroy the pericervical tissues, particularly the less vitalized cancer cells, throughout quite an area.

The wound is not packed, but when a discharge begins the patient is put on mild antiseptic douches. Surprisingly little pain results. Advanced cases are no bar to the operation. It exerts a retarding effect in all cases of cancer of the cervix uteri. Instead of removing the tissues by knife and then applying the cautery, the entire operation may be performed by the cautery knife, but more slowly.

The Treatment of Advanced Carcinoma of the Cervix Uteri —This embraces removal of all sloughy and necrotic tissue, so far as is possible, in order to secure local cleanliness. During the application of the curette and scissors frequent digital examinations should be made to determine the thickness of the tissue remaining around the cavity. Should the peritoneal cavity or the rectum or bladder be entered, the patient's danger is much augmented. If the peritoneal cavity is entered it should be drained, not sutured; and if the bladder or rectum be wounded suture is useless, for cancerous tissues will not unite, and consequently the organ entered must be kept empty in the hope, usually vain, that the opening will close. If the peritoneal cavity is entered the drainage is to be effected by means of a catheter; but if the rectum is penetrated a rectal tube should be used for this purpose. In cases in which no damage has been done to any adjacent organ, after all sloughing tissue has been cut and scraped away, the bleeding is to be checked by the application of the galvano-cautery. This cauterization will produce a superficial slough, which in a few days will separate, leaving a granulating wound. Further removal of tissue can be secured by the following method of treatment: Thin circular pieces of cotton, about one-half an inch in diameter, are squeezed out in an aqueous solution of chloride of zinc of twenty-per-cent. strength. These are packed snugly all around the cervical cavity so as completely to fill it. Over the whole the vaginal vault is packed with large pieces of cotton wrung out in a saturated solution of bicarbonate of soda. This is essential, because as the serum percolates through the zinc-laden cotton it would cauterize the vagina unless caught and neutralized by the soda solution.

The dressing is left in for two days. Upon its removal the cervical cavity will be found lined by a grayish slough. Two days later this can be picked away by forceps. In this way repeated sloughs can be produced and removed. When the physician is not provided with an actual cautery, this treatment by means of caustic solutions can be begun after the operation for removal of the cancerous outcroppings, as soon as the bleeding has ceased. I have tried all the various methods of local treatment and find this the simplest and most efficacious. Immediately upon the completion of this treatment the patient should be put on thyroid extract. I have seen good results follow in many cases, and in no case have I failed to see the disease arrested, for a time at least. The thyroid should be pushed to the point of tolerance.

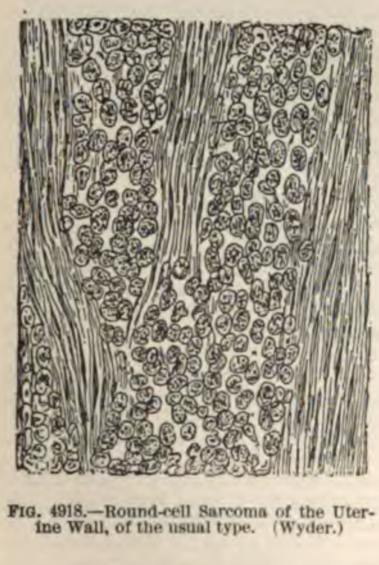

FIG. 4918.—Round-cell Sarcoma of the Uterine Wall, of the usual type. (Wyder.)

Pain in carcinoma must be relieved by opiates. At first, codeine suppositories are employed, then the stronger preparations of opium.

Section of the spinal nerves I cannot recommend.

Hemorrhages occurring during the course of cancer are best treated by tamponade with vinegar-soaked cotton.

As the pelvis becomes blocked with cancer masses, obstruction of the bowel may occur. It is then the surgeon's duty to perform colostomy.

The rapidity of growth of a cancer of the uterus may be checked by ligating the blood-vessels which nourish it. The plan which I adopt—and which, I believe, I was the first to advocate—is to ligate, through the median abdominal incision, the ovarian, the internal iliac, and the obturator arteries. When the operation is completed, a short incision is made into the peritoneum—one just long enough to enable the operator to reach the vessels. After completion of this operation the cancer masses are scraped away through the vagina, and every facility is offered for the freest escape of the necrosing tissue. The patient is put upon thyroid extract and tonics. By this treatment life is much prolonged and suffering diminished.

Other Methods of Treatment.—Serum therapy has been employed in a number of cases and in various forms, but without benefit. The cases reported to be relieved have upon critical examination proved worthless for statistics.

Owing to the inaccessibility of the cancerous uterus, the *x*-ray treatment can be carried out only with difficulty. It is as yet in a purely experimental stage.

Injections, into the cancer mass, of various drugs, such as methylene blue and alcohol, have been employed, but with little or no benefit.

SARCOMA OF THE UTERUS.—*Frequency.*—Von Franqué, Gualt, Gessner, and Roger Williams, in analyzing 19,263 uterine tumors, found sarcoma but 44 times. In 1894 J. Whitridge Williams, of the Johns Hopkins Hospital, could find in literature reports of but 144 cases, in 34 of which the cervix alone was involved. The disease is undoubtedly more frequent than these reports would indicate, being often classed as fibromyoma in its beginning, and as cancer after ulceration has set in.

Age.—Sarcoma of the uterus is most frequent before the menopause. Gusserow, in analyzing 73 cases, found 52 under fifty years of age. The youngest child in which it has occurred, according to the report of Holländer, was but seven months old.

Fertility.—About forty per cent. of sarcomatous women are sterile, and in those who bear children the average to each is 1.46 children.

Pathology.—The disease may occur as either a spindle-cell or a round-cell sarcoma. It may involve the mucous membranes of the organ or its parenchyma.

Sarcoma of the Cervix. The cellular invasion becomes so great as to produce knobbed projections into the vagina. The growth is hard and nodular at first, but after a time it sloughs. Or there may be "grape-like" polypi hanging from the cervix. These are always multiple, oval in shape, and yellowish-brown in color, and about one-third of an inch in diameter. They are translucent and easily broken, affording escape to a thick fluid. They strongly resemble a portion of a hydatidiform mole. These projections are composed of epithelium overlying layers of sarcoma cells, with clear spaces between.

Sarcoma of the Corpus Uteri. The surface of the uterine cavity is nodular but smooth, but may be rough after ulceration begins.

Symptoms.—The growth causes a general enlargement of the tissues in which it arises. The uterus is increased in size, is movable until the surroundings become involved by an extension of the new growth, is insensitive, and in all respects resembles either fibromyoma or cancer.

But one form of sarcoma is at all clinically easy of recognition, viz., the "grape-like" form of cervical sarcoma. Even the microscopic diagnosis is often most difficult, and yet upon the microscope alone does a positive diagnosis rest. The subjective symptoms are at first those of fibromyoma and later of cancer. Sarcoma, however, grows more rapidly than fibromyoma, and the metrorrhagia is in disproportion to the size of the growth. If a nodule projects into the vagina and is seen early, it will be found to present a smoother aspect than cancer and to be more friable than fibroid. The sarcomatous nodules are readily broken into, while submucous fibromyomata, which can be palpated through a dilated cervix, are firm. Sarcoma occurs usually before the menopause, while cancer is most common later in life.

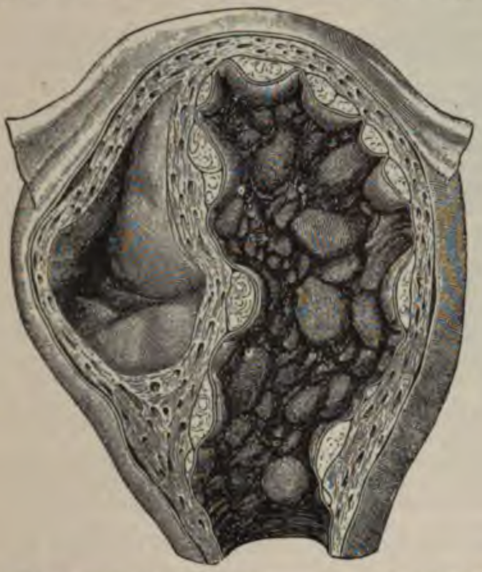

FIG. 4919.—Sarcoma of the Uterine Mucosa, with a Blood Cyst in the Uterine Wall. (Péan.)

That fibromyoma not uncommonly breaks down into sarcoma must be remembered.

Treatment.—As soon as the diagnosis is made, and if the disease has not progressed too far, abdominal removal of the uterus, ovaries, and tubes is indicated, and should be accomplished by a broad dissection. Although the uterus may be small enough to admit of its removal by the vagina, this should not be attempted because of the exceeding vascularity and friability of these growths. In the removal of the organs by way of the abdomen, the vessels should be ligated at some distance from the uterus so as to add to the prognosis the benefits which such a procedure is known to secure in the treatment of sarcomata.

The injection of Coley's fluid, so successful in the treatment of sarcoma on the surface of the body, is contraindicated in sarcoma of the uterus, owing to the certainty that a fatal sepsis will result.

Even in cases too far advanced for a successful radical operation, the internal iliac, ovarian, and obturator arteries should be ligated.

DECIDUOMA MALIGNUM.—Called also "sarcoma choriocellulare," "syncytioma malignum," "sarcoma deciduocellulare," etc.

Definition.—Deciduoma malignum, first described by Sänger in 1888, is a malignant neoplasm of the uterus occurring only with or after conception.

Frequency.—The disease is about as frequent as sarcoma, 132 cases having been reported up to January, 1902.

Age.—The average age in 124 cases was thirty-two years, but 112 of the 124 cases occurred after the forty-fifth year. The disease is unlike epithelioma in respect of the age at which it occurs.

Fertility.—In 90 of the cases reported the pregnancies are given, and the women averaged 4.2 conceptions. The disease is unlike sarcoma in this regard.

Pathology.—We have not space to discuss the various theories regarding the nature of this interesting disease. The reader is referred to the exhaustive article by Frank Pierce in the *American Journal of Obstetrics* for March, 1902, and also to the article on this subject in the preceding volume of the HANDBOOK. It is my belief that the uteri in which these growths develop are already sarcomatous before the occurrence of the pregnancy which always accompanies deciduoma. The rapidity of the growth after delivery or abortion is not strange, but conforms to the progress of all malignant growths about the pregnant uterus. Microscopically, the growth consists of irregularly shaped protoplasmic masses, of deep color, nucleated, and resembling the syncytium of a chorionic villus; and, in close relation with these, are the cellular masses called Langhans' cells (Fig. 4920).

The growths develop rapidly, the nodular masses soon appearing in all parts of the uterus and pelvis. Metastases are commonly present in fatal cases.

Symptoms.—As already stated, the patient, in every case, either is or has recently been pregnant. About forty per cent. of all cases have been preceded by hydatid mole. Therefore in every case of such a mole, deciduoma malignum should be suspected. The disease is also seen to follow ectopic gestation, normal labor, and abortion. The first symptom after delivery is hemorrhage. This does not occur very soon after delivery, as does a post-partum bleeding, but is first seen during the puerperal months or a little later. The hemorrhages are severe, repeated, and rapidly recurrent. Profound anæmia soon occurs. Soon after the first bleedings a profuse discharge of muddy watery fluid occurs, and is seen when the patient is not bleeding. Metastases occur in the vagina and such distant organs as the lungs, but seldom in the liver.

The patient usually has an elevation of temperature, and an increase in the pulse rate proportionate to the hemorrhages. Pain is not an early symptom, but occurs when the pelvic nerves become pressed upon by the mass.

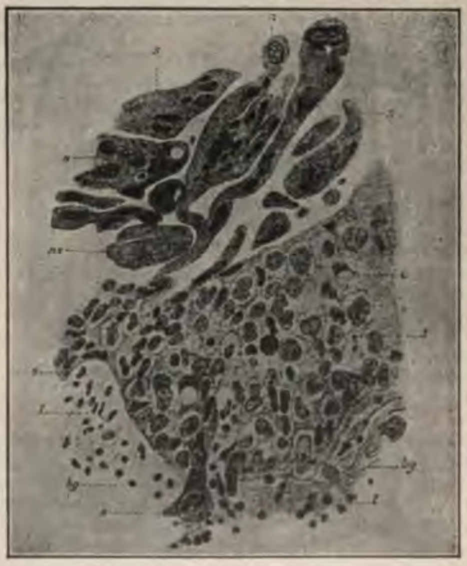

FIG. 4920.—Syncytioma. *s*, Syncytium; *ns*, necrotic tissue; *l*, leucocytes; *bg*, connective tissue; *c*, cellular (decidual) part of the tumor; *n*, nuclei in the syncytium. (Marchand.)

Upon examination the enlargement of the uterus is first noted. If the nodules have penetrated the uterine wall, the peritoneal surface of the uterus will be found nodular. The cervix is commonly dilated enough to admit the examining finger, upon introducing which the friable spongy mass may be felt. It bleeds readily.

Whereas usually the primary tumor is in the uterus, occasionally it will occur first in the vagina.

Deciduoma malignum is of more rapid growth than any other neoplasm.

The patient dies from anæmia, hemorrhage, or metastatic complications.

Diagnosis.—In every case of labor or abortion, in which late hemorrhages occur, an immediate intra-uterine examination is indicated. If a rough surface is found, and if, after the roughnesses have been removed, they soon reappear and are accompanied by hemorrhage, this disease must be suspected and the microscope appealed to. The very frequent association of hydatid mole with deciduoma must compel keen watchfulness in all cases of such moles.

Marchand found that eleven patients died in less than six months, and five within a year, while only one lived as long as three years. When the disease occurs primarily in the vagina, the progress is not so rapid.

Treatment.—As soon as a diagnosis is made, if the disease be limited to the uterus, total abdominal hysterectomy should be performed according to the technique laid down for cancer.

William R. Pryor.

UTERUS, DISEASES OF: NON-MALIGNANT NEW GROWTHS.—The benign neoplasms affecting the uterus may be divided into two groups according to their histogenesis:

1. Those originating in the uterine parenchyma—fibroma, myoma, and adeno-myoma.
2. Those originating in the remains of embryonal structures—cysts of the Wolffian duct and cysts of the Müllerian duct.

Relative Frequency.—The uterus is extremely prone to invasion by non-malignant neoplasms, especially fibromyomata. Thus, in W. R. Williams' series of 2,649 uterine new growths 883 were myomata. In Gurlt's series of 4,115 uterine neoplasms 481 were fibro-myomata.

The relation of non-malignant new growths of the uterus to malignant ones is 40.62 per cent. of the former to 58.38 per cent. of the latter. The non-malignant glandular tumors occur with much less frequency.

Of the neoplasms originating in the uterine parenchyma the fibromata and myomata are recognized as being of identical structure, varying only in the relative proportion of the fibrous and muscular elements present. They are therefore grouped under the common head of myoma.

Etiology.—The etiology of myomata, in common with other neoplasms, is not as yet understood. These tumors usually develop during the period of sexual maturity, seldom if ever before puberty (never according to Gusserow), and they very rarely appear after the menopause. They are more common in the negro than in the white race, and it would seem from many case-histories that heredity is a predisposing factor.

Myomata may be said to be in general growths of the menstruating uterus, since their greatest activity of growth is during this period. They frequently atrophy after the menopause.

Morphology.—According to their situation uterine myomata are divided into those of the body of the uterus, those of the cervix, and intraligamentous tumors. Those of the body of the uterus are again divided into subserous, interstitial, and submucous tumors.

Strictly speaking, the subserous variety should include only those tumors which are sheathed with peritoneum and lie free in the abdominal cavity, attached to the uterus only by a pedicle. Submucous tumors should include only those which hang free in the uterine cavity, are attached only by a pedicle, and have no muscular coat. All intermediate forms should be designated as interstitial. Ordinarily, however, those growths which project into the abdominal cavity and which originate in the subperitoneal layer of the uterine muscle are called subperitoneal, and those projecting in a like manner into the cavity of the uterus, whether or not they be covered with muscle, are known as submucous tumors.

Besides these situations the tumor may be confined between the layers of the broad ligament, the intraligamentous form.

Subperitoneal myomata are single or multiple nodules which, from being primarily interstitial, have secondarily become subperitoneal. They are closely covered by the peritoneum and are attached to the uterus by a broad pedicle. The tumor is immediateln surrounded by loose connective tissue. Torsion of the pedicle may occur with entire detachment of the tumor from the uterus. Through inflammatory adhesions the growth may become attached to surrounding structures, or it may remain as a migratory tumor in the abdominal cavity. The intraligamentous myoma is a subperitoneal growth arising from the lateral wall of the uterus or from the supravaginal cervix. It pushes apart the peritoneal folds of the broad ligament, and grows either beneath or between them, being thus extraperitoneal. The intraligamentous myoma from its position may exert pressure upon important structures and cause grave symptoms. Usually firmly bound down and in close relation with the pelvic vessels and nerves and the ureters, the intraligamentous myoma is extremely difficult of access.

Interstitial myoma, the primary type of all myomata of the uterus, occurs as circumscribed tumors lying in the uterine wall and attached to the myometrium by a loose connective-tissue capsule. In some cases the capsule cannot be differentiated, and in other rare cases there occurs a diffuse myoma of the myometrium. Submucous myomata are those in which the greater part of the nodule projects into the cavity of the uterus as a polypus, having a pedicle of varying lengths. The tumor is soft in consistence, usually has a free blood supply, and is covered with loose connective tissue and to some extent with endometrium. The pedicle is formed of dense fibromuscular tissue, with a sheath of mucous membrane, and contains a few blood-vessels.

The submucous myomata may become adherent to the neighboring uterine wall by inflammation.

Cervical myomata are of rather infrequent occurrence, forming from five to six per cent. of all uterine myomata. They develop either from the infravaginal or from the supravaginal cervix, the former growing usually into the vagina, the latter into the retrocervical connective tissue.

Myomata in general are multiple; sometimes they are single oval nodules, usually sharply circumscribed and surrounded by a capsule of loose connective tissue. The growth may be hard or soft, is whitish or pinkish in color, and may vary greatly in size. Arising in the myometrium, the tumor develops in the direction of least resistance, and eventually assumes one of the positions described above. On section the tumor is glistening and may be of homogeneous structure, though more frequently it is divided into lobules by septa of dense fibrous tissue which give it, on section, a striated appearance. The consistence of the tumor varies from the soft pure myoma to the hard fibromyoma and the almost stony pure fibroma. The blood-supply of the tumor substance is poor, being limited to a few small vessels. The connective-tissue capsule is freely supplied with large arteries and venous sinuses.

Histologically, myomata are formed of a muscular tissue the cells of which possess the spindle-shaped nuclei and the homogeneous protoplasm characteristic of unstriped muscle in other localities. The muscle bundles are separated into lobules by septa of dense connective tissue. In certain cases this dense connective tissue forms the basis of the tumor. In all cases mast cells of various shapes—long, spindle, ovoid, or round—are present in varying numbers, occurring mostly in the neighborhood of the blood-vessels.

The myometrium undergoes an associated true hypertrophy in interstitial and submucous myomata, as well as in some cases of subperitoneal myomata. The uterine walls become thickened and the cavity is distorted and enlarged. The endometrium also undergoes hypertrophy in myomata, some cases showing a hyperplasia of the gland substance, some a thickening of the stroma, some both.

In the presence of a large myoma the Fallopian tube frequently is the seat of a salpingitis, while the ovary almost always undergoes a hyperplasia of the connective tissue, with some degeneration in the neighborhood of the blood-vessels.

The myoma itself very frequently undergoes pathological change. Among the conditions which may result are atrophy, calcareous infiltration, fatty degeneration, amyloid degeneration, maceration, myxomatous degeneration, inflammation, necrosis and gangrene, thrombi, telangiectatic change, sarcomatous degeneration, and the association of carcinoma.

Atrophy results when the myoma undergoes a part of the general physiologic involution of the genital system following the puerperium, the menopause, or after a bilateral oöphorectomy. The muscle cells decrease in number and the relative proportion of fibrous matter is greatly increased, the tumor being converted into a dense structure of practically cicatricial tissue. Occasionally the growth entirely disappears.

Calcareous infiltration may take place locally or generally. It occurs with advanced atrophy, and in some instances the entire myoma is converted into a calcareous mass by the deposition of lime salts—the so-called womb stone. Bony changes or osteomyoma have also been described.

Fatty degeneration occurs in the muscle fibres and is frequently found in the interstitial and submucous tumors, rarely in the subperitoneal. It occurs after pregnancy and also in those growths which have a dense consistence.

Amyloid degeneration of the tumor alone or of the tumor and the myometrium may be found, but this change is of rather rare occurrence.

Maceration of the tumor may occur as a result of an acute disturbance of the circulation; the tissue becomes soft, infiltrated with blood, and finally assumes a brownish-green color. Myxomatous degeneration occurs frequently, more especially in the intraligamentous variety, and rarely in the subperitoneal variety. It begins with softening, the consistence of the tumor becomes cystic, and finally cavities filled with mucoid substance are formed in the centre of the nodule. Tumors undergoing myxomatous degeneration increase rapidly in size.

Inflammation, necrosis, and gangrene of myoma are frequent, the pathogenic organisms entering through the vagina, or, in the case of subperitoneal myoma, through the intestines.

Thrombi may be found in the blood-vessels, especially following torsion of the pedicle and incarceration.

Telangiectatic change is an occasional condition. The tumor tissue is infiltrated with numerous dilated blood-vessels. In some instances the lymph vessels may undergo dilatation, as a result of which numerous cystic cavities lined with endothelial cells (cystic myoma) are formed.

Malignant Degeneration.—Myomata may undergo a sarcomatous metaplasia, or they may be associated with carcinoma. The transition into sarcoma is thought to be due to a direct change of the muscle cells into sarcoma cells. The tumors increase rapidly in size, undergo necrotic change, and the sarcoma infiltrates the surrounding structures.

The association of carcinoma with myoma is thought to be due to an inversion of the polypoid growth of the mucous membrane into the myoma tissue, or it is a carcinoma developing from the glandular elements of an adenomyoma, or there may possibly occur a true metaplasia of the myoma elements into carcinoma.

The *symptoms* of myoma uteri are hemorrhage, pain, intermenstrual discharge, and pressure symptoms. Hemorrhage is present in the great majority of myomata of all kinds; it occurs as a menorrhagia or a metrorrhagia. There may be an increase in the menstrual bleeding, or the hemorrhage may appear at irregular intervals, following unwonted exertion, coitus, etc., or it may occur as a continuous bleeding from the uterus. Usually the hemorrhage is not alarming in amount, and can readily be controlled by rest in bed and the exhibition of astringent drugs, as ergot. In some cases, however, a profound and sometimes fatal anæmia is produced. The hemorrhage is independent of the size of the tumor, but varies greatly with its position and variety. Thus the bleeding is most severe in the uterine polyp, less marked in the interstitial variety, and least in the subperitoneal form. Again, the hemorrhage is more severe in the soft and œdematous myomata than in the dense fibrous forms. The hemorrhages are caused by the increased area of the endometrium, due to the uterine enlargement and to a hemorrhagic endometritis set up by the irritating presence of the tumor.

Pain is a more or less constant symptom. It varies greatly in character and degree. It may be referred to the occiput, the top of the head, or the sacral region. Bearing-down and dragging sensations in the pelvis and expulsive contraction of the uterus are frequent. The pain is always increased during the menstrual periods, and during the early growth of the tumor it may be present only at these periods; later, it becomes constant.

Intermenstrual discharge, the result of a profuse secretion from the utricular glands, occurs between the hemorrhages. The secretion is usually thin and serous, and may be very profuse. In some cases in which hemorrhage is not marked its place seems to be occupied by this serous discharge. Dysmenorrhœa is a common symptom.

Pressure may cause many mechanical disturbances: constipation or mucous diarrhœa, hemorrhoids, difficult, painful, and frequent micturition. Pressure upon the ureters may cause hydronephrosis and eventually death from uræmia. Pressure upon the pelvic nerves may cause neuralgia or even paralysis of the legs.

Fatty degeneration and brown atrophy of the heart are sometimes noted. Thrombosis and embolism are frequent complications, especially in the telangiectatic myomata. This is probably the cause of some of the sudden deaths following operations upon these tumors.

The *diagnosis* of myoma is made from a study of the symptoms and a physical examination of the patient. The symptoms described above, while characteristic, are in no sense pathognomonic, and the diagnosis usually depends upon a careful physical examination. In tumors large enough to be palpated through the abdominal wall, the dense consistence and irregular outlines of the myoma may be noted. Bimanual examination detects the general enlargement of the uterus, the outline of the tumor and the consistence, hard and dense, fluctuating or semifluctuating, according as the myoma is hard, œdematous, or cystic. The growth is found to be attached to the uterus and movable with it. Sometimes in the case of a small interstitial myoma a slight elevation or merely an area of induration may be felt. The presence of such an area, together with the increased length of the uterine cavity, is strong evidence of the existence of a small myoma. The symmetrical enlargement of the uterus which occurs in some cases is more difficult of diagnosis.

Differential Diagnosis.—Myomata must be differentiated from pregnancy, ovarian cysts, retroflexion of the uterus, etc. The separation of a myoma from pregnancy is usually easy. The irregular hemorrhage, the mammary changes, the nausea, and the skin pigmentation may be present in both. The absolute signs of pregnancy—the fœtal movements and heart sounds, the bluish discoloration of the ostium vaginæ, and the soft cervix—will usually establish the diagnosis. Should the pregnancy be complicated by myoma the difficulty of diagnosis is much enhanced.

The differentiation between ovarian cysts and myoma is not difficult, and a mistake is not at all serious, cœliotomy being indicated in both conditions.

Small myomata in the posterior uterine wall may be mistaken for retroversion. This mistake may be avoided by feeling with the abdominal hand the fundus uteri in its normal position and by the passage of a sound.

Treatment.—Operative treatment is usually demanded in a case of myoma. Palliative measures are of little value, and are indicated only where serious degenerative changes in the heart, lungs, or kidneys preclude the possibility of surgical interference. Operation is indicated because of the danger of the accidents possible to myoma, viz., inflammation and infection, malignant degeneration, etc., and because of the very faint hope of spontaneous cure and atrophy of the growth following the menopause. Should the patient be a young woman with a small tumor, and desirous of maternity, the expectant treatment is justifiable. The patient should be warned that the tumor may interfere seriously with labor, may cause her to abort, and may grow with great rapidity during pregnancy. On the other hand, there is a possibility that the tumor may disappear after labor. Should the tumor be intraligamentous and of pelvic growth, expectant treatment is not justifiable, as dangerous pressure symptoms may result and labor be certainly obstructed should pregnancy occur. In the case of a woman who has reached the menopause, in whom menstruation has ceased, and who suffers from no serious symptoms, expectant treatment may be tried in the hope that the disease may become quiescent.

Among palliative measures may be mentioned the exhibition of drugs, electricity, and various palliative operations. Drugs have no effect upon the growth of the tumor. Ergot perhaps does good in arresting hemorrhage in some cases, but is of no other value. Electrolysis has been practised by Martin, Engelmann, Keith, and others, but it does no good; and, on the other hand, it may do positive harm by setting up inflammatory adhesions, thus rendering the subsequent operation more difficult.

Thorough curettage of the uterine cavity, by removing the hemorrhagic and chronically inflamed endometrium, is a very efficient means of checking hemorrhage. The bleeding is usually much diminished for several months after this procedure, though recurrence of the symptom almost invariably occurs. Curettage, which may be expected to check hemorrhage and to remove polypi, is indicated in all those cases in which the physical condition of the patient does not warrant more radical measures.

Ligation of the uterine arteries and broad ligaments to shut off the blood supply of the uterus and thus to cause atrophy of the tumor, has been practised. While this operation seems to have done good in some reported cases, it is now used only as a rare palliative measure. Salpingo-oöphorectomy has been of value in many cases. Its dangers are as great as those of hysterectomy, and at the same time it does not remove the disease. It is not available in all varieties of myomata, and is of no value after the menopause.

Of the radical operations salpingo-oöphoro-hystero-myomectomy is the operation of choice in the great majority of cases. The operation is indicated in the presence of large adherent tumors, when radical measures are necessary, and where degenerative or inflammatory changes are present in the ovaries or Fallopian tubes.

Myomectomy is the least mutilating of the radical operations. Its advantages are the possibility of pregnancy after operation and the avoidance of the surgical menopause. Its dangers are the liability to recurrence of the tumor and the frequency of post-operative hemorrhage. It is also applicable only to isolated pedunculated tumors and some few isolated sessile, interstitial, or broad ligament growths so situated that they may be easily shelled out without undue injury or loss of tissue. This operation, which preserves the uterus, tubes, and ovaries intact, is the most conservative operation in the treatment of myoma of the uterus.

Further conservative measures are hystero-myomectomy, an operation which leaves the ovaries and tubes intact wherever possible, and a hystero-myomectomy with high amputation of the cervix. This latter procedure is of greatest value in those cases in which total hysterectomy is not necessary and myomectomy is impossible. The tubes and ovaries are left intact, and the uterus is amputated at the highest possible point, so that a portion of the uterine body, lined with corporeal endometrium, even though it be small in amount, may be left in the stump.

Adeno-myomata are rare forms of uterine myomata containing glandular elements. The epithelial structures are derived either from the endometrium or from the remains of the Wolffian body. In those developing from the endometrium the tumors are situated in the anterior, posterior, or lateral uterine wall, and have the usual characteristics of myomata, except for the presence of glandular elements and the absence of capsule. Those derived from the remains of the Wolffian body are found on the posterior surface of a uterine cornu, in the tube, or occasionally in the peripheral layers of the myometrium. These growths occur in the following forms: A dense, hard tumor in which the muscle tissue is in excess of the adenomatous tissue; a cystic tumor with many distinct cystic cavities; a soft adenomyoma in which the adenomatous tissue is in excess and in which germinal epithelium is present; and a telangiectatic adenomyoma.

Histologically, the tumor is composed of muscle tissue containing epithelial canals. The cystic cavities may contain pigment or bloody fluid.

Rhabdomyomata are pedunculated polypi of the cervical canal which always contain sarcomatous elements.

The treatment of adenomyomata should be radical, a supravaginal hysterectomy being the operation practised.

The cysts of the uterus developing from the remains of the Wolffian or Müllerian ducts are of very infrequent occurrence. They are usually small, though they may attain the size of a fœtal head. They are lined with cylindrical or cuboidal epithelium, which may be ciliated. Polypoid pseudoplasms, the outgrowth of subacute inflammatory processes, occur more especially in the cervix, the mucosa of the corpus being rarely affected independently of the cervix. These pseudoplasms are usually small, multiple, soft, vascular growths.

The round ligament, which may properly be considered a part of the uterus, is at times the seat of certain benign neoplasms. Myomata and adenomyomata, having the same histogenesis as similar growths in the uterus, are sometimes observed in this part. Myomata of the round ligament are more common in nulliparæ, and are more frequently found on the right than on the left side. They may be intra- or extraperitoneal, are usually pedunculated, hard, painless and of slow growth, and when they are large they may give rise to pressure symptoms.

Hydrocele of the canal of Nuck may be present, forming a cystic tumor in relation with the round ligament. A true cystic myoma may develop in the parenchyma of the round ligament. Clinically, these tumors are found in the inguinal canal, beneath Poupart's ligament, or in one of the labia majora.

The treatment of these round ligaments consists of extirpation of the sac and direct suture. Should the myomata of the round ligament attain a size sufficient to cause pressure symptoms they should be removed.

Henry D. Beyea.

UTERUS, INVOLUTION, SUBINVOLUTION, AND SUPERINVOLUTION OF THE.—I. Involution.—Involution is the process of retrograde metamorphosis by which the puerperal uterus returns from its condition of physiological hypertrophy to the normal non-gravid state. There is a broader sense in which the word is occasionally used, including those cases of reduction in the size of the uterus following the evacuation of retained contents, as in physometra, hydrometra, or hæmatometra, or after the removal of submucous fibroids, uterine hydatids, or other tumors accompanied by hypertrophy. The processes in these cases are identical, but the latter conditions are relatively so rare that it is fair to disregard them and use the word in its relations to pregnancy only.

Every writer upon the subject calls attention to the wonderful nature of the change which occurs. Striking as is the alteration effected in the uterus during the nine months of gestation, by which its weight is augmented from twenty-one to twenty-four times, even more remarkable, if possible, is the process of involution by reason of its great rapidity. The increase in size of the uterus is due almost wholly to hypertrophy of the individual muscular fibres, together with the development of new fibres from previously existing embryonic cells, this latter process being probably confined to the inner layer of the muscular wall, and occurring wholly during the first six months of pregnancy.

Many authors claim that, in the process of involution of the uterus, the muscle fibres undergo fatty degeneration, that absorption takes place, or that the fatty material is carried off in the lochial discharge, that this process is followed by regeneration, that new cells which develop into muscle fibre are seen in the midst of the fatty mass, and that a new uterus is formed. The blood-vessels, both arteries and veins, participate in the process of fatty degeneration, and from the fragments of the mucous membrane which remain intact at the placental site a new one is formed.

Others of a later date, since histology has developed, claim that it is a process of atrophy—that is, a diminution in volume of the muscle fibres.

Helme[1] has made a study of the process in rabbits at all stages of the process and has examined many specimens immediately after death. He finds no evidence of a fatty degeneration and a later regeneration. There is not a pathological atrophy, but a shrinking of the muscle tissue—a physiological retrogression. It may be a chemical change, but not a fatty change. The contents of the cells become more soluble so that they can pass into the lymph stream. The atrophy continues alike in all parts of the uterus, but there are no groups of degenerated cells found in the midst of the healthy tissue.

At first the muscular fibres which at the end of labor are translucent become cloudy or dusky, and diminish in volume very rapidly for the first thirty-six hours. Then follows a more gradual shrinking up to the tenth day. Helme finds that there is no evidence that old muscle fibres are destroyed and new ones produced, but that it is a retrograde change or shrinking and that the larger fibres simply become smaller. It is simply a diminution in volume.

The change that takes place in the connective tissue is a different process. There is a gradual diminution in amount and a disappearance of the connective tissue. The connective-tissue fibres and cells become granular, and some entirely disappear, while others do not undergo the degeneration.

The veins and arteries of the uterus show the same diminution, and some again entirely disappear.

It would seem that, concerning so universal and carefully observed a phenomenon as involution, there need be no difference of opinion as regards the rate of its progress and the time of its completion, and yet absolute knowledge of the matter does not exist. The modifying conditions are so numerous, and the methods used by which to arrive at conclusions so various, that no two observers appear to agree. Pathologists judge from appearances found after death, clinicians from the relations of the fundus to the symphysis pubis, statisticians from measurements made either with the pelvimeter or with the intra-uterine sound. Sources of error only too readily creep into the observations in each case and seriously affect the deductions. Post-mortem examination furnishes, of course, positive results, and yet who can say how much the retrograde process has been interfered with, in any given case, by the illness causing death, or by the other attending circumstances during life? The relation of the fundus uteri to the pubis may depend more upon the amount of prolapse, version, or flexion, the fulness of bladder and rectum, the size of the pelvic cavity, and the degree of tension of the abdominal walls, than upon the size of the uterus. It has seemed to me that measurement of the vertical diameter of the uterus by means of a pelvimeter must be unreliable. by reason of uncertainty as to the thickness of the abdominal wall, and as to the importance of existing flexion and of longitudinal compression resulting from the necessary expenditure of force.

Unquestionably, the best results must be looked for from the actual measurement of the depth of the uterine cavity in a large number of normal cases, at intervals, during the puerperal month. Much has been done in this line of investigation, and yet I know of no results which are at all satisfactory or conclusive. Up to eight or ten years ago, it was taught that reduction in the size of the uterus was most rapid during the second week after delivery, but that not until the end of six weeks or two months was the normal size regained, and this statement was regarded as authoritative until the appearance of a series of intra-uterine measurements,[2] begun by A. D. Sinclair and continued by W. L. Richardson, both of Boston. From these figures there has frequently been deduced the conclusion that involution is much more rapid than was formerly believed, and teaching has been modified in accordance with this belief. This conclusion has been partially corroborated by Charpentier, though his averages are materially larger than those of Sinclair; and Skene, in his recent work, accepts it completely.

Now were the question at issue merely one of scientific interest, having no important practical bearing upon the management of the puerperal state, it would not properly arise for discussion in this article, but it has a very vital connection with the vexed questions as to how long a patient should keep her bed after delivery, and how much latitude should be permitted her in resuming her customary avocations; and it has also a plain relation to the remaining topics to be considered under this heading. This being the case, it is not out of place here to call in question the accuracy of the reported measurements, and to assert that the old belief, founded upon post-mortem investigation, is the correct one, the one upon which all rules of conduct should be based. The reason for so confident an assertion is the knowledge that the measurements, as reported in the papers above mentioned, vary more with the skill and boldness of the house physician in passing the sound than with the condition of the patient or the duration of her puerperal period. A part of those published were made by myself, and, though septicæmia was rife in the hospital at the time, they evidenced a most phenomenal involution amounting in some cases to superinvolution. These results I knew to be untrustworthy, and yet they corresponded with the work of my predecessors.

I was succeeded in this line of work by Dr. W. J. Otis, who, believing with me that his sound rarely reached the fundus, and fearing to do injury to a soft and friable uterus by the employment of greater force, entered upon the use of a Jennison elastic sound, to which he adapted a sliding marker or guide. With this soft and elastic instrument, used with gentle yet persistent manipulation, the whole aspect of the figures at once changed, and from that time on only once did the measurement fall below three inches. He has very kindly furnished me with the results of his examination in thirty cases, after the adoption of the new instrument, and from his figures I select the following as indicative of the general conclusion. Of the 30 uteri, 6 had a depth of three inches, 5 of three and a half inches, 4 of three and three-quarter inches, and 7 of four inches. The average depth was 3.63 inches, and the average day of measurement was the seventeenth.

I learn from the house physicians of more recent years that the depth of the uterus always increases after a few weeks' experience in measuring, and that the figures are uniformly much greater during the service of some men than they are recorded by others. Though septic influences have been absent of late, yet the average depth, I am assured, is greater rather than less than it was found by Dr. Otis. The fallacy in this method of investigation lies in the fact that the uterus is so softened as to be easily perforated, or, at least, penetrated by the sound, thus staying the examiner's hand through fear; is often flexed; is not yet lined by normal mucous membrane, but by a soft exudate in which the instrument is readily entangled; and that upon its inner surface is an elevation corresponding to the placental site, an elevation sufficiently great to obstruct the passage of the sound. The custom of examining upon the back tends to increase existing difficulties, so that I believe the fundus is by no means always reached, even by the most skilled observer, and under the most favorable conditions.

A very important series of measurements is reported by Hansen, in the *Zeit. f. Geburt. u. Gyn.*, 1887, a review of which has been made by Parvin.[3] He examined 200 women, making in all 1,048 measurements with the sound. He announces that "the duration of involution was in general ten weeks; the shortest period observed was four weeks, and this in only one case, while the longest period was three months, which was observed in four women." Parvin concludes by stating that "one of the most important practical lessons to be learned from the investigations of Hansen is, that obstetricians should insist upon a longer rest for the puerperal woman. When we remember that many a woman is up and at work two or three weeks after childbirth, and that even those whose circumstances in life do not require labor are frequently participating in social pleasures and fatigues at the end of six weeks or two months, we can easily understand why disorders of the genital organs not infrequently result."

It was also found that involution was delayed in those who did not nurse.

The questions as to the influence upon involution of normal lactation, and of the routine use of ergot after delivery, are eminently practical ones, and deserving of notice. It would seem that so physiological and essential a process as suckling ought to have a favorable influence, especially in view of the intimate relation existing between the breasts and the uterus, any excitation of the former stimulating contractions in the latter. Yet this view is opposed by many observers, notably among the French. Tarnier takes conservative middle ground, holding that "the individual conditions have a much greater influence upon the course of uterine retrogression than lactation." In the face of such contradictory faiths the chances are that Tarnier is correct, and the influence of nursing is a factor of minor importance. My own belief is that it is favorable rather than otherwise, provided, of course, that the patient has sufficient strength and vigor for the physiological performance of the function. Under other circumstances the drain might easily result in such physical deterioration as materially to interfere with the restoration of the uterus.

Unquestionably, it is the custom of the majority of American physicians to administer ergot, as a routine measure, at the close of labor. Subsequently, should the uterus fail to contract firmly or retrogression prove tardy, the exhibition of the drug is continued with anticipation of benefit. Of late years, however, the wisdom of these procedures has been disputed by those who believe, not only that the practice is useless, but that it is actually harmful, it being claimed that involution is retarded thereby. This theory, while given a respectful hearing, has not as yet found favor in practice, the sanction and approval of the profession being still given to the use of ergot as outlined above.

Among other factors in determining the rapidity and completeness of involution are the duration of labor and amount of resultant fatigue; the condition of the patient's health before labor; the occurrence of lacerations of cervix or perineum; the occurrence of septic poisoning, or of local inflammatory conditions from any cause. These matters will receive more especial mention in the consideration of subinvolution. After abortion or miscarriage, unfavorable conditions being absent, involution proceeds as after normal labor, only more slowly.

II. SUBINVOLUTION.—Subinvolution is simply a state of persistent incomplete involution, the process having by some means been arrested before the uterus has fully regained its normal state. Corresponding with the intensity of the acting cause and the time of its occurrence, the uterus may remain very large, as at the close of the first week, or it may be only moderately hypertrophied. From this fact probably has arisen much of the uncertainty which still exists as to the exact nature of the condition and of the subsequent changes which take place. So great, in fact, is this uncertainty that few writers can agree even upon a name which suitably indicates the nature of the disease, those who make use of the term "subinvolution" acknowledging that it is only clinical in its application, and by no means covers the progressive pathological changes; those who classify it under the heading "chronic metritis" for the most part disclaiming any belief in its inflammatory origin or course; and the terms "engorgement" and "infarctus" indicating only phases of, or steps in, the progress of the disease. "Chronic parenchymatous metritis" is open to the same objection as "chronic metritis," because suggesting inflammation. Thomas, in absolutely denying any inflammatory element, suggests and uses the title "areolar hyperplasia," as descriptive of a condition of the uterus of which subinvolution is by far the most frequent cause, thus regarding the latter not as a separate disease, but rather as a merely fugitive condition giving rise to "areolar hyperplasia."

However, it matters little what one chooses for a name, if only he recognizes the fact of arrested involution and acts accordingly, as witness the statement of Hart and Barbour[4]: "The term subinvolution is *etiological*, and simply expresses one mode, the most important, in which the condition to be described (chronic metritis) is produced. *Apart from the history*, it is not possible to diagnose between a subinvoluted uterus and one enlarged from chronic metritis alone. Further, the condition of subinvolution is maintained by the process of chronic metritis—that is, by the formation of connective tissue. Finally, the treatment is the same in both cases." In other words, whatever the conditions in the early stages of the disease,—whether involution has been arrested in the first puerperal week by septic absorption, with a resultant uterine or peri-uterine inflammation, or in the fourth week by a mechanical displacement,—there results sooner or later, in consequence of continued hyperæmia and irritation, a proliferation of connective tissue, with ultimate contraction and hardening of the whole uterine mass. These later stages constitute the "chronic metritis," or "areolar hyperplasia," above mentioned.

As regards the method by which the normal enlargement is perpetuated, there are at least two definite and diametrically opposed views, both of which, as has already been intimated, may be consistently held to be correct. Courty says[5]: "The hypertrophy of the uterus, by failure of the retrograde evolution, is a pathological hypertrophy by its permanence, but resulting from a purely physiological hypertrophy in its origin." He quotes West as claiming a fatty change with lack of absorption of the product, and claims the contrary to be true. He states that there is not a change in the texture of the uterus, but a "persistence in the number and volume of its component elements. There is not a fatty change of the uterus," but an hypertrophy by excess of nutrition.

On the other hand, Hart and Barbour state that "the condition of permanent enlargement of subinvolution is not due to the non-degeneration of muscular fibre, but to the substitution of connective tissue for the products of this degeneration."

In view of this difference of opinion, and in the lack of positive testimony on either side, it is fair to infer that subinvolution is produced in both ways, the precise process being determined in any given case by the acting cause. In either case the final result would be the same, the method of its production having been minutely described by Dr. Mary Putnam-Jacobi,[6] as a structural alteration in the walls of the enlarged blood-vessels, "in virtue of which nutritive transudations of an albuminous plasma took [*take*] place, which gradually caused [*cause*] a local development of connective tissue (perivascular sclerosis)." This process she claims to be inflammatory in its nature.

Etiology.—In entering upon the subject of the causation of subinvolution, we are at once in a wide and important field for discussion—wide because of the multiplicity and variety of the causes alleged, important because of the necessity for their recognition and consequent avoidance or removal. The first and most fruitful source of subinvolution is without doubt laceration of the cervix. There are some who still dispute this fact, but their number is rapidly growing less, and it is to be hoped that before many years there will be as great unanimity in asserting the necessity for closing lacerations of the cervix uteri as there is now in urging repair of the perineum after injury.

The testimony of Emmet in this matter may be considered somewhat biassed, yet the accuracy of his observation and the truthfulness of his statement can hardly be called in question. He says[7]: "In closing this brief chapter, I would state that, for many years past, I have met with few or no cases of subinvolution which were not due to laceration of the cervix." T. A. Reamy, in the "American System of Gynecology," pointedly remarks "that if a laceration of the cervix is observed, more or less subinvolution, either of the whole uterus or of the cervix alone, is almost absolutely certain."

The means by which the result is produced are not difficult to understand. In the first place the presence of an open wound, and, later on, of either a mass of cicatricial tissue or an everted and eroded surface of mucous membrane, serves as a constant source of irritation to keep up an active hyperæmia of the uterus. However, in the early weeks, the very effort of nature to repair the damage is opposed to the process of involution, and subsequently, as the wound remains and the irritation persists, the permanence of the hypertrophy is insured by the development of an endocervicitis and an endometritis. It is not necessary that the laceration should be a large one, for even very superficial tears, if exposed to the deleterious influences of an irritating vaginal discharge and denied, by the restlessness or too early effort of the patient, the quiet needed for repair, may fail to heal kindly, and so produce the same result as the deeper lesions —at least so far as our subject is concerned.

Septic absorption is, without question, a far more frequent cause of subinvolution than will be admitted by the mass of practitioners, and a present shame it is, in this age of preventive medicine, that this statement should be true. Not that in every case of subinvolution due to this cause there should have been a well-marked run of "puerperal fever" so-called; but where antiseptic, or at least aseptic, methods are despised or neglected, nothing is more common than to have, during the first week of convalescence, a rise of two or three degrees in the temperature (commonly called milk fever), the presence of fœtid lochia, and moderate abdominal tenderness. In many of these cases there is set up a sufficient degree of uterine or peri-uterine inflammation to interfere seriously with the process of involution; and if this be true of these mild cases, much more surely will subinvolution follow the more marked instances of septic intoxication. Given a case of puerperal septicæmia, and subinvolution may be confidently predicted.

The next cause to receive attention ought perhaps to have been given precedence over the last. It is the faulty management, or rather the mismanagement, of the period of convalescence; and by mismanagement I mean the permission of too much freedom in movement and of too early rising. I am well aware of the fact that patients are not only allowed to be up and dressed before the end of the first puerperal week, but that such a course is even advised by men who are otherwise safe and skilful practitioners and good observers. That the reasons which they give for such a custom have some weight is not denied, but it is far from true that the custom is either a safe or a desirable one. The general weakening and loss of tone of the muscular system, due to a stay in bed of three weeks' duration, is far more than compensated for by the complete rest of the nervous system and the diminution in size of the soft and heavy uterus. The emptying of the uterus and vagina of clots and lochial discharge can be better accomplished by ergot and a douche than by sitting up upon a chamber vessel or chair as advised and practised by Goodell, and without the danger of the latter course.

Another frequent cause is the nervous condition.

Bennett[8] says that he believes that, in subinvolution, the nervous power is so altered in its constitution that vascular congestion of an immoderate amount is permitted, which in itself further increases the trouble by paralyzing the nervous control over the emptying channels, the loose cellular tissue of the late pregnant uterus being well suited for such lesion to occur in. And then we must consider the rapidity of its growth, the enormous distention of its walls, the pressure both from within and from without which it has to bear, as well as the nervous shocks conveyed from mental impressions.

It is a well-known fact of physiology that if a nerve has been bruised or injured between the point of irritation and the muscle, such an injury will often be followed by defective nutrition of the part supplied. We have injuries here which may pass unseen, due to the long-continued pressure of the fœtal head in tedious labors—especially where the delay is in the first stage—the division and bruising of the nerves causing a subsequent loss of function.

The way in which subinvolution is caused by early exertion, and especially by a too speedy assumption of the upright posture after labor, is by the production of displacement of the uterus, prolapse, version, or flexion, and consequent interference with the local circulation, and hence with the process of fatty change and absorption. The uterus remaining large, the displacement continues and increases, the hyperæmia is perpetuated, and the chronic changes already outlined proceed to their full accomplishment. By far the safest course is to take conservative ground, and insist upon a sufficiently prolonged rest in the horizontal posture to permit of a near approach of the uterus to its normal size, and then to make a gradual and cautious return to the ordinary habits of life. The rule of Tarnier is a good one, and certainly does not err on the side of conservatism. Provided the uterus cannot be felt above the pubis, the lochia are no longer bloody, and no fever exists, he permits his patients, between the fifteenth and twentieth days, to be moved to a reclining chair where at first they remain only one hour. The time being lengthened by one hour daily, in three or four days they are ready to try a few steps, and so gradually to gain power to walk without fatigue or injury.

Very painful and tedious labors, by leaving the patient in a state of complete exhaustion from which recovery is slow and uncertain, are probably not infrequently the cause of subinvolution. In this case there is a lack of tonicity in the vessels, the active process of removing the waste and building up the new uterus is imperfectly carried on, a passive hyperæmia persists, and the disease is gradually developed. Severe hemorrhage, either before or after delivery, would act in the same way, by lowering the vital powers and by diminishing the oxidizing properties of the blood.

If the subinvolution is due to hypertrophy of the decidua or to retention of parts of the placenta, membranes, or clots, these should be removed by the use of the curette. Placental adhesions form a source of especial danger, for they keep up an irritation which causes a localized subinvolution, and this in turn has a tendency to become general.

Various other causes have been suggested, such as incomplete emptying of the uterus at the completion of labor, the presence of tumors in or about the uterus, and sexual excitement due to too early intercourse, or even to sharing the same bed by husband and wife. It is to this latter cause, doubtless, that not a few cases of puerperal hemorrhage may rightly be attributed; and it is therefore fair to assume that it is capable of setting up a sufficient amount of pelvic congestion to render subinvolution likely.

As predisposing causes may be mentioned a poor state of health from whatever cause, frequent and rapidly recurring pregnancies, and abortions.

Frequency.—For some years after Simpson first called attention to the "Morbid Permanence of the State of Puerperal Hypertrophy," occasional cases were reported from various quarters, but the condition was considered to be an infrequent sequel to pregnancy. Of late years, however, with improved methods and more exact knowledge in the matter of gynecological diagnosis, subinvolution is found to be one of the commonest of the morbid results of childbearing. If it be true that the above-mentioned causes are apt to produce a "morbid permanence of the state of puerperal hypertrophy," then it is by no means to be wondered at that subinvolution is a frequent condition among parous women. It is impossible to give statistics of any value on this point as, in the nature of the case, they must vary materially in the practice of different men, in hospital and in private practice, and also because of the confusion in nomenclature and classification.

The condition once established, from whatever cause, it tends to develop into the more intractable, and oftentimes incurable, disease already referred to as chronic metritis, or areolar hyperplasia; hence the importance of the early recognition of the danger, that the cause may be removed and complete involution secured at the proper time. This point will receive more particular consideration under the head of treatment.

Symptoms.—The history of the case from the patient's own lips indicates that the commencement of the trouble began at a previous confinement. Frequently there has been a previous attack of puerperal sepsis, peritonitis, parametritis, or evidence of some form of septicæmia. Post-partum hemorrhage is often a precursor of this condition.

Such patients almost always complain of backache, and this may be the chief cause for which treatment is desired. There is almost always some disturbance in the menstrual function. This is usually an irregularity indicated by a menorrhagia, a condition in which the periods are of longer duration and come more frequently than is normal. Metrorrhagia may be present often in connection with menorrhagia, and the result of the latter may be so profound as to produce an excessive anæmia. Dysmenorrhœa is often present, due to the engorgement of the already enlarged uterus, which also causes the severe pain. Leucorrhœa, although not always present, may be an accompanying symptom. Its presence, however, denotes an inflammation of the endometrium rather than a simple subinvolution. In weak and debilitated patients there is usually amenorrhœa.

Pain is a very uncertain symptom. Headache is sometimes present; it is referred especially to the crown of the head and is burning in character, occurring at or near each catamenial period. Pain is also localized in the pelvic region, but may be referred to more remote parts of the body, such as the back, hips, legs, and also the breasts. The pain is not of so severe a type as that of chronic metritis.

When the uterus is large and heavy and retroverted, as is often the case, there may be persistent constipation, which usually results in hemorrhoids. Vesical tenesmus may exist from pressure on the bladder or from dragging upon that organ.

The physical signs are especially valuable when acquired by a careful examination. The uterus is found to be soft, flabby, and symmetrically enlarged, more globular in form than normal, and is often displaced. The cervix is also large, with usually a laceration, and the os is patulous, often permitting the entrance of a finger as far as the internal os. The sound passes to a greater depth than normal, and is quite easily moved about; its introduction may cause a profuse bleeding.

Diagnosis.—It is by no means a simple and easy matter to make a positive diagnosis in any given case, unless the patient has been under continuous observation since the pregnancy from which the condition dates, for the reason that the term is rather expressive of a clinical fact than of a pathological process. The uterus may have undergone a perfect involution, the hypertrophy developing subsequently as a result of an endometritis, of a displacement, or of ovarian disease. A probable diagnosis may, however, be made in most cases by a careful comparison of the symptoms and physical signs, the former having dated from a previous confinement or from a period not long thereafter.

On account of the softness and moderate sensibility of the uterus in many cases, the condition may be mistaken for pregnancy in its early weeks, or *vice versa*. In case of doubt, it is far better to wait for time to indicate the true diagnosis than to run the risk of producing abortion by passing the sound. This word of warning is not an idle one, for the accident has often happened to the impatient and thoughtless, and should be guarded against by excess of caution. It is not impossible that the two conditions may coexist, and this possibility furnishes an additional cause for care.

In view of the uncertain relations existing between subinvolution and chronic metritis, and because, if they be separate diseases, the treatment of each is the same, it is hardly worth while to attempt a nice discrimination. If the disease be subinvolution pure and simple, with no metritis or "perivascular sclerosis" grafted upon it, the uterus will be softer and more doughy than normal, will measure three inches or more in depth, and pressure upon it will be easily borne. Where there exists the condition described as chronic metritis or areolar hyperplasia, the uterus is hard and sensitive, and there is usually more or less constant pain in the hypogastric region. The uterus is movable in both conditions, unless there be adhesions or accompanying perimetritis.

Fibroid tumors increase the bulk of the uterus and elongate its cavity, but they can almost always be felt as local enlargements of the uterine mass, or at least the enlargement is not uniform. The history of the case will usually fail to show any causative relation of pregnancy. The appearance of the cervix will often be of assistance, it being usually of normal size and density in the case of tumors wholly confined to the uterine body. Malignant disease confined to the body of the uterus might be mistaken for subinvolution on account of the tendency to hemorrhage, the uniform enlargement, the lack of pain, and the absence of sensitiveness commonly noted in the early months. The age of the patient, the continual presence of a watery discharge, and sometimes the offensive odor, together with the wasting strength, should suggest the nature of the disease, and microscopic examination of shreds removed by the curette will determine it.

Prognosis.—The prognosis of simple subinvolution which has not yet progressed to the sclerotic stage is good, provided suitable treatment be adopted. When the condition is allowed to go untreated, its tendency is to run through the several stages of fibrous deposit, induration, contraction, atrophy. Under these conditions its course is very variable, being influenced by a great number of factors. In some instances the complete course outlined above appears to have been run through inside of a year, yet on the other hand there are cases which seem to remain almost stationary for years. When the stage of fibrous infiltration has been reached—and most cases presenting themselves for the relief of symptoms have already entered upon it—the prospect of complete cure and restoration to the normal is poor. As a rule, the most that can be expected is the relief of the principal symptoms, partial reduction of the existing hypertrophy, and the avoidance of more serious complications. The uterus may also be placed in a more favorable condition for the occurrence of pregnancy, and for its successful completion.

Treatment.—To a very considerable extent subinvolu tion is preventable, and hence prophylactic measures should be first considered, and uniformly practised. It is unnecessary to urge the importance of having every woman approach her confinement in the best possible state of health. Of course existing disease will be combated and removed so far as possible, but let the physician also set his face against every depressing influence so often invoked by women to diminish the size of the fœtus and thus to insure an easier labor. Let good diet, fresh air, and plenty of exercise be invoked to aid in establishing or continuing a condition of vigorous health previous to delivery.

The importance of insisting upon a recumbent posture and absence of effort during the first two weeks, and upon a gradual and cautious getting up after labor, has already been referred to.

As septic causes have much to answer for in the production of the disease in question, they must by all means be guarded against, and with the present light upon the subject of aseptic midwifery there is no excuse for the man who neglects such simple precautions as are universally agreed upon. In this connection Goodell[9] says: "The day is surely coming when, to have a case of puerperal fever in one's private practice, will be deemed a crime."

Tedious and very painful labors being, by their exhausting influence, factors in causing, or at least in favoring, the occurrence of subinvolution, they should be avoided so far as possible by the use of forceps and of the various anæsthetic agents. Chloral during a long first stage is capable of giving rest and relief from pain, with proportionate lessening of exhaustion. Ether and chloroform properly used are perfectly safe, and they can be given, if necessary, for long periods without materially delaying the progress of labor, and even with the effect of shortening the duration in many cases. Furthermore, they diminish rather than increase the risk of hemorrhage, and in almost every instance they diminish the severity of the suffering, reduce the fatigue to a minimum, render the convalescence more speedy, and insure a more rapid and certain involution. There is less need of commendation of the forceps, yet if the baneful influence of an unnecessarily prolonged second stage be borne in mind, it will be acknowledged that no mere prejudice against operative interference should be permitted to prevent the timely employment of this means of abridging wear and tear.

Lacerations of the cervix having been shown to result almost inevitably in subinvolution, it follows, as a corollary, that the presence of such tears should always be sought for after labor, in order that this and other possible consequences may be averted by suitable treatment addressed to the lesion. Conversing with a successful fellow-practitioner recently upon this subject, I was assured that not one physician in a hundred makes a practice of examining his patients during or at the close of the puerperal month, and that such a custom is uncalled for. If this belief is general and the former assertion correct, and I believe them so to be, the frequency of subinvolution is to a large extent accounted for. He is a bold man who will fly in the face of such unanimous testimony as now exists to the contrary, and assert that laceration of the cervix is not liable to result in subinvolution, or that it matters not if it does, as the latter condition is one of no importance; yet one of these positions must be taken by the man who disbelieves in the practice of examining his puerperal patients before permitting them to pass from his hands. Unless some special symptoms seem to demand interference, it is well not to examine until after the completion of the second week, and better still is it to wait until the close of the third week, or even of the puerperal month. By this time involution should be well advanced, and the cervix should have returned nearly enough to the normal to enable one to judge well as to the extent of any laceration, should one be present. The treatment of such lacerations needs no consideration here, as this branch of the subject has been fully covered in another article; but the importance of caring for them at an early date cannot be too strongly enforced.

When the examination is made as recommended, any other existing condition which may serve as a possible cause of trouble can be noted and will receive due attention. It is taken for granted that any rupture of the perineum has been previously sutured, but the success of the operation is now to be assured. If the uterus is displaced, it must now be returned to its normal position, and sustained there by glycerin tampons or a pessary.

When subinvolution is discovered soon after labor, simple removal of its causes will usually suffice for a cure. Later on, when the patient applies for treatment for the relief of symptoms, the problem is by no means so simple. Measures directed toward the elevation of the general tone of the system are always called for. Tonic remedies, liberal diet of the right sort, general sponging followed by brisk rubbing, and, in those cases in which suitable exercise cannot be taken, the employment of massage, are to be advised. It being assumed that we have removed all existing local conditions which may serve to perpetuate the disease, our efforts must be turned more directly to the removal of hypertrophy and the restoration of function of the diseased organ.

In almost all cases there exists hyperæmia, which is, indeed, the important element in the continuation of the trouble. This should be attacked by puncture, by scarification, or, better still, by the application of leeches to the cervix; the use of glycerin tampons and of hot douches also aids in reducing hyperæmia. If hot douches are to be of any value, they must be administered while the patient is lying upon her back, with her hips raised; the temperature of the water must also not be less than 110° F., and the douching should be continued for at least fifteen minutes. Painting the cervix with Churchill's tincture of iodine can do no harm, and is often of great benefit. In those cases in which the cervical canal is patulous, and active endometritis is absent, the application of iodized phenol to the uterine cavity by means of an applicator is of marked utility. Such an application should be made about once a week.

Electricity is highly recommended by many writers of recent years, and it has given good results where other means have been tried in vain. Both the galvanic and the faradic currents are of value, either separately or in combination. The faradic current is chiefly available, in recent cases, for promoting contraction of muscular fibre and diminution of hyperæmia. The galvanic current finds its most important application in the later cases, in which fibrous deposit has already taken place.

Massage[10] has not as yet formed an important factor in the treatment of subinvolution, but there are men who advocate its use very strongly. If no contraindications exist, massage may be employed to the best advantage in the first stages of subinvolution, when the uterus is hyperæmic, and when it is found low down in the pelvis, tender, spongy, and having a doughy, elastic condition. If there is an accompanying retroversion this treatment is not precluded; but when the uterus has become hard and firm and has lost its soft spongy feel, massage is useless.

Not infrequently there coexists with subinvolution, or springs up in consequence of it, a condition of hyperplastic endometritis, which is largely accountable for the hemorrhagic symptoms. In such cases it may be necessary to remove the diseased membrane by the use of the sharp curette, following it, in intractable cases, by the application of tincture of iodine, or even of iodized phenol. This, of course, is to be regarded as a surgical operation, strict aseptic precautions being observed, and the patient being confined to bed for several days thereafter.

In some refractory cases of subinvolution, operative interference has been practised by Reamy and others. This consisted in "removing a wedge-shaped piece from the cervix, and closing the rent with sutures as in trachelorrhaphy. . . . when laceration of the cervix did not exist." Good results are reported from this operation.

When a patient has advanced beyond the puerperal state and subinvolution still persists, notwithstanding all our efforts to remedy the condition, relief may be looked for in pregnancy. If the patient becomes pregnant the uterus may, in its natural evolution and in its subsequent involution, if no contrary condition hinders, return to its natural size again.

Subinvolution of the Vagina.—In the vagina, as in the uterus, the process of hypertrophy and development continues throughout pregnancy, to be followed after delivery by a process of involution almost identical in its method and purpose with that which occurs in the uterus. By this means the vagina is restored, in about two or three months, very nearly to its normal nulliparous condition, remaining permanently, however, a little larger than before. This perfect result is, unfortunately, by no means always accomplished, and subinvolution of the vagina is, like subinvolution of the uterus, of common occurrence.

The causes of incomplete involution of the vagina are, for the most part, those that have already been assigned as factors in the production of uterine subinvolution, the latter almost always being accompanied by more or less vaginal subinvolution. The cause which most uniformly and certainly interferes with the process of involution in the vaginal walls is, without doubt, laceration of the perineum or pelvic floor. While laceration of the perineum in its entire thickness is common, laceration of the posterior vaginal wall, together with the inner portion of the perineal body, is, if possible, a still more frequent accident, and is followed by more disastrous results. When a rupture extends through the fourchette, and even more deeply into the skin of the perineum, the injury cannot fail to be noticed by the most casual observer; but when internal inspection is necessary to disclose the rent the chances are strongly against its discovery. The average physician considers his duty done when he inspects the perineum externally, and to his great satisfaction finds that "not even the fourchette is torn," forgetting or not knowing the fact, so strongly insisted upon by Mathews Duncan, that the point at which laceration usually, and in primiparæ almost inevitably, begins is at the ostium vaginæ, not at the ostium vulvæ—at the plane of the hymen, not at the fourchette. In examining the perineum after labor, therefore, look carefully to the mucous surface.

Prophylactic methods of treatment will be the same as those outlined above for subinvolution of the uterus, especial stress being laid upon the care of the perineum both during and after labor. Curative treatment, after known or possible factors in the production of the disease have been removed, will consist in the use of douches, occasional applications of iodine, with insertion of glycerin and alum tampons, and the employment of electricity. While both the faradic and the galvanic currents are of utility, and many prefer the latter, my own preference is strongly for the former. By the employment of a bipolar electrode active contraction of the muscular fibres is brought about, their tone is thereby improved, passive hyperæmia is removed, absorption is stimulated, and the uterus is more firmly supported.

Operative interference is often called for to repair old injury to the perineum or cervix, to remove cystocele and rectocele, or to narrow and shorten a redundant vagina, which, by the simpler means mentioned, cannot be reduced to the normal.

III. SUPERINVOLUTION.—Nominally, superinvolution is an excess of involution, by which the uterus is reduced to less than its normal size, yet it is an open question whether just this process really occurs. Undoubtedly cases are noted, and with increasing frequency, in which, at some time after the completion of puerperal convalescence, the uterus is found in a state of atrophy; but is this atrophy due to excess of the normal process with failure in the regeneration of muscular fibre; or is it not rather fibrous contraction following upon actual inflammation or occurring as a sequence of subinvolution; or, finally, is it not possibly a result of disease of the ovaries by which their function is destroyed, and hence corresponding to the senile atrophy of the menopause? The present attitude of the profession toward this disease is one of observant scepticism. It is too soon for any one to assert dogmatically that superinvolution, pure and simple, does not exist; yet before making that diagnosis in any case it would be well to consider carefully if there be not some other disease of which the atrophied uterus is merely an expression or consequence. Even the classical case of Simpson—the case which first suggested to his mind the title under consideration—is more likely to have been one of premature atrophy and cessation of function due to tuberculous disease.

But whatever opinion may be held concerning the accuracy of the term, it must be admitted by all that uterine atrophy does occur, without apparent cause, in a certain number of cases, not long after delivery, and to this condition has rightly or wrongly been given the name superinvolution. That the condition is a rare one is shown by the scarcity of reported cases, and by the fact that most writers upon the diseases of women ignore the subject completely.

As regards the pathology of superinvolution, it can only be said that the uterus resembles that organ in a state of senile atrophy. Observations are too few to afford any definite information concerning the morbid processes involved.

There are no distinctive or constant symptoms which belong to the disease, with the single exception of amenorrhœa, or scanty menstruation. Besides this, there is the ordinary train of symptoms common to many another form of uterine disease. Examination reveals simply a non-sensitive uterus, of less than the normal size and depth. The ovaries, if found at all, are commonly much smaller than normal, and are not infrequently bound down and compressed by adhesions.

The disease is a very intractable one, though the prognosis will vary in accordance with the pathological conditions which stand in causative relation to the atrophy. In some cases, diagnosticated as superinvolution, a cure has been achieved and pregnancy has followed; but it may be laid down as a rule that most cases will prove absolutely rebellious to treatment, and sterility will be permanent.

The only treatment which has been found of value is one having for its purpose stimulation of the uterus, and this is best accomplished by the conjoined use of moderate cervical dilatation and electricity. Either a Hanks or a steel-branched dilator may be used to stretch the cervix slightly every week or ten days. Rockwell recommends that both the faradic and the galvanic currents be utilized, and relates one case in his own practice in which menstruation was thus induced in a patient whose uterus measured but one and three-quarter inches. The poles of the faradic battery may be used indifferently, but when the galvanic current is employed Rockwell advises that the negative pole be placed within or against the uterus.

Rufus A. Kingman.

UTERUS, VAGINA, ETC., TUBERCULOSIS OF.—The relationship between tuberculosis of the uterus, vagina, and vulva, and tuberculosis of the Fallopian tubes, ovaries, and peritoneum, is so close that in the general consideration of the subject it will be necessary to make reference to tuberculosis of the structures above the uterus, which subjects do not strictly belong to this particular chapter. (For a full consideration of tuberculosis of the uterine appendages and peritoneum see the articles on *Fallopian Tubes, Diseases of; Ovaries, Diseases of;* and *Peritonitis, Septic and Tuberculous* [in the Appendix].

General Considerations.—Tubercle bacilli gaining entrance to the circulatory systems of the body show what appears to be an elective preference for certain organs. Thus, in the order of frequency, it is found that the involvement affects the lungs, lymphatic glands, mucous membranes, serous membranes, bones, spleen, kidneys, adrenals, brain, genital organs, bladder, and skin. Age has an influence upon the relative susceptibility of the organs, the lungs being most frequently involved in adults, and the lymph glands, bones, joints, and meninges in children. In the female organs of reproduction the order of the frequency of involvement is: Fallopian tubes, uterus, ovaries, vagina, cervix, and vulva. As tuberculosis of these parts is frequently overlooked or mistaken for other lesions, this order may be subject to later modifications. Tuberculosis of the genitals is nearly seven times more frequent in women than in men. Gonorrhœal and other chronic inflammatory conditions appear to increase the susceptibility of the generative organs to tuberculosis.

That the more frequent involvement of certain parts of the body over others is due less to the portal of entry than to differences in the relative susceptibility of the organs themselves, is indicated by the observations made upon lower animals that have been infected by subcutaneous inoculation, intravenous injection, ingestion or inhalation of the bacilli. In such animals a tendency of the bacilli to grow more frequently and more luxuriantly in certain organs is observed. The susceptibility of a particular organ obviously is modified by the degree of general resistance to tuberculous infection possessed by the individual, and by the virulence of the special bacilli concerned. Against the most virulent forms of the tubercle bacilli it is probable that no man and few organs are immune, while other species of the micro-organisms are so attenuated as to be able to produce disease only in persons of greatly enfeebled resistance, and then only in the more vulnerable organs.

Although it is probable that the organs most frequently involved, such as the lungs and lymph glands, are, as a general rule, most susceptible, it is not improbable that in certain individuals the order of the relative resistance of the special organs varies. In this way may we explain the occasional primary colonization of tubercle bacilli in the female genital organs, despite their entrance into the body through the digestive and the respiratory tracts, or through some other remote portal. In such instances it may be that no lesion marks the point of entry of the bacilli, nor the channels traversed by the micro-organisms in passing to the reproductive organs.

Character of the Infection.—Much stress has been placed upon the question as to whether the lesion in the genital organ be primary, or the initial tuberculous focus in the body, or secondary to some other lesion in a contiguous organ or in a distant part from which the bacilli have been carried by the blood- or the lymph-stream. Practically, however, the secondary character of the disease of the genitalia has little influence upon the treatment in the case, provided that the primary lesion be of a trifling character. Far more important is the determination of the dominant, determining, or dangerous lesion in the body. Thus, a tuberculous uterus or ovary, whether primary or secondary, rarely requires the attention of a gynecologist in the presence of advanced pulmonary disease, yet is of great importance when the lesion elsewhere in the body, even though it be primary, is slight and stationary in character.

More important than the primary or secondary nature of the disease—for this may have little influence upon the treatment—is the consideration of the mode of entry of the bacilli, which concerns the prophylaxis against these lesions. As a rule, however, the portal of entrance is difficult to determine, as the bacilli may pass through the mucous membrane and traverse the lymphatic or blood channels without leaving any gross or microscopic evidence of their path. Again, evident primary lesions may indicate the portal of entry.

The bacillus may enter directly through the external genitalia, a condition known as *ascending* infection, or through contiguous organs and remote portions of the body, by means of the blood- or the lymph-stream, designated as *descending* infection.

Mode of Infection.—Ascending infection may occur through contact with contaminated fingers or utensils. Thus, a consumptive may reinoculate herself by sputum carried on her hands, while the more serious danger of initial infection may attend the ministrations of a careless tuberculous physician, midwife, or nurse.

While it is difficult to offer the convincing evidence of concrete instances, the possibility of infection in coitus from disease of the genito-urinary organs, or from the use of tuberculous sputum as a lubricant, is to be considered. The descending form of infection is much the more frequent, although usually it is as difficult to determine the precise portal of entry as it is to give absolute evidence of the primary nature of the lesion. It is apparent that for the most part this will remain suppositifious.

The bacilli may be directly carried in the blood or lymphatic vessels from the mucous membranes of the respiratory, digestive, or urinary systems, or from surface lesions of the skin, to the pelvic organs. Often primary lesions mark the path of the invaders, and not infrequently the genitalia are infected by proximity to tuberculous organs, such as the intestines and bladder, or because their peritoneal covering shares in a generalized tuberculous peritonitis.

Character and Frequency of the Lesions.—The lesion may appear in the form of either gray or yellow miliary tubercles, cheesy or puriform foci, masses of imperfectly organized peritoneal exudate, granulation tissue, or chronic ulcerations of the mucous surfaces. The liquid exudate may differ from other inflammatory peritoneal effusions in the presence of small numbers of polymorphonuclear leucocytes and of fibrin, and the presence of many mononuclears and the tubercle bacilli. Most frequently the disease occurs in the form of miliary tuberculosis of the pelvic peritoneum, and is but a part of a more generalized process. At times the tubercles, which appear as slightly raised, firm, grayish or yellowish nodules, from 1 to 3 mm. in diameter, are limited in their distribution to the peritoneal covering of the uterus and its appendages, and may or may not be associated with pelvic exudate and adhesions.

The Fallopian tubes are affected more frequently than any of the other reproductive organs. Besides the form in which only the peritoneum is involved, there is the interstitial type, in which the tube shows a great thickening of its walls, the presence of tubercles, and at times of a serous inflammatory œdema in the muscular walls. Finally, the chief involvement may be the mucous lining, which may show miliary tubercles, or, if the process be advanced, ulceration, or the mucous lining of the tube may be entirely destroyed and the organ greatly distended by a puriform or caseous material. This resembles a pyosalpinx, but the microscope shows the fluid to consist largely of necrotic substance rather than of pus. There is also less tendency for the ostium to become closed than in other forms of salpingitis.

The tube may contain many ounces of fluid, giving it an enormous size. Localized collections of a more or less puriform fluid, walled by masses of exudate and adherent organs, may be mistaken for ovarian cysts. The ovary may be infiltrated by tubercles or distended by large necrotic and cheesy foci.

In the uterus, apart from the miliary tuberculosis of its peritoneal covering, the disease chiefly attacks the endometrium. Miliary tubercles, ulcers, or, when the process is more progressive, the destruction of the endometrium and adjacent muscularis, and the distention of the uterine walls with caseous material, may occur. This process usually begins in the fundus, and may be especially marked at the cornua. Rarely does it pass the internal os. In the early stage a fine nodular roughening of the endometrium may be detected, but this may be indistinct, and a precise diagnosis is possible only after microscopic study. Later, irregular ulcers with yellowish necrotic bases and edges infiltrated by tubercles may be formed. A diffuse caseous necrosis with a complete destruction of the endometrium is the most common form in the uterus. It may occur in childhood, in middle or in advanced life. The internal os may be obstructed, and the process at times advances to the point of causing a perforation of the muscular wall of the uterus. Rarely there may develop in the uterus a pure interstitial or muscular form that may progress until it produces a perforation into the abdominal or uterine cavity. Early in the process such an involvement may predispose to uterine rupture during pregnancy or labor.

Primary tuberculosis of the uterus is very rare. It is usually secondary to tuberculosis of the Fallopian tubes or to phthisis pulmonalis. As a secondary condition it is not uncommon, and in such cases the tuberculous process is usually limited to the corpus, the cervix being healthy. On the other hand, in the rare cases in which the cervix is attacked, the corpus is usually normal. Merletti (*Archivio di Ostet. e Ginec.*, December, 1901) states that in one hundred and seventy-two cases of genital tuberculosis, seventy-five had the uterine body affected.

Tuberculosis of the cervix usually proceeds to the formation of ulcers or fungating papillary masses. The ulceration may extend over the vaginal portion of the cervix, the base of the ulcer showing reddish granulations and a superficial mass of caseous necrosis. Minute, firm, grayish or yellowish tubercles may be present throughout the surface of the ulcer or in the adjacent tissue. In the papillary form masses occur within the canal, and the clinical picture resembles that of carcinoma. There is, however, less bleeding on manipulation, and the induration is less wooden. Tuberculosis of the cervix is very rare. The first case was described by Virchow ("von Rud. Tuberkulose der Scheide," *Virchow's Archiv*, Bd. v., p. 404). In the majority of cases of cervical tuberculosis, tuberculosis of the vagina has been present. Tuberculosis of the corpus seldom exists in conjunction with tuberculosis of the cervix. J. Whitridge Williams ("Tuberculosis of the Female Generative Organs," Johns Hopkins Hospital Reports, 1892, vol. iii., p. 85) was able to collect only seven cases. It is probable that certain cases of tuberculosis of the cervix have been diagnosed as instances of cancer, thus forming a possible source of error in estimating the permanent results of hysterectomy for cancer of the cervix.

In the vagina and upon the labia miliary tubercles and irregular ulcers with indurated yellowish or reddish bases and thickened borders have in rare instances been noted. In the vagina the posterior wall is the seat of election for the disease. Tuberculosis of the vagina is usually secondary to tuberculosis of the higher portions of the genital tract, though it may occur independently of any tuberculous infection of the rest of the genitalia. Tuberculous ulcers may perforate the wall of the vagina and, according to their location, lead to the formation of recto-vaginal and vesico-vaginal fistulæ.

The lupus occurring upon the vulva resembles that which occurs upon other portions of the body. The vulva is less often the seat of tuberculosis than any portion of the genitalia. J. Whitridge Williams ("Tuberculosis of the Female Generative Organs," Johns Hopkins Hospital Reports, 1892, vol. iii., p. 85) was able to collect only three cases in which the diagnosis, based upon microscopic and bacteriologic examinations, was undoubted. Many cases of supposed lupus have been due to syphilis or to non-tuberculous ulceration.

It seems probable that the supposed rarity of the disease below the Fallopian tubes is due in part to the lack of pathologic or bacteriologic study of obscure lesions.

Under the microscope the tubercles found in the genitalia resemble those found elsewhere in the body, frequently combining giant cells and caseous centres with a peripheral zone of epithelioid and lymphoid cells.

DIAGNOSIS.—Cover-glass smears made from the secretions of the uterus or local lesions when properly stained may show the characteristic bacilli. Care should be taken by inoculation experiments, or other tests, to exclude the smegma bacillus.

The most delicate reaction is by the injection of suspected secretion into the peritoneal cavities of guinea-pigs. In from three to six weeks, should virulent tubercle bacilli be present in the secretion, the animals will show a characteristic involvement of the organs. Uterine scrapings, scrapings or sections from ulcers, when sectioned and stained, may show characteristic tubercles or the bacilli. I have observed typical tubercles in bits of granulation tissue scraped from a pelvic sinus. Sections should be made of all excised organs, and, in doubtful cases, inoculation experiments in the lower animals should be carried out.

Clinically, tuberculosis is to be thought of when a marked salpingitis, perimetritis, or endometritis occurs in young children or in adults, provided we can exclude gonorrhœal or puerperal infection. The diagnosis is rendered more probable when tuberculous foci are present in the lungs or other organs. Tuberculosis of the vulva, vagina, and cervix may be suspected when these tissues are infiltrated or ulcerated. The lesions resemble those of tuberculosis upon other mucous structures, but the diagnosis must rest upon histologic and bacteriologic studies. In tuberculosis the adhesions about the Fallopian tubes may be extensive, and yet the ostia of these tubes may not show the same tendency to undergo closure that is observed in other forms of salpingitis. As to the general symptoms, the great disproportion which exists between the marked cachexia and the insignificant amount of local disease is suggestive, while the injection of tuberculin causes a well-marked reaction. The pathologic process is aggravated by pregnancy, by coitus, and generally by debilitating conditions, especially such as occur in diabetes.

TREATMENT.—Tuberculosis of the uterus, whether of the corpus or of the cervix, when primary or when secondary to tuberculosis of the uterine appendages or of the peritoneum, should be treated by hysterectomy. Abdominal hysterectomy should be preferred as affording the opportunity of dealing more satisfactorily with the involved appendages and of inspecting the abdominal peritoneum. When tuberculosis of the uterus is secondary to tuberculosis in the lungs or other organs of the body, hysterectomy is still indicated, provided the tuberculous process elsewhere is not extensive and is not progressive, and provided also that the nutrition and vitality of the particular patient is sufficiently good to enable her to withstand a major operation. When tuberculosis of the uterus or cervix is secondary to or complicated by active tuberculosis in other organs of the body, or when the vitality of the patient is too greatly reduced to render a major operation advisable, treatment addressed to the cure or amelioration of the complicating conditions should first be instituted. Admission should be sought in a well-equipped sanitarium for the treatment of tuberculosis; or, if this is not available, the influence of rest, forced feeding, life in the open air, and tonic medication should be advised. During the continuance of such general treatment, should the discharges from the uterus be annoying or offensive, bland aseptic or mild antiseptic vaginal douches should be employed. In cases in which local discharge, whether of blood or of pus, is a marked feature, and in which a radical operation is contraindicated, curettage, with local applications of silver nitrate, iodoform, etc., may occasionally be indicated.

The treatment of tuberculosis of the vagina depends upon the character of the lesions, upon whether they be primary or secondary, and upon the complications in the particular case. Isolated lesions, when not too extenpiece of ice in the mouth for a few moments before the operation is effective and free from the objectionable features of cocaine. Pain during and after the operation will vary greatly in different cases. While in the case of a slender, anæmic uvula it may be very slight, in a thick, congested, hyperæsthetic one it may be severe and annoying, and the process of healing may be protracted for from two days to a week. Morell Mackenzie insisted that, where there is any follicular disease of the throat, it is most important to cure that affection before the uvula is amputated, as, owing to the after-pain caused by the removal of the uvula, patients will not submit to any further treatment when they have recovered from the operation. Hence the patient remains uncured, and the operation, and he who performed it, are brought into discredit. The amount of relief, however, which is possible from this apparently insignificant procedure is sometimes remarkable, the whole train of symptoms, local and reflex, vanishing as if by magic, the general health returning to a normal basis, and the voice gaining markedly in quality and power. This, however, is not invariably the case, as the reflex symptoms may be slow in leaving, not disappearing entirely until a considerable length of time has elapsed. This possibility should be recognized and explained to the patient in order that he may not be subjected to unnecessary disappointment.

While the operation of uvulotomy is attended with the slightest possible degree of danger, and the bleeding which follows it is seldom more than a few drops in amount, in certain rare instances hemorrhage, more or less troublesome in its character, has resulted. The existence of an anomalous distribution of the arteries or veins of the velum palati may be an important factor in producing hemorrhage, while excessive hypertrophy or the presence of a varicose or hemorrhoidal condition of the vessels would certainly predispose to bleeding. Operations performed during the existence of acute inflammation, œdema, or ulceration are more likely to be succeeded by bleeding than when made for simple prolapsus.

The character of the bleeding is usually arterial, as is evidenced by the color of the blood, the spurting of the vessels, and the pulsation of the stump. Nevertheless, venous hemorrhage is sometimes noticed.

Troublesome bleeding is not necessarily attributable to the removal of too much of the uvula, for a simple clipping has caused profuse hemorrhage, while extensive removals may be almost bloodless. The existence of the hemorrhagic diathesis would of course exert an influence in rendering bleeding after uvulotomy persistent, although there is not a clearly established case of this nature on record.

The most reliable surgical methods for controlling uvular hemorrhage are the ligature, compression by the clamp or forceps, or the use of the galvano- or the actual cautery.

The most reliable styptics are, in the order named, adrenalin, solutions of antipyrin, tannogallic acid, alum, or the solid silver nitrate, directly applied to the bleeding stump, the local use of ice, ice water, and vinegar.

Ordinarily, the best plan for preventing bleeding is to urge the patient to refrain from attempts at clearing the throat. Should the hemorrhage persist, it may usually be checked by the sucking of cracked ice, or by gargling the pharynx with hot water. Applications of the solid nitrate of silver, or of the galvano-cautery, are also effective, or in severe cases a ligature may be applied to the stump. A device at once simple and effective is the method of applying direct pressure. One of the small spring clamps used in retaining shirt sleeves in position is trimmed down with shears, the spring weakened, and a string attached to a perforation made in one of its arms. The arms of this improvised instrument are widely separated by means of a dressing forceps, and quickly slipped over the uvula and well up on the soft palate; the forceps are then withdrawn, and the clamp remains securely fastened and in the desired position. The teeth of the clamp should be slightly filed down prior to introduction, and the string attached to the instrument secured to the patient's ear.

Occasionally the operation of uvulotomy is followed by a somewhat slow process of healing, and attended with considerable pain, deglutition becoming almost impossible, and even the swallowing of the saliva causing inconvenience. In such cases the patient should be directed to abstain from such articles of diet as seem likely to increase the irritation. Indeed, it is well in all cases to recommend that bland and unirritating food be taken until the healing process is fairly completed. Gum arabic, or a marshmallow drop allowed to dissolve in the mouth, will give decided relief, while, in case the granulations become exuberant, an application of the solid nitrate of silver will hasten recovery. When much pain is experienced in swallowing, the application of a two-per-cent. solution of cocaine is indicated. Pain reflected to the ears may be annoying. The highest authorities are unanimous in insisting upon the deleterious effects of an elongated uvula upon the voice, and upon the vital importance to that function of remedying the evil.

MALFORMATIONS of the uvula are not infrequently observed. In addition to asymmetry or absence of the part, two common varieties of deformity are met with, viz., congenital elongation or undue length, and the condition known as bifid or double uvula. In the former the whole structure, including the muscular tissue, is lengthened to a greater or less degree beyond the normal limit, the amount of elongation in some recorded instances being incredible.

Congenital elongation of the uvula has been observed by the writer as an hereditary trait, several members of the same family showing the same condition of general hypertrophy and lengthening. The condition is easily remedied by the amputation of the redundant part.

Bifurcation of the uvula, a result of arrested development, is quite common. It may be regarded as the least possible manifestation of cleft palate, and may occur in any degree, from a slight indentation at the tip of the organ to complete division of it to its base. It often exists without giving rise to symptoms indicative of its presence. When it is attended with much hypertrophy it causes the same abnormal symptoms which are observed in ordinary hypertrophy. Abscission of the redundant portion is effective in securing relief. This, however, is a clumsy method of operation, since, if the bifurcation be extensive, a broad, truncated stump is left. To avoid this, in the opinion of the writer, some attempt at a plastic operation should be made, in order to secure, if possible, the union of the two stumps in the median line. This may be accomplished, in the majority of instances, by first removing the tips of the two uvulæ, and then denuding, with small curved scissors or the galvano-cautery, the inner aspect of each well up to the base.

NEW GROWTHS.—Papillomatous growths, generally of small size, but sometimes of sufficient dimensions to cause irritation, are occasionally seen upon the uvula. They are usually located near its free extremity and may be either pedunculated or sessile. They are also found independently of any diathesis. Myxomata of the uvula are occasionally seen. Angiomata or vascular growths may also occur.

Occasionally a benign growth may be attached to a pedicle so long that the tumor itself escapes observation until drawn upward and forward. In all of these cases amputation of the uvula above the site of the growth is at once successful in relieving the difficulty.

Malignant growths of the uvula and soft palate are occasionally encountered, usually, however, as an extension of the disease from adjacent parts.

Syphilis, tuberculosis, lupus, and lepra of the velum and uvula are met with, the first often, the last three rarely.

The main points in the differential diagnosis between them are, that in syphilis the various lesions common to this disease are usually disposed upon the soft palate in a markedly symmetrical arrangement, they are but slightly painful, and they yield quickly to specific treat-rise to lancinating, almost unbearable pain. Respiration, besides, is more or less seriously impeded. In such cases the inflammation involves both the mucous membrane and the submucous connective tissue, and also the azygos muscle, and it may extend to the neighboring parts.

The causes of the above-mentioned forms of inflammation of the uvula are, in general, as follows: Influence of cold, or of irritating substances, such as too hot food or drink, burning or irritating alkaline substances or mineral acids; and, finally, progressive inflammation extending from the neighboring parts. As already mentioned, the symptoms of acute uvulitis do not last long, and the disease can usually be shortened by the application of medicines such as are generally used for similar conditions elsewhere. Sometimes the disease becomes chronic, especially when the inflammation is often repeated, or the patient is suffering from constitutional disease or general disturbance of nutrition.

The chronic catarrhal form of uvulitis presents all the well-known changes in appearance which are common in like affections of the pharynx and larynx. A granular condition of the mucous membrane is especially frequent, originating in a hyperplastic inflammation of the mucous glands. The surface of the uvula is hard, reddened, and covered with small nodules. Between the latter the mucous membrane is indurated, hyperæmic, and insensitive. The condition is often associated with a similar disease of the pharynx, and it occurs most frequently in strumous and anæmic subjects, or in those whose general nutrition has become impaired. It is a somewhat stubborn affection, for which general as well as local treatment is required.

Relaxed Uvula.—Chronic inflammation of the uvula usually ends in prolapse and hypertrophy, a condition which may give rise both to direct and to reflex irritation of a serious nature. One of the chief causes of relaxed uvula or, more properly speaking, of the catarrhal troubles which occasion it, are vicissitudes of climate and variations of temperature, especially in countries where there is a frequent combination of cold and wet weather.

Exposure to night air, or to the vitiated atmosphere of crowded and overheated rooms, overindulgence in eating or drinking, and excessive smoking are among the causes of relaxed throat. It is a common companion of the alcoholic habit, often being associated with the gastric catarrh which attends that condition. Occurring in the morning, it is probably due to mouth-breathing from nasal or naso-pharyngeal obstruction; in the evening, from fatigue. It is often seen in those suffering from general depression, and when it is observed in women in whom uterine disease is present, it is probably the result of the general enfeeblement caused by the latter, rather than of any distinct reflex influence. Marked elongation of the uvula is often present in strumous children and in those in whom the tonsils are enlarged. It is sometimes congenital. In general, any cause which may produce a relaxation of the velum palati may also be followed by relaxation and elongation of the uvula.

The symptoms of an acute attack of relaxed palate are a sensation of fulness and stiffness of the throat, together sometimes with the sensation as of a foreign body. There are also an uncomfortable feeling of dryness, and a desire to make repeated efforts to dislodge the supposed foreign substance.

The symptoms may quickly subside, or they may continue for several days. Examination reveals more or less congestion of the parts, although this is sometimes so slight as hardly to be noticeable. There are also slight swelling, and often a varicose condition of the smaller veins. The elongated state of the uvula may give rise to a greater or less degree of local irritation. Sometimes this becomes excessive, occasioning persistent and severe attacks of coughing. In case the uvula be long enough to touch the epiglottis or the larynx, severe paroxysms of coughing may occur whenever the patient lies upon his back. This may cause him much distress upon lying down at night, and, should he turn upon his back during sleep, may waken him with a sense of impending suffocation. When the condition has become chronic, or is congenital, these suffocative attacks may be of almost nightly occurrence, the patient being obliged to sleep with the head raised by several pillows to obtain any immunity from them. Sometimes the attendant hyperæsthesia of the pharynx is so pronounced that the patient may be subject to sudden fits of violent, spasmodic cough upon the slightest provocation, or even without any apparent reason at all. The writer has seen a case of spasmodic stricture of the œsophagus, in a patient suffering with elongated uvula and hyperæsthesia of the pharynx, which was cured by amputation of the uvula. Again, so great may be the irritation that cough, loss of appetite and sleep, and nausea and vomiting may result in such pronounced emaciation, anæmia, debility, and malaise that the case may, upon superficial examination, be taken for one of phthisis. Indeed this error is not infrequently made.

Proper treatment of relaxed uvula generally results in the cure of the disease. The various exciting causes of the trouble should, if possible, be carefully avoided. The patient should be directed to live in a dry and bracing climate. Indigestion or constipation, if present, should be corrected. Anæmia and debility must be removed by the administration of tonics, and the local condition is to be treated by the application of mild astringent sprays or insufflations. If the uvula be much elongated, if it be a source of irritation, and if it refuse to retract under the influence of local treatment, it should be shortened.

Amputation or abscission of the uvula has been practised among many peoples from a very early date. Although in itself an apparently insignificant operation, it is one of great utility and practical importance.

At the present day uvulotomy is practised with an increasing degree of discretion, as some reproach has been cast upon it by the indiscriminate and clumsy manner in which it has sometimes been performed.

For the more convenient and perfect performance of the operation many instruments have been devised.

By far the simplest and best instrument is a pair of long-handled scissors, having the blades curved sideways toward the right hand, and one blade hooked at its tip so that the uvula may not slip from its grasp. A holder, made on the principle of Sims' uterine thumb forceps, an instrument about eight inches in length, possesses the advantages over other forceps that it has not the inconvenient scissors handle, that it may be held firmly and with great steadiness by allowing its proximate end to rest in the hollow between the thumb and forefinger, the whole hand meanwhile being steadied by resting the fourth and fifth fingers against the patient's chin, and, finally, that in applying the scissors the forceps may be used as a guide.

In operating, the patient's tongue should be held down by himself, or by an assistant, with a tongue depressor. The amount necessary to be removed having been carefully estimated, the uvula is grasped by the forceps at a point below the proposed line of incision and drawn slightly forward. The scissors, carefully guided by the hand and eye of the operator, are then applied, and the separation of the redundant tissue is completed. The same result may be obtained by means of the Jarvis snare, in the use of which it is only necessary to seize the part to be removed in the loop of the écraseur, without the aid of the forceps. This latter method is not painful if cocaine anæsthesia is employed, and it has been found by the writer to be particularly convenient and effective. Should there be any fear of exciting undue bleeding, the galvano-caustic loop may be used, the uvula being first drawn forward as in abscission by the scissors. As was long ago pointed out by Llewellyn Thomas, the line of incision should be directed from below obliquely upward and backward, in order that the wound may be exposed as little as possible in the act of deglutition. Local anæsthesia should always be secured before the operation. For this purpose the holding of a ment. Tuberculous ulcers are far less common than the former; they are usually superficial; they often give rise to extreme pain, and they coexist with well-marked disease of the lungs, and generally with other manifestations of ulceration in the pharynx. The differentiation of lupus from syphilis of the soft palate is sometimes difficult, especially if the patient be also suffering from general syphilis. The chief characteristics of lupus are that the normal sensitiveness of the part is maintained; or, if altered, there is anæsthesia. The tubercles are multiple, which distinguishes the disease from carcinoma; they are rounded, their surface is smooth and glistening, and their color is bright red. They are firm in consistence, but less firm than epithelioma. The diagnosis may be confirmed by the presence of external manifestations of the disease. Lesions of the mucous membranes, common in leprosy, never occur until the disease has clearly manifested itself in other parts of the body. As a rule, therefore, little doubt can arise as to the true nature of the pharyngeal disease. Here, as elsewhere, the course of lepra is one of active and widespread destruction.

SYPHILIS OF THE VELUM PALATI.—The occurrence of the primary lesion of syphilis, although now and then observed upon the tonsil, is, upon the velum, almost unknown.

In the secondary manifestations of the disease, however, the soft palate and uvula are frequently involved. The conditions presented are those commonly seen in the adjacent parts of the oral cavity, and include simple erythema or congestive patches symmetrically disposed, submucous infiltration, mucous tubercles, followed by mucous patches, or by the formation of condylomata. A peculiar feature of these manifestations is their symmetry, which, as is often seen upon the uvula, is so well marked as to attract the attention of the observer. Early in the disease the congestion may be so indistinct as to escape observation. Gentle irritation, however, will often cause the distinctive character to be intensified. Considerable rise of temperature often accompanies the first appearance of this form of sore throat.

The tertiary form of syphilis may occur in the soft palate at any period of time beyond two years after the primary infection. It is characterized by true ulceration or loss of tissue, and is the result of the degeneration of gummatous deposit.

The effects upon the velum palati of tertiary syphilis are often most disastrous. A frequent seat of gummatous infiltration, its exposed situation and delicate texture render it liable to serious injury as the result of tertiary ulcerative processes. These are often characterized by extensive loss of substance, and are followed by marked cicatricial contraction and the formation of adhesions between the remaining tissue and the neighboring soft parts, which not only destroy the velum itself and abolish its functions, but result in a closure or a shutting off of the upper pharynx from the lower. This closure is more or less complete in proportion to the extent of adhesion present, and may vary from a slight narrowing of the aperture, due to adhesions at the outside angles of the velum, up to a degree of occlusion which seems absolute. Two varieties of cases may be described: (1) Those in which simple ulceration has taken place, at or near the margins of the velum, without material loss of substance. In such cases, the adhesions being limited to a somewhat narrow band of union between the edge of the velum and the pharynx, and the greater part of the velum itself being intact, the prognosis is good. (2) When the loss of substance has been considerable, and when the soft palate has become extensively adherent to the pharynx, relief becomes a matter of extreme difficulty, and, in many cases, is next to impossible by any known plan of treatment. In the worst cases the whole posterior surface of the velum, and the superior surface of the soft palate, seem to be firmly incorporated with the posterior pharyngeal wall. In these cases the roof of the mouth and the posterior wall of the pharynx seem to be continuous, the line of adhesion not being traceable in the confused mass of cicatricial bands which represent the original structures, and which are sometimes disposed in the shape of irregular vertical digitations, between which there may be one or more places in which the adhesion is incomplete, and through which a probe may be passed. Cases, however, in which complete occlusion has actually taken place are rare. Should the opening be invisible upon inspection of the pharynx, it may generally be demonstrated by forcing air into the nasal cavities by means of a Politzer inflator. If an opening exists, its presence will be indicated by the appearance of bubbles in the pharynx, when the air is forced through the opening.

The results of extensive adhesion of the velum to the pharynx are most distressing, and may be summed up as follows: (1) Mouth-breathing, with all of its attendant evil results; (2) impairment of the quality and tone of the voice; (3) interference with drainage from the nasal cavities and nasopharynx; (4) consequent upon this, loss of hearing from irritation of the Eustachian tube, and from the almost inevitable occurrence of serious middle-ear disease; (5) loss of the sense of olfaction, owing to the lack of a current of air through the nasal passages, such a current being necessary to bring the odoriferous particles in contact with the olfactory membrane. When the passage to the lower part of the pharynx is contracted, there is sometimes dysphagia as well as dyspnœa.

The treatment of this condition consists in the attempt to separate the adherent tissues, and to establish, more or less perfectly, communication between the upper and the lower pharynx. To carry out this design with success is one of the most difficult problems of surgery. Perforation of the velum through the breaking down of gummatous deposits is said to be a cause of serious danger to that organ, since, having thereby lost to a greater or less degree its muscular vigor and resiliency, it is liable to swing backward against the pharynx, instead of being held at a normal distance from it. Furthermore, a perforation renders it all the more liable to form adhesions subsequently with neighboring parts. The mechanism, however, by which adhesion commonly takes place, is the same as that which is observed in the cicatricial union of the fingers of the hand following burns. Despite all possible care, the cicatrizing surfaces begin to unite at the bottom of the angle between the members, and the process of adhesion continues until the denuded surfaces, throughout their whole extent, have become firmly joined to each other.

In the treatment of these unfortunate cases the first care should be to prevent adhesion, by checking with all possible diligence the appearance and spread of ulceration upon the parts. Not only should the iodide of potassium be freely administered, combined if necessary with mercury, but local applications should also be made to the ulcers: of nitrate of silver, or the acid nitrate of mercury, if they be spreading, or of a solution of sulphate of copper (gr. xv. ad ℥ i.) if they be indolent. If this treatment fails, means should be used to keep the ulcerated surfaces apart. For this purpose several methods have been proposed, but as they apply as well to the separation of the parts after operation, they will be described later.

The prognosis as to the results of operation must depend largely upon the extent of deformity present in a given case. Where the degree of adhesion is comparatively slight, the adherent surfaces may be separated by means of a small, flat knife. As, however, the separated parts have a very strong tendency to reunite, it will be necessary, after operation, to use means for preventing such a reunion. Of these the simplest is the application to the cut surfaces of monochloracetic acid. This forms an adherent eschar, under which the healing process seems to progress to such a degree that, when the eschar separates and comes away, the period in which adhesion would have taken place has passed, and the parts heal without uniting

Few cases, however, are so simple as to render the above method possible. Perhaps the most valuable plan of treatment yet suggested is to separate the united parts by means of the galvano-cautery, and then to use great diligence in keeping them apart, and in maintaining full dilatation of the passage. This may be done by repeatedly drawing forward the remnant of the velum by means of a palate hook—a procedure which the patient can carry out himself; or, as has been suggested, a piece of tape may be passed through each nostril and out at the corresponding angle of the mouth, the velum being thus drawn away from the posterior pharyngeal wall; or, finally, given the best results, a piece of metal shaped to fit the space between the velum and the pharynx may be suspended from two stout threads passed forward through the nose, and tied so as to hold the plate in position. This, worn constantly, serves as a permanent dilator.

Since readhesion after operation is due to granulation and union at the external angles of the wound, as in web finger, Nichols has devised the following excellent operation: Before attempting the separation of the velum from the posterior wall of the pharynx, openings should be made through the adhesions and at their extreme outer angle, one on each side. These openings should be kept packed until their surfaces have healed. Thus the granulating angle will have been destroyed, and in favorable cases the remaining adhesions can be separated and kept apart with success.

In cases in which the degree of deformity is excessive, the best that has hitherto been accomplished has been to widen the channel of communication between the upper and lower pharynx sufficiently to allow the nasal secretions to be drained away. This has been done by applications of the galvano-caustic knife, followed by persistent dilatation, practised by the patient himself by means of some form of sound. It is highly probable that by the last-mentioned method an opening of considerable size may be maintained. Preliminary to operating upon such a case, much aid may be secured by passing a sound backward through the nose, and demonstrating the lowest and most superficial point of the pharyngeal pouch. By cutting against the point of the sound used as a guide, an entrance may easily be effected.

Finally, it must be said that, although the prognosis as to relief of adhesion of the soft palate to the pharynx is often most unpromising, much may be done to help the sufferer by skill, ingenuity, and unremitting patience in the application of the means already at hand.

Neuroses of the Velum Palati and Uvula.—These may be either sensory or motor. With the former may be classed anæsthesia, hyperæsthesia, paræsthesia, to which may be added vaso-motor neuroses, and, possibly, neuralgia. Motor disturbances include spasm, or increased mobility, and paralysis, or diminished mobility. The causes of these neuroses may be either central or peripheral, and they may be either unilateral or bilateral.

In addition to the central causes which may produce anæsthesia of the velum, it may also be present in epilepsy, chorea, and hysteria. It commonly occurs after diphtheria. It may be caused artificially by certain drugs, among which may be mentioned cocaine, morphine, chloral, and bromide of potassium. The symptoms, if present, consist usually in a feeling of relaxation of the part, or a sensation as of the presence of cotton or wool in the pharynx, sometimes associated with a feeling of pain.

Hyperæsthesia is often met with, and may be due to elongation of the uvula, inflammations of the pharynx, acute and chronic, the presence of a new growth, or a dilated condition of the blood-vessels.

Neuralgia seems to exist in certain rare cases, in which, without apparent cause, lancinating pain is experienced, and areas of localized tenderness may be found.

Paræsthesia often occurs. Schech observes that the affection, when independent of disease of the mucous membrane, is most frequently associated with hysteria and hypochondriasis, or with a fear of diphtheria or syphilis. Those individuals are most prone to it whose occupation demands excessive use of the vocal organs, as also are chlorotic or anæmic persons, women who suffer from gastric or uterine disease, and those whose temperament is excitable; more rarely it is a symptom of disease of the brain, or of bulbar paralysis.

Of the motor disturbances from which the velum may suffer, spasm is the more unusual. It is almost always associated with a similar condition of the pharynx, and is found associated with the same disorders as those which cause it in the latter region.

Paralysis of the velum is a common condition, and one of much importance. It may be due to central causes, such as acute, chronic, and degenerative diseases of the brain; to diphtheria; to local diseases; or, finally, it may be associated with facial paralysis. The paralysis may be either unilateral or bilateral, partial or complete. When it is unilateral the velum and uvula are drawn toward the unaffected side, the faucial arch on the affected side is wider, and that of the sound side is narrower than normal. During phonation there is distinct distortion toward the healthy side. In bilateral paralysis the uvula hangs loosely in the pharynx, showing no sign of voluntary motion, and flapping back and forth with the acts of respiration. During phonation, in partial paralysis, a slight upward movement of the soft palate may be noticed, while, when the paralysis is complete, it remains immovable.

Besides the causes mentioned, there are several influences under which paretic conditions of the velum may occur. Thus, it is not uncommon to find this organ more or less paralyzed after severe acute affections of the pharynx other than diphtheria, and while the presence of such paralysis, after what appeared to have been a simple follicular tonsillitis, may cause the accuracy of the diagnosis to be held in question and suggest the presence of diphtheria, there are so many other disorders, evidently not diphtheritic, by which it may be brought about that the possibility of its occurrence from simple causes is beyond doubt.

Not only may paresis be found after acute affections of the throat and nasopharynx, but, as is more common, it may be present in chronic conditions, as, for instance, chronic pharyngeal catarrh, chronic hypertrophy of the tonsils, and hypertrophy of the adenoid tissue at the pharyngeal vault. It is found in cases of chronic nasal catarrh, and associated with posterior hypertrophy of the inferior turbinated bodies. It may also occur as an accompaniment of an elongated uvula.

The results of this condition are generally evident, both to the patient and to the observer, and it is probable that the defects of speech generally present in, and attributed to, adenoid hypertrophy at the vault, are due rather to the attendant paresis of the soft palate than to the mechanical obstruction of the pharynx.

The treatment of neuroses of the soft palate must be conducted in accordance with the exciting cause present in a given case. This must be demonstrated, and, if possible, removed. Catarrhal conditions must be treated, hypertrophied masses of adenoid tissue must be removed, and the various systemic disorders with which it may be associated properly dealt with.

Locally, direct therapeutic measures are required, the most important thing being to restore tone to the enfeebled muscular structures. To this end the faradic current is valuable, the negative pole being applied to the affected part, or outside, along the angle of the jaw. Systematic exercise of the velum is also beneficial, and may be secured by such gymnastic exercises as frequent gargling, the singing of high notes, or, better still, blowing through a small tube. In the case of children this may be accomplished by allowing the patient to practise daily at blowing soap bubbles. *D. Bryson Delavan.*

VACCINATION is defined as "Inoculation with vaccine, or the virus of cowpox, as a preventive of smallpox; in an extended sense, inoculation with the virus of any specific disease. . . . It consists in the introduction under the skin, or application to an abraded surface, usually on the upper arm or thigh, of a minute quantity of vaccine."—*Century Dictionary*.

"Inoculation with the attenuated or modified virus of a disease, to produce a mild form of it, and so prevent a virulent attack; specifically, and originally, inoculation with cowpox as a preventive of smallpox; performed by introducing vaccine through a puncture of the skin, or an abraded surface."—*The Standard Dictionary*.

For legal purposes, it should be added that the term "vaccination" not only implies the application or introduction of vaccine to or into the body, but its *successful* application or introduction.

In this article the term will be employed only in its limited sense, as applied to the specific disease vaccinia or cowpox.

The *object* of vaccination is, ultimately, protection against smallpox. As a means to the same end, it is also largely employed for the purpose of propagation, continuance, and multiplication of the virus of vaccinia.

History.—To Edward Jenner, an English surgeon of the eighteenth century, must be accorded the honor of introducing and establishing the practice of vaccination as a protective measure against smallpox. The history of vaccination is like that of many other important discoveries. It had a traditional existence from an earlier period, and had undoubtedly been practised to a limited degree in other countries. Von Humboldt states that it had been known and practised from an early period among the Mexicans. Sülzer in 1713, and Sutton and Fewster in 1765, called attention to the properties of vaccine.[1] But no one had given to the subject careful observation and study until Jenner, then a surgeon's apprentice living at Sodbury, near Bristol, noticed that people who acquired cowpox by milking cows affected with that disease acquired an immunity from smallpox. From the time of his first observation, in 1768, to the date of his announcement of the result of his researches to the world, a period of thirty years elapsed, during which time he had patiently and carefully investigated the subject both by observation and by experiment. Dr. H. A. Martin says of him: "He was a truly great and philosophic man, worthy to be, as he was, the chosen pupil and life-long friend of John Hunter. If ever a discovery was announced to the world with due deliberation, it was that of vaccination. We have evidence that for at least thirty years, during which he encountered many perplexing and discouraging obstacles, and one by one mastered and overcame them, this mighty matter occupied the brain of Jenner before he published 'An Inquiry into the Causes and Effects of the *Variola Vaccinæ*, a Disease discovered in some of the Western Counties of England, particularly Gloucestershire, and known by the name of Cowpox.' It was ten years after the discovery first engaged his attention that, in the year 1780, timidly, and under the seal of confidence, he revealed to his bosom friend, Gardner, his mighty hopes for the great good of his fellow-creatures. . . . Such was the slow, careful, almost painful deliberation and completeness with which the mind of Jenner moved to its great goal."[2]

Jenner made his first vaccination upon the human subject in 1796, published the results of his inquiries in 1798, and established the first public institution for the performance of vaccination in 1799. In 1800 the practice was introduced into Germany, France, and the United States.

To Dr. Benj. Waterhouse, of Cambridge, Mass., must be credited the honor of introducing vaccination into New England in 1800, and to President Thomas Jefferson that of introducing it into the Southern States a few months later. It was also introduced into France in May, 1800, by Duke de Rouchefoucault, his efforts being seconded by Napoleon, and especially by his brother Lucien Bonaparte, who was then Minister of the Interior. Dr. Woodville also came over from London to insure the success of the movement.

The following were the principal points which Jenner had established by his inquiries:

1. That the vaccine disease casually communicated to man has the power of rendering him insusceptible to smallpox.
2. That the specific cowpox alone, and not other eruptions affecting the cow which might be confounded with it, has this protective power.
3. That the cowpox may be communicated at will from the cow to man, by the hand of the surgeon, whenever the requisite opportunity exists; and
4. That the cowpox, once engrafted on the human subject, may be continued from individual to individual by successive transmissions, conferring on each the same immunity against smallpox as was produced in the one first infected directly from the cow.

The practical usefulness of this great discovery lies in the possibility of transmitting vaccinia from one human being to another, or, as is largely practised at the present time, from the cow to the human species.

Phenomena of Vaccinia in the Cow.—Vaccinia in the cow is an eruptive vesicular disease, the eruption being usually limited to the udder and the teats. It may occur in single cases, either in an animal kept alone, or in a single animal of a herd, or it may attack a whole herd, or a part only.

It is confined almost exclusively to milch-cows. Ceeley's earlier observations supported this statement; but in a later paper he reports a single case of primary infection in an animal not giving milk. The earlier stages of the disease are so mild as rarely to attract attention, and hence are rarely seen by the expert at this period, except in herds in which the disease attacks a considerable number. After its first appearance in a herd, it is readily conveyed from one animal to another by the milker's hands, unless the greatest care is taken to prevent infection.

Distribution.—Vaccinia has been met with and described in all parts of the world where the cow exists. In Great Britain, France, Germany, Holland, Italy, Bengal, South America, Mexico, New England, and other States of the Union, cases have been reported and described, and in not a few of these the genuine character of the disease was proven by experiment. It was found in epidemic form at Valladolid and at Atlisco, in Mexico (near Puebla), in 1803. Genuine cowpox was also observed in Würtemberg, on 69 different occasions, between 1827 and 1837, and was transferred successfully to the human subject in at least 170 out of 210 trials (Hering: "Ueber Kuhpocken an Kühen"). Seaton says of its prevalence: "After the first ardor of search had relaxed, there were for many years but few recorded instances of the disease being found, and it was believed to have become much rarer, in great measure, no doubt, because it was less sought for. There can be no doubt that much more would be found than really is found, if it were only looked for." Other noted cases were those which were observed at Passy (1836), at Esneux (1868), at Rouen, at Dijon, at Stuttgart, at Beaugency (1866), at St. Mandé, and at Cerons (1884).

A very careful report of an epidemic of vaccinia is presented in the Eighteenth Report of the Local Government Board of England (supplement containing the report of the medical officer for 1888).

Not far from the foregoing case, at Cricklade, in the neighboring county of Wiltshire, other cases of cowpox were discovered in the autumn of 1887, of which an account is given in the second volume of Crookshank's "Vaccination: Its History and Pathology."[3] This region also is not far from the district in which Jenner made his early observations. In a herd of one hundred and twenty cows here, all were attacked except a dozen, which proved refractory.

Occurrence of Natural Kinepox in the United States.—Kinepox is not of unusually rare occurrence, as some have believed. It has been observed on various occasions, and at various places, in the United States, and reported as follows:

1. Dr. John Yale, of Ware, Mass., reports having observed it in 1844, at Torringford, Conn., and in 1855 at

Ware; in the latter case confirming its character by testing it upon the human species, and also by continuing its use upon calves. (Transactions of the American Medical Association, 1872, p. 216.)

2. Dr. Currier observed it at Lexington, Mass., in 1850, and tested it by insertion upon infants.

3. Dr. E. Cutter observed it upon several occasions, as stated in his report of 1872.

4. Dr. H. Darlington observed it and reported upon it as occurring at Concordville, Pa., in 1872.

5. Drs. McMillan and Trask observed it in Marion County, Cal., in 1871, and confirmed its character by experiment.

6. Dr. Jonathan Brown observed it in Wilmington, Mass., in 1867, and tested it by experiment.

7. Dr. H. A. Martin reported a case as observed by him at Cohasset.

8. Cases were reported at Reading, Pa., in 1872.

9. The writer has also visited and inspected at least twenty cases which occurred at seven different dairies or farms in Middlesex and Essex Counties, in Massachusetts, in 1872, 1873, 1881, and 1882. These all occurred during the prevalence of the two smallpox epidemics of those years. They were examined at different stages of the disease, and were found to have the characteristic appearances described by the earlier investigators upon the same subject. At one large dairy farm, where about ninety cows were kept, several cases were seen in different stages, and the disease was prevented from spreading only by isolation and absolute separation from the milkers who milked the remainder of the herd.

Dr. Petry, a noted veterinarian, of Esneux, says: "This disease is much more frequent than is commonly believed. Cowpox may be found in every place, in every land, and in every season of the year; but oftener, it is true, in spring, and in summer at the time of calving." ("Quelques réflexions sur la prétendue rareté du cowpox chez la vache," par M. Petry, M. V. à Esneux. *Annales de la Soc. Méd.-Chirurg. de Liége*, 17, 1878).

Other cases have been observed in recent years in the same vale of Gloucester in which Jenner made his original researches, and also in many other English localities. The writer also has examined dairies at which animals were pointed out by the owners as having had cowpox in previous years. In several of these, by way of experiment, the animals were vaccinated by an expert vaccinator, and in such cases the vaccination invariably proved unsuccessful—a point which may be adduced in support of the genuineness of the disease as at first observed.

In a case observed by the writer at Saugus, in the winter of 1881–82, a lad, twelve years of age, presented the characteristic appearances of infection upon the grasping surface of the index finger and thumb. When first observed most of the vesicles had been broken by the use of the hand in milking. The herd consisted of thirteen animals, but one only of which was found to be suffering with cowpox.

The disease, though not by any means of rare occurrence, is evidently not so common as it was in the eighteenth century, and Dr. Seaton reasonably adduces as causes of its comparative rarity the more common practice of vaccination, whereby milkers do not become susceptible of infection, and, as a consequence, are not the conveyers of such infection from one animal to another; and secondly, the more limited diffusion of variola.

The term "spontaneous" formerly applied to such cases should be abandoned as entirely opposed to all observations as well as modern medical belief as to the natural history of infectious diseases.

Incubation.—The incubative period is probably about three or four days, prolonged occasionally to seven or eight days (Ceeley). At first there are heat, swelling, and tenderness of the parts affected, hard papules are developed of the size of a small pea, especially at the base of the teats, at the junction with the udder. The signs of constitutional disturbances at this time are but slight. In thin-skinned animals the disease may be found, by careful observation, when accidentally transmitted, as early as the fifth day. The papules increase daily, and in three or four days from their first appearance become distinctly vesicular, and have a more or less central depression.

The change from the papular to the vesicular stage is indicated by the appearance of a dull yellowish point at the apex of the prominence; the circumference then increases in substance and extent, and the centre becomes wider and deeper, till at last the flattened vesicle with depressed centre is formed. It increases in size until, in three or four days more, its full development is reached. Their number and size vary. The amount of eruption varies with the severity of the disease. With animals having loose, fleshy, hairless udders, and long, thin-skinned teats, the eruption is ordinarily copious. The shape of the lesions is usually determined by their position, being for the most part circular at the base or neck of the teats, and oval on the body of the teats. Their color varies with the stage of the disease and the color of the skin. When completely formed the vesicle is often from 15 to 20 mm. in diameter, and has a solid, tense, shining margin of a glistening white or silvery hue, and a bluish or slate-colored centre. It contains a viscid, clear lymph, which is at this period quite scanty. Around the base a narrow, rose-colored areola begins to spread with a circumscribed induration. The color of the areola varies with that of the skin. The disease reaches its crisis about the tenth or eleventh day. The lymph becomes more copious, the vesicle becomes more globular in form, and if it is broken, the lymph flows freely. At first it is of a light amber color, and then becomes turbid and opaque. Incrustation now begins at the centre and advances steadily, the crusts attaining their largest size by the thirteenth or fourteenth day. They are of a dark-brown color, and adhere more or less firmly to the skin, the areola and the induration gradually subsiding. The crusts continue to dry and to diminish in size, and become loose and fall off about from the twentieth to the twenty-third day. The cicatrices left are shallow, smooth, and of a pale-rose or whitish hue.

These are the appearances of undisturbed vaccinia in the cow, and they are rarely seen in their perfect form, since the handling of the teats by the milkers injures the vesicles, rupturing the cuticle, and allowing the serum to exude. Raw surfaces and dark crusts are often seen coalescing, and becoming rapidly detached by rough usage. The tender teats, with their raw surfaces, bleed, and finally heal, leaving cicatrices of varying size.

Constitutional Symptoms.—These are usually slight. The appetite of the animal appears to be affected but little. The secretion of milk may be slightly diminished, and the amount actually obtained may be much lessened in consequence of the annoyance to the milkers and trouble in milking.

There is no evidence that the quality of the milk is in the least modified. Both in the casual form of vaccinia and in that which is artificially produced, animals have been known to give milk uninterruptedly through the course of the infection, and such milk has been in constant use, without perceptible detriment to consumers.

Spurious Eruptions.—The cow is liable to other eruptive diseases which may be mistaken for vaccinia. Ceeley mentions three varieties, under the names of the yellow, the black, and the white or blister-pock, the latter being quite contagious. More recently other eruptions of a contagious nature have been observed and described, especially that which is associated with scarlatina, and which appears to have given rise to that disease in human beings, either through the medium of the milk or otherwise ("Local Government Board Report," 1882. Inquiries by Mr. Power and Dr. Klein, p. 63).

THE RELATION OF VACCINIA TO VARIOLA.—*The Unity or Duality of the Two Diseases.*—Seaton states that the common origin of the cowpox, horsepox, and smallpox has been established by conclusive experiments, and adduces the experiments of Gassner, of Günsburg, in 1801, who inoculated eleven cows with smallpox virus, in one of which vesicles appeared, from which several children were successfully vaccinated, the ordinary phenomena of vaccination ensuing (Henke's *Zeitschrift, Ergänzungs.*, p. 57).

In 1865 a commission at Lyons published the following conclusions concerning the relation of these diseases to each other:

1. Cowpox and smallpox can be inoculated in bovine and equine animals; the first energetically, the second feebly.
2. Whatever may be their successive transmissions, direct or crossed, these two diseases breed true on every soil.
3. The protection from one by the other is assured in every case.

Some interesting experiments have been made by Haccius and Eternod, of Geneva, which tend to confirm those already published by Fischer in the *München. med. Wochenschrift*, and make the identity of variola and vaccinia more than probable. The conclusions at which Thiele, Ceeley, Voigt, and Depaul arrived many years ago, namely, that cowpox is a modified form of smallpox, attenuated by its passage through the organism of an animal, were disputed by the Lyons commission, which adduced seemingly unimpeachable experiments of their own, contradictory to the observations of the earlier experimenters.

Haccius and his colleague, following the operative method of Fischer, claim that they have succeeded in imparting smallpox to animals, and in transmitting it through several generations, the disease finally manifesting itself in a mild form not distinguishable from true cowpox, and like it, conferring immunity from variola.

In one of these series of experiments, Haccius and his colleague succeeded in transmitting the smallpox virus from heifer to heifer to the fourteenth generation; and side by side with a set of similar observations where vaccine virus was used, they had a series under observation where the heifers were inoculated with virus from a case of confluent smallpox. Lymph from "the fourth generation" has given the results of ordinary vaccine when used for purposes of vaccination.

Their conclusions were as follows:

1. Variola is inoculable *with certainty* on the bovine species when the operative method is such as it should be, and the virus is collected at the opportune moment.
2. The inoculation of the heifer with smallpox constitutes a valuable source for new reinforcements of animal vaccine. This may be of great practical benefit, not only to the vaccinal institutes of Europe, but also to tropical countries, where smallpox is endemic, and where the generations of vaccine tend rapidly to deteriorate.
3. Smallpox inoculated in the heifer becomes transformed into vaccine in the course of several generations, by transmission through the animal. *Duality is thus disproved.*
4. Our practical conclusions confirm the views enunciated by Depaul, in 1863, to the Academy of Medicine of Paris.

Following these experiments Chauveau was led by a similar mode of investigation to very different conclusions.

His paper ("Sur la transformation des virus à propos des relations qui existent entre la vaccine et la variole") was presented at the sessions of the Academy of Medicine of October 20th and 27th, 1891. His conclusions are as follows: (1) Vaccine virus never gives smallpox to man. (2) Variolic virus never gives vaccine to the cow or horse. (3) Vaccine is not even *attenuated smallpox*, and cannot be compared to the benign anthracoid infection which is communicated to animals by inoculation with *attenuated anthracoid virus*. (4) If vaccine is a derivative of smallpox it is by reason of a *radical transformation* of the variolic virus, a transformation thus far unattainable by experimenters. (5) These last propositions lead to another more general proposition, which is this: the *attenuation* of virus is not a physical process which can be identified with the *transformation* of virus. The weight of scientific opinion to-day, however, is decidedly against these conclusions of Chauveau.

Satisfactory experiments of this kind are difficult of performance, for no experimentation on animals can be regarded as complete the results of which have not been checked by inoculations practised on the human subject. Now, Haccius and Eternod did not try their lymph—rendered vaccinal, as they believed, by several removes—on the unvaccinated child, nor did Chauveau make any such trials (*Boston Medical and Surgical Journal*, 1891).

On the other hand, it appears that the experiment has been tried upon unvaccinated children in Calcutta, as detailed by the experimenter, Dr. W. J. Simpson, medical officer of health of Calcutta, at a meeting of the Calcutta Medical Society, April 13th, 1892.

Dr. Simpson comments upon Chauveau's experiments as follows: "Seventeen animals were inoculated by that commission with lymph from virulent cases of smallpox, and some small papules were obtained, the secretions from which, when inoculated into other cows, gave rise to papules of an insignificant kind, but which when inoculated into children gave rise to smallpox. On this slender foundation the theory has been based, and is very forcibly put forward, that smallpox in man produces a real smallpox in the cow totally differing in every respect from cowpox.

"To those who have studied the subject these experiments are by no means conclusive. They only show that Chauveau with his coadjutors failed to inoculate the cows successfully, and that the papules raised were rather due to the irritation of the points of insertion by the smallpox lymph, and that the serous matter taken out of these papules was the smallpox lymph itself, which had remained in them unchanged; and under these conditions it was not surprising that smallpox was produced in the children inoculated with this virus.

"Nothing further was attempted in the way of experiment until Dr. Klein, in 1879, inoculated thirty-three cows with smallpox lymph, but failed to raise any vesicles on the cows. Papules appeared in some of the cows at the seat of inoculation, but these were not considered to have turned the experiments into a success, and no serum was taken from these papules and inoculated into children. If such a procedure had met with favor, there would probably, as in Chauveau's cases, have been an after-history of smallpox in the children inoculated.

"Dr. Klein's failure served to accentuate the theory based on Chauveau's disaster, and both failure and disaster were employed as a basis on which arguments were founded against the pathological identity of smallpox and cowpox. So confident have the supporters of this view since become, that strong doubts have been expressed by them as to the genuineness of the experiments performed by previous observers. A favorite argument appears to be that what was accomplished in the earlier part of the century cannot be done now, and therefore the experiments are not altogether to be trusted. The reason of this is not far to seek. All the conditions under which the cow may be successfully inoculated are not known, and hence it is not every cow that can be inoculated with success. This entails on the investigator much expense, the exercise of a great deal of trouble and patience, and of course it is much easier to read up the subject as Professor Crookshank has done, and side with the view for which you may have the greater predilection, than thoroughly to investigate the subject, not being satisfied with dubious results.

"Apart from the controversial question, it has for a long time been a matter of thought with me as to whether there is any relationship between cowpox, horsepox, sheeppox, and smallpox; whether these four diseases have for their cause a common origin which may be designated by the letter x, this common origin having not yet been discovered; or whether horsepox, cowpox, and sheeppox, or any of them, are descendants of smallpox; or thirdly, whether smallpox may be looked upon in the light of a parasitic disease which comes to its full development in man, enters some animal as the cow, losing that which gives it its infectious properties, and then in some other animal, unknown as yet in the soil, regains that element which it had lost in the cow, and which once more renders it infectious.

"I am inclined to think that it is in this latter direction that investigation will ultimately succeed in discovering the cause of the periodicity of smallpox.

"Vaccine and chickenpox have always seemed to be two elements of smallpox which have become separated in some unknown way, the vaccine retaining the peculiar qualities belonging to the smallpox which affects the body in such a manner as to render it immune from a second attack, while the chickenpox has none of these qualities but has retained the infectious element. If this were true, it might seem to be easily proved by experiment. I have tried the experiment by mixing the two viruses, but without success. There is a difference, however, between mixing and combining, and it is possible that the conditions which affect this have to be found in some other less simple way.

"It is for the reasons stated, and for some others which I need not mention here, that I have been engaged for years, as opportunity arose, in experimenting with smallpox on animals.

"When in Aberdeen I used to search the farms in the country for cowpox, and not without success. I have inoculated cows, horses, sheep, pigs, goats, fowls, monkeys, and dogs with smallpox virus to ascertain the result, and in these experiments I have succeeded incidentally; for it was not the primary object for which I began the investigation, in converting smallpox into ordinary vaccine by passing the virus from an unprotected smallpox patient through the cow.

"In December, 1884, I first succeeded in raising a vesicle in a cow after inoculation with smallpox virus. The lymph was transferred to a ewe lamb, and raised a vesicle in every appearance similar to a vaccine vesicle. This lymph was taken and introduced into a young pig six weeks old, and here it was lost.

"In November, 1885, with smallpox lymph from an unvaccinated patient, I inoculated a cow with fifth-day lymph, and a ewe with eighth-day lymph from the same patient. Both presented vesicles on the seventh day, the lymph of which I sent to London to be used by Dr. Cory, the director of the Animal Vaccine Institute in London. This calf lymph, which Dr. Cory passed through a second calf before using on children, was the starting of a new stock of vaccine at the Institute.

"Between November 21st, 1885, and May 6th, 1886, 1,247 children had been vaccinated with this lymph, and gave 98.4 per cent. insertions of success."

These experiments of Dr. Simpson were also confirmed by similar experiments made by Dr. W. G. King, of Madras, and by Dr. T. W. Hime, of Bradford, England (*Practitioner*, vol. xlix., 1892; *Brit. Med. Jour*, July, 1892).

The Phenomena of Vaccinia in Man.—Vaccinia is communicable to man only by inoculation, and may be communicated with equal certainty from the cow or from other human beings.

When fresh vaccine lymph is introduced into the unvaccinated human subject, either by puncture or by abrasion of the skin, local effects are not usually noticeable within the first forty-eight hours. The period of incubation is brief, and if the vaccination is successful, at about the end of the second day a slight redness and swelling are observed at the seat of insertion. On the third or fourth day a little vesicle appears at the summit of the papule, filled with a clear liquid, which gradually grows larger and larger. As the size of the efflorescence increases, an umbilication appears, similar to that of the genuine variola pustule, which corresponds to the shape of the original wound of insertion; an insertion by simple puncture producing a circular vesicle, and an insertion by a longitudinal incision producing an oval vesicle. The vesicle attains its largest size about the seventh or eighth day, when it contains a clear liquid, which, if the vesicle is punctured, will ooze out upon the surface sparingly. The construction of the vesicle is cellular, like that of the pustule of variola. After the eighth day, and sometimes a few hours earlier, a ring of inflammation called the areola begins to form about the base, and the vesicle and areola together continue for the next two days to spread. The areola is circular, and when fully developed has a diameter of 1–3 in. (2½–7 cm.). It is often attended with considerable hardness and swelling of the subjacent tissues. The establishment of the areola demands attention as the evidence that the specific effects of vaccinia have been produced. If several insertions have been made near each other, the areolæ coalesce.

After the tenth day the areola begins to fade, the vesicle begins to dry in the centre, the lymph remaining in it becomes opaque, the pearly colored pustule becomes yellowish, while at the centre, at the location of the original insertion of the virus, a crust has begun to form. By the fourteenth day the crust has become dry and hard, and gradually assumes a darker hue, and usually falls off from the twentieth to the twenty-fifth day, leaving a cicatrix, commonly permanent, which is usually circular, slightly depressed, foveated, or indented with minute pits, and sometimes radiated. (Plate LVIII.)

There are also constitutional symptoms more or less severe, in proportion to the intensity of the local symptoms. There are fever, restlessness, derangement of the digestive organs, and occasionally swelling of the axillary glands. The constitutional symptoms are usually most severe at or a little before the time when the areola has reached its fullest development. Infants usually suffer less than older children, and these less than adults. In adults the course of primary vaccinia is apt to be more retarded than it is in infants, the areola is often more diffuse, and the swelling of the axillary glands more common.

All of these phenomena may be modified by acceleration, by retardation, or by irregularity of development.

1. The most common form of modification is a slight *delay* in the development of the usual symptoms, of one or more days, so that by the ninth day the vesicle has arrived at the usual condition seen upon the seventh or eighth day. Seaton mentions cases in which a week's delay was observed, and after success had been given up; and Bousquet mentions a case in which a dormant vaccination was revived at the end of three weeks. This delay is sometimes due to the incubation of other diseases. If the phenomena follow a regular course, this retardation does not necessarily imply an interference with the protective power of the vaccination.

2. *Acceleration* of the phenomena of vaccination is to be regarded with more suspicion than retardation. If the acceleration amounts to not more than one day in advance of the usual appearances, and the vesicle and the consequent areola assume the typical form and color, the protective value of the vaccination is not necessarily impaired.

3. Vaccination may present *irregular forms.* The formation of the vesicle may be accompanied by considerable itching and irritation. Its shape may be acuminated or conoidal, and without the central depression, and the fluid contents may not be a clear serum, but a cloudy liquid. The areola may be formed early and may be irregular in shape, arriving at its height on the fifth or sixth day. A crust may form and fall off as early as the tenth or twelfth day. The local effect may have been still more accelerated, and a thin scale formed which is readily detached.

Other irregular forms may be seen, none of which should be depended upon as protective against smallpox, nor should virus be taken from them for the purpose of vaccinating others. Such irregular conditions are doubtless due, either to the use of vaccine lymph which is not sufficiently recent, and has consequently lost much of its active infective power, or it may have been inserted in a subject whose health is bad; so that the results of the vaccination may appear uniform from virus employed under the first of these conditions, but not under the second.

Mechanical irritation, such as may be produced by a coarse woollen sleeve, may occasionally interfere with the usual phenomena of the vesicle, by causing its rupture or irregular appearance, and these phenomena may be aggravated if the garment is colored with poisonous dyes. It is a matter of necessity that proper instructions should be given to parents or guardians for the protection of the vesicles, that they may remain uninjured.

With reference to the general question of irregular phenomena, it may be taken as a rule of practice that *any vaccination which presents a deviation from the perfect character of the vesicle, and the regular development of the areola, should not be relied upon as protective against smallpox, nor should lymph be taken from such a vesicle for further use in vaccination.*

Effect of Climate.—In temperate climates the utmost effect of season, either hot or cold, is only to accelerate or to retard (and that exceptionally and seldom beyond a few hours) the usual course of vaccination. According to the best authorities, the excessive heat and moisture of certain seasons in the tropics interfere considerably with the regular progress of vaccination. In India vaccination is less successful after the advent of the hot season, and it is peculiarly so in the rainy season in Bengal, "so much so that vaccination must necessarily be suspended for a time" (Report of Smallpox Commissioners in 1850. Indian Government).

In other parts of India these precautions are not found to be necessary. In the cooler parts of India vaccination may be performed at any time, but in the hotter portions the best season for vaccination is from October to March.

REVACCINATION.—In some people the regular phenomena of vaccination can be produced but once in a life-time. A subsequent introduction of vaccine virus either fails to produce any effect whatever, or it produces a modified effect, like that of spurious vaccination. Revaccination is desirable in all cases of imperfect vaccination, and in all persons at the end of ten or twelve years after a primary vaccination in infancy; and also, in case of immediate exposure to smallpox, it is advisable in those who have not been vaccinated within five years. It should be understood, however, that the human body is not subject to mathematical rules and limitations, and hence, like many other principles of medicine, no precise limit of safety can be stated. The writer has vaccinated persons successfully, who had been successfully vaccinated within a year previous, and has also found many in whom vaccination with fresh lymph was unsuccessful after twenty years or more from the date of a previous vaccination.

Under no circumstances should the lymph from a vesicle of revaccination be employed for further use in vaccination.

As revaccination is a preventive measure, like vaccination, it should not be left until the occurrence of an epidemic. In the United States, where public vaccination is imperfectly carried out, it is a common custom to await the outbreak of smallpox, at which time it is more likely to be done with less care, and in consequence of individual fear rather than according to the discretion of the physician.

The immediate results of revaccination may be either the development of a typical umbilicated vaccine vesicle or of a modified vesicle, or entire failure.

The claim once made by the earlier vaccinators, that a singe primary vaccination was absolutely protective for life against smallpox, is no longer tenable, since experience in severe epidemics in large communities has shown abundant proof to the contrary. After several years had elapsed from the date of the introduction of vaccination, it was observed that cases of smallpox occasionally occurred in the persons of those who had been vaccinated; such cases, however, being of a mild type and rarely fatal. It was therefore urged that the protective power of vaccination was only temporary, gradually becoming less as the individual grows older. By some, the occurrence of such cases was attributed to an improper or an inefficient performance of the primary vaccination. Early observations in support of such belief were made in Copenhagen, and also in London.

In every community a certain proportion of the inhabitants will take smallpox, if they rely merely on the protection which is afforded by a single vaccination performed in early life.

The great standing armies of Europe afford conclusive evidence as to the need of revaccination. It was introduced into the Russian army in 1831, and for the ensuing years from 1831 to 1857, the number of revaccinations was 733,332, of which number 391,574, or 56 per cent., were successful, and 228,848, or 31 per cent., were unsuccessful; the remainder were imperfect.

Seaton lays down the rule that *carelessness in primary vaccination should not be excused on the ground that revaccination will supply its defects.* "It has too often happened," he says, "that vaccination has taken, but has taken badly; either at once or at some not distant period it has been repeated, and has perhaps been performed a third time, but ineffectually (for it will constantly happen that spurious vaccination will prevent subsequent vaccination from taking effect properly); then no more is thought about it, or the child is declared 'insusceptible'; it grows up, gets smallpox, and very likely dies. Take it at its best, an originally imperfect or incomplete vaccination is a very great misfortune."

Age at which Revaccination Should be Performed.—There are circumstances which would call for its performance in childhood, as when the primary vaccination is found to be spurious, imperfect, or irregular in character. If, however, the child's health appears to be such as to account for the irregularities and imperfections, the vaccination should be deferred until its health is corrected. Especially should children having imperfect cicatrices be revaccinated, if there is danger of immediate exposure to infection from smallpox.

Revaccination should be performed with the same care as primary vaccination and always, when possible, with fresh lymph.

It should not be left to periods when smallpox becomes epidemic, and its performance upon persons arriving at a certain age, say twelve years, should be as systematically carried out as in the primary vaccination of infants.

From the results observed as to the performance of revaccination in the armies of Great Britain and of Würtemberg in 1831, 1835, and 1861, it was concluded that the local results obtained by the revaccination of any individual gave absolutely no information whatever as to the constitutional condition in which the revaccinated person was with regard to his liability to contract smallpox.

Dr. R. Gerstäcker, in a paper entitled "The Hygienic Significance of Revaccination,"[4] gives some valuable data compiled from the reports of the Imperial Board of Health, and also from the report of the Vaccination Commission. From their tables it appears that the mortality from smallpox in Prussia, formerly differing but little from that of other countries, has fallen to a minimum under the operations of the vaccination law, so that smallpox may now be regarded as having disappeared, except in some frontier districts; while Austria, with her defective regulations as to vaccination, and still more so as to revaccination, suffers severely from smallpox. Dr. Gerstäcker presents the following table as to the mortality from smallpox in London and in Berlin, with the comment that, while London enforces vaccination of the children, it has not enforced revaccination. He attributes the difference in the relative mortality from smallpox in the two cities to these facts.

DEATHS FROM SMALLPOX, PER 100,000 INHABITANTS.

	1875.	1876.	1877.	1878.	1879.	1880.	1881.	1882.	1883.
In London	1.3	20.8	71.0	38.8	12.1	12.5	61.9	11.1	3.4
In Berlin	5.2	1.8	.4	.8	.7	.8	4.7	.4	.3

Dr. Gerstäcker further agrees with the conclusions of the earlier observers, as to the immunity against smallpox produced by primary vaccination in childhood being of limited duration, and as to the possibility of renewing

EXPLANATION OF
PLATE LVIII.

EXPLANATION OF PLATE LVIII.

The vaccinations shown in this plate are those of three infants, from four to ten months old, at different stages of vaccination. Figs. 2 and 3 are from the same child on different days. Four insertions were made in each case, according to the usual practice of official English vaccinators. These insertions are usually made by light parallel scratches, two or more in number, and about 3–5 mm. in length.

Fig. 1 presents the appearance on the fifth day. The linear depressions in the vesicles indicate the location of the insertions of lymph. A faint flush is appearing around each vesicle.

Fig. 2 shows the appearance on the eighth day.

Fig. 3 presents the appearance at the end of twelve days. In this and in Fig. 2 some supplementary vesicles are shown, a matter of common occurrence. The course of development has been more than usually rapid in this case from the eighth to the twelfth day, desquamation being active around the vesicles and the brownish coloration of crusts appearing.

Fig. 4.—Appearance on sixteenth day. Shows typically the usual method of desiccation of the vesicle.

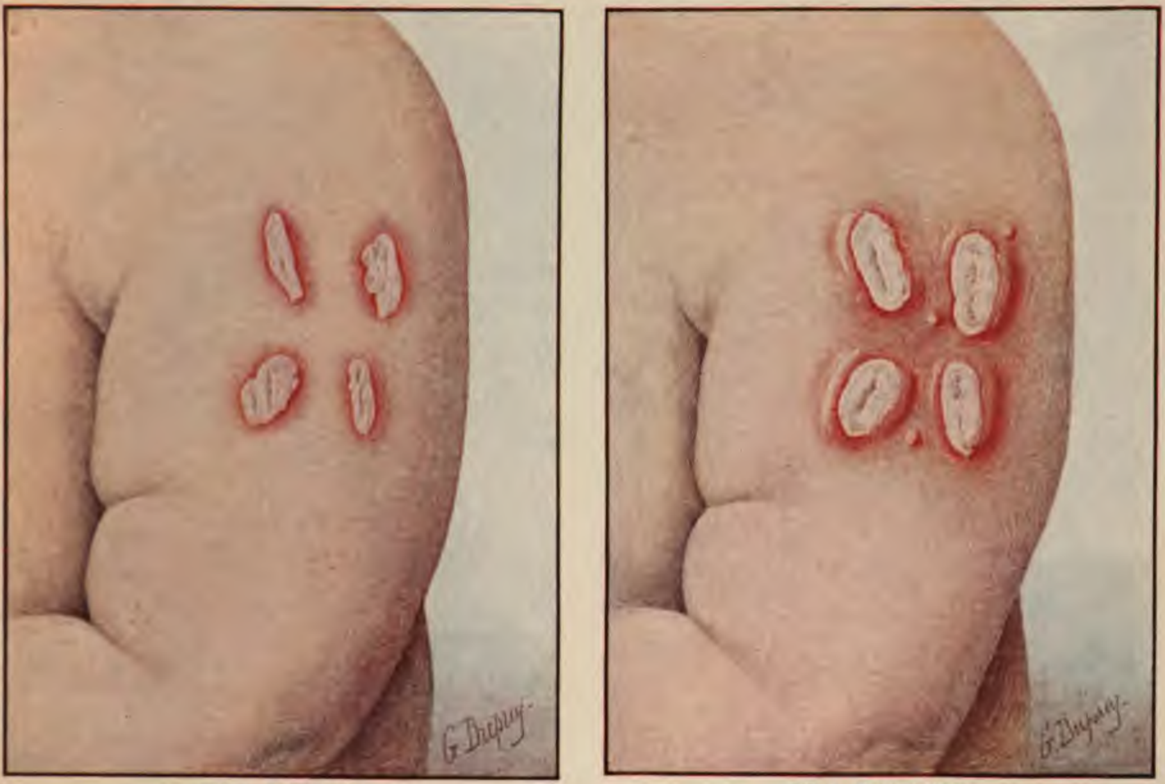

FIG. 1. FIFTH DAY. FIG. 2. EIGHTH DAY.

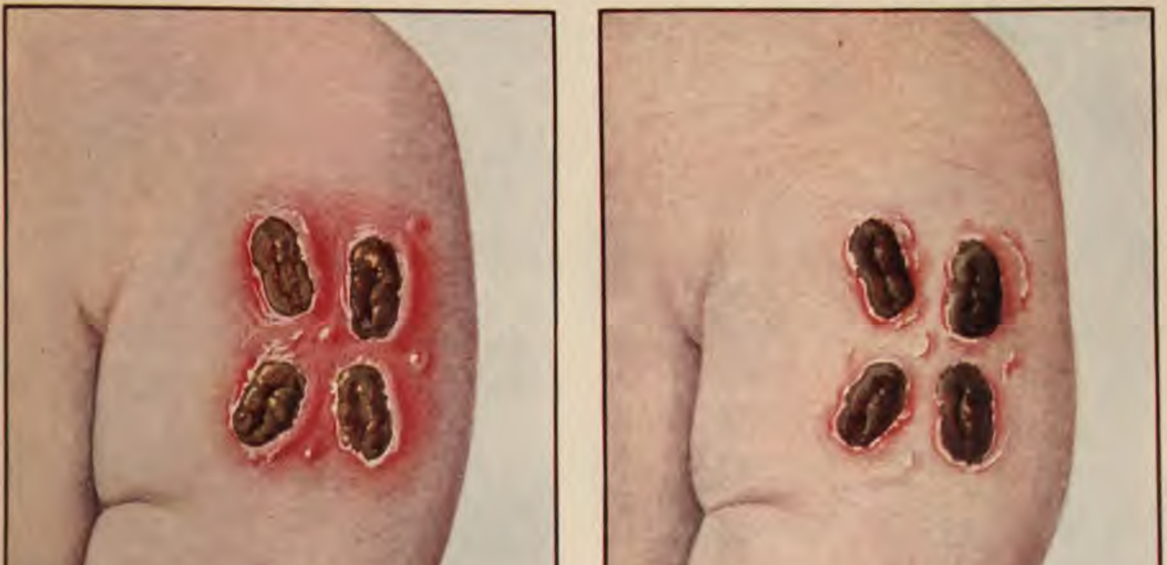

FIG. 3. TWELFTH DAY. FIG. 4. SIXTEENTH DAY.

PRIMARY VACCINATION.

(Redrawn with corrections from Plate shown in British Medical Journal, July 1902.)

its influence by repetition. Revaccination, therefore, as he expresses it, forms an essential part of the measures of prevention against smallpox, and its hygienic importance extends not only to the individual, but also to society, the relative immunity of which is warranted only by the immunity of the individual from smallpox. He reckons the protective period of primary vaccination at an average of ten years, and therefore believes the revaccination of school children in the later years of school life to be essential to complete immunity.

Dr. Seaton sums up the purposes of revaccination as follows:

1. To repair whatever was irregular in the course of a primary vaccination.
2. To supply what was imperfect in the amount of infection, in cases in which the course of the disease was regular.
3. To extinguish the susceptibility to smallpox which may remain, or may rearise, in an indeterminate number of persons whose primary vaccinations may have been complete as well as regular ("Seaton's Handbook," p. 300).

Autovaccination.—By this term is meant the reinsertion of fresh vaccine lymph upon the same person from whom it is taken, either by the vaccinated person himself or by some other person, and also either intentionally or by accident.

Vaccinization.—In a paper published by the Belgian Academy of Medicine, entitled "La Pratique de la Vaccine; ce qu'elle est, ce qu'elle devrait être" (1885), the author, Dr. Titeca, concludes that the principles of vaccination should be raised to the state of an axiom; in other words, that it may be made perfectly protective. Dr. Warlomont has expressed a similar belief.[5] They have crystallized this belief under the name of the school of vaccinization (école vaccinisatrice), wherein they are in accord with the views of many others, both in America and in Europe.

The author concludes that vaccination is in many cases *nothing but a deceptive operation performed with a hypothetic virus.*

The following questions are also discussed by the same author:

1. *No vesicle follows a given vaccination.* We are not therefore to infer that the subject is wholly insusceptible and abandon the attempt to secure a successful result.
2. *One or more vesicles are developed.* The subject, therefore, *ipso facto*, should not be regarded as having acquired immunity from smallpox. An old regulation of the German army required twenty insertions, ten in each arm.

In Holland, a modified vaccination has been practised for a long time, ten insertions being made upon each subject, and the results classified in accordance with the number of good resulting vesicles, certificates being given to such as have more than five good vesicles. All others are submitted to a supplementary, or an autovaccination.

Dr. Titeca gives the results of twenty-three primary vaccinations of children of various ages from three months to five years: twelve boys and eleven girls, showing the possibility of exhausting the susceptibility of the subject by means of repeated vaccinations.

From a general review of the subject the author concludes that vaccination, to be perfectly protective, should be practised under the following conditions:

1. The employment of a vaccine virus which has lost none of its vitality.
2. The number of inoculations should be in accordance with the individual vaccinal receptivity, even to the extent of the exhaustion of that condition.

The first of these conditions is fulfilled by the use of living (*vivant*) vaccine, collected at the time of the operation; the second by the operation to which Dr. Warlomont gives the name of vaccinization.

Every vaccination made in default of these conditions is deceptive, and to such faulty methods the antivaccination school owes its existence. Its faults and grievances will cease when the school of vaccinization is recognized.

The author recommends the following practice:

1. Vaccinization of infants within six months of birth.
2. Revaccinization every ten years, when no epidemic is prevailing, and general revaccinization in time of epidemic.

Insusceptibility.—It is quite probable that under the most favorable circumstances for vaccination (absolutely fresh lymph in each instance), insusceptibility in primary cases does not exist.

Dr. Robertson says, in the twenty-fifth "Report of the Registrar-General of Scotland": "Constitutional insusceptibility, as expressed in the returns, is virtually a confession from an operator that he has made three unsuccessful attempts to vaccinate a child without ascertaining the cause of his failures, and the fact that a child has a certificate of insusceptibility does not absolve its guardians from the duty of having the reality of the conditions tested from time to time."

Dr. Cory says[3] upon this point: "Of my own vaccinations, I may say that I have in my time performed over thirty-eight thousand primary operations with human or with calf lymph, and that it has only once fallen to my lot to fail twice at an attempt at vaccination. This subject was a ten-year-old child, in whom, as stated by its mother, vaccination had been attempted on previous occasions without result. My operation failed at the second attempt, and I did not get the opportunity to try a third time."

Dr. Thorne, chief medical officer of the Local Government Board, says[6]: "I would point out that the number of consecutive primary vaccinations by the board's own officers, without the occurrence of a single instance of so-called insusceptibility, now reaches 107,180."

THE TECHNIQUE OF VACCINATION.—Since vaccination with humanized lymph has been generally superseded by the use of vaccine from the calf it is unnecessary to present detailed instructions for collecting lymph from the arms of infants. Direct vaccination from arm to arm, with fresh fluid lymph, is superior to any other form of humanized vaccination, and should be performed when it is impracticable to obtain bovine virus.

Methods of Inserting Lymph.—The methods of insertion of either form of vaccine material are the same. The essential characteristics of a successful insertion are that the vaccine collected at the proper period of maturity should penetrate the superficial layer of the skin and be brought in contact with the rete Malpighii, or mucous layer. Bousquet states that smallpox was thus inoculated by Eastern nations in early periods.

The part usually selected for insertion is the outer part of the arm, at or near the lower insertion of the deltoid muscle, the left arm being usually preferred. Successful vaccinations may be made upon any part of the body. Among females it is quite a common practice to make insertions upon the thigh. In the case of young infants there are decided objections to this method.

Number of Insertions.—At least two insertions should be made in every case, and there can be no valid objection to a greater number. Heim recommends six, three on each arm; Bousquet, six; and Steinbrenner ten, five on each arm. Warlomont recommends six, three on each arm, and that they be arranged triangularly in boys, and in a horizontal line in girls, at the distance of a thumb's-breadth apart. He adds: "If one desires to please the mothers and spare subsequent reproaches, he will ask the mothers to point out where they wish the insertions to be made; the horizontal arrangement allows concealment by a short sleeve."

The Age for Primary Vaccination.—In all cases vaccination should be performed in early infancy, health permitting. Young unvaccinated children are the chief sufferers from smallpox. (Statistics relative to this point will be introduced later on.) There is great risk in delaying the operation, especially in the cities and large towns. Seaton advises that plump and healthy children living in large towns should be vaccinated when they are a month or six weeks old; and in more delicate children the operation might be postponed until they are two or three months of age; but all whose health does not offer some positive contraindication should be vaccinated by the age of three months.

The writer has, under conditions of special exposure to smallpox, vaccinated several infants within the first forty-eight hours after their birth, with perfect success, and with typical vesicles resulting.

Health of the Individual to be Vaccinated.—It is not essential that the persons who are to be vaccinated should be in robust health. They should, however, be free from any acute disease, and also from any severe chronic disease which would be likely to interfere with the regular course of the vaccine vesicle. Many diseases do not interfere at all with the progress of vaccination.

In many countries, and also in some of the United States, vaccination is made a statutory prerequisite to school attendance, and the important question occasionally arises, "Shall exception be made in the case of scholars suffering from ill health?" From the standpoint of public hygiene, it must be urged that such scholars constitute a public danger, and a constant menace to the community, and it may also be added that a scholar whose health is not sufficiently good to permit of vaccination is not, as a general rule, in a condition of health to endure the routine of school attendance, and should remain out of school until recovery will permit of both school attendance and vaccination.

Methods of Insertion.—For precautions to be taken at the time of vaccination see No. 6 of the following instructions of the Local Government Board of England.

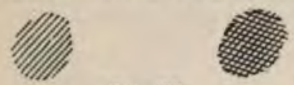

FIG. 4921.

1. One of the best methods, and also one most commonly employed, is the method of *scarification*. The arm of the person to be vaccinated should be grasped by one hand of the vaccinator, so as to put the skin upon the stretch. With a sharp lancet several fine parallel scratches, or incisions and cross incisions, should then be made upon the skin in the following manner (see Fig. 4921):

These incisions should be carried only to such a depth that the surface becomes slightly reddened by the appearance of blood. They may often be made upon sleeping children by means of a sharp lancet, without awakening them.

Several such scarifications should be made, never less than two, preferably of a smaller size than that which is shown in the cut, at a distance of about 1 in. (2–3 cm.) apart. Upon these should be applied the fresh lymph, rubbed lightly into the scarifications from the point of a lancet, and if preserved lymph is used, the contents of the tubes, points, or other appliances upon or in which it is stored should be transferred to the scarifications. If there is a free oozing of blood or serum, it is not necessary to moisten the dried lymph.

2. *Scraping.*—The outer skin may be scraped away with the edge of a sharp lancet over a surface 5–8 mm. in diameter, until a slight redness appears, but not sufficiently to induce a free oozing of blood. The lymph may be applied to this slightly reddened surface.

3. *By Puncture.*—By this method a sharp lancet is inserted obliquely to a depth of about one-eighth of an inch (2–3 mm.) or more. From two to five such punctures should be made at a distance of at least three-fourths of an inch apart. A common sharp-pointed lancet is best adapted to the purpose. The fresh lymph may be introduced into these punctures.

4. The method by puncture may be modified by making a considerable number of small punctures close together, or, in other words, a tattooing in several spots, the lymph being spread upon these spots.

The following are the revised instructions given by the Local Government Board of England to vaccinators under contract[1]:

1. Except so far as any [illegible] danger of smallpox may require, the public vaccinator must vaccinate only subjects who are in good health. As regards infants, he must ascertain that there is not any febrile state, nor any irritation of the bowels, nor any unhealthy state of the skin, especially no chafing or eczema behind the ears, or in the groin, or elsewhere in folds of skin. He must not, except of necessity, vaccinate in cases in which there has been recent exposure to the infection of measles, scarlatina, or diphtheria, nor in which erysipelas is prevailing about the place of residence.

2. A certificate of postponement must be given by the public vaccinator in the form prescribed by the Local Government Board or to the like effect: (*a*) If in his opinion the child is not in a fit and proper state to be vaccinated, or (*b*) if in his opinion the child cannot be safely vaccinated on account of the condition of the house in which it resides, or because there is or has been a recent prevalence of infectious disease in the district; and in any such case the public vaccinator is required forthwith to give notice of such certificate to the medical officer of health for the district in the proper form.

3. All public vaccinations are to be performed with glycerinated calf lymph or with such other lymph as may be issued by the Local Government Board. If the parent or other person having the custody of the child requires that it shall be vaccinated with lymph issued by the Local Government Board, the vaccination must be performed with such lymph.

4. The public vaccinator must keep such record of the lymph he uses for vaccinating as will enable him always to identify the origin of the lymph used in each operation. He must not employ lymph supplied by any person who does not keep an exact record of its source.

5. The public vaccinator must keep in good condition the lancets or other instruments which he uses for vaccinating, and he must not use them for any other purpose whatever. When he vaccinates he must cleanse and sterilize his instrument after one operation before proceeding to another, and must always, when vaccinating, have with him the means of doing this. When once he has unsealed a tube of lymph he must never attempt to keep any part of its contents for the purpose of vaccination on a future occasion. Under no circumstances should the mouth be applied directly to the tube in which the lymph is contained for the purpose of expelling the lymph. In the case of ordinary capillary tubes an artificial blower may properly be employed for this purpose.

6. Vaccination should at every stage be carried out with aseptic precautions. These should include: (1) The cleansing of the surface of the skin before vaccination; (2) the use of sterilized instruments; and (3) the protection of the vaccinated surface against extraneous infection both on the performance of the operation and on inspection of the results. Advice as to the precautions to be taken in this respect until the scabs have fallen and the arm has healed should always be given to the person having the custody of the child.

7. In all ordinary cases of primary vaccination the public vaccinator must aim at producing four separate good-sized vesicles, or groups of vesicles, not less than half an inch from one another. The total area of vesiculation resulting from the vaccination should not be less than half a square inch.

8. The public vaccinator must enter all cases in his register on the day when he vaccinates them, together with all particulars required in the register up to and including the column headed "Initials of the Person Performing the Vaccination." The results of the vaccination, which must be attested by the initials of the person who inspects the case, are to be entered upon the day of inspection. In cases of successful primary vaccination the public vaccinator must record the number of separate scarified areas, punctures, or groups of punctures made, and the number of separate normal vaccine vesicles or groups of vesicles which have been produced. In cases of revaccination, he must register as "successful" only those cases in which either vesicles, normal or

modified, or papules surrounded by areolæ have resulted. When any operation (whether vaccination or revaccination) has to be repeated owing to want of success in the first instance, it should be entered as a fresh case in the register.

Instruments Employed.—1. The common *lancet*, with a sharp point and edge, is undoubtedly the best instrument that has been devised for vaccination. It is simple, easily cleaned, easily sharpened, and may be used either for puncture or for scarification, the point being used for the former, and the edge for scarification.

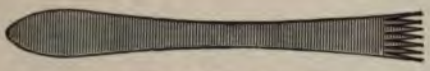

FIG. 4922.—Vaccine Scarifier.

2. *Needles.*—Steel needles or pins answer the same purpose, and may be easily cleansed either by heat or by disinfectants, or may be destroyed after each use.

3. Another instrument which proves quite efficient for scarification has the following shape. The only objection to this instrument is the greater difficulty in cleaning the spaces between the points (see Fig. 4922).

4. *Ivory Points.*—One of the advantages claimed for ivory or bone points is that they may serve two purposes: first, for the storage of lymph; and second for use in scarification, the edges near the point being sharpened or chamfered for the purpose (see Fig. 4923). They are poorly adapted for such use, it being impossible to give them a hard cutting edge as sharp as that of a lancet. In consequence of the porous quality of ivory and bone, and its consequent liability to retain pathogenic germs, an enterprising American firm has introduced a glass point with smooth surfaces, which may be used both for storage and for scarification.

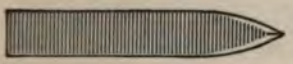

FIG. 4923.—Ivory Point for Vaccine.

Various other instruments have been devised, many of them more or less complicated, and therefore not so well adapted for vaccination, in consequence of the greater difficulty in cleaning them, a point which deserves most careful attention in a matter of such great importance as that of vaccination.

Dr. Sagrandi, a surgeon of the Eleventh French Dragoons, has recently invented for use in vaccinating large numbers of people vaccinostyles or small metallic lances, one for each person vaccinated, which are sterilized by placing them to the number of fifty or more in racks in a small metallic cylinder, which is put into a larger cylinder containing a two-per-cent. solution of borate of soda, which is kept at the boiling point by a spirit lamp. This method has the advantage of rapidity and complete sterilization.

Dr. Burdon Sanderson employs a gauge for measuring vaccine vesicles (which is of the following shape), and estimates their protective value by the aggregate area of surface foveated in a characteristic manner. (Sixth Report of the Privy Council of England, p. 205.) (See Fig. 4924.)

Lymph which has been stored upon points for a month or more will often produce small vesicles, not more than 4-6 mm. ($\frac{1}{6}$–$\frac{3}{16}$ inch) in diameter, with very slight areola, but otherwise characteristic. The protective power of such a vaccination would presumably be but slight, and the vaccination should be repeated with fresh lymph.

Care of Instruments.—In consequence of the importance of this operation, it should invariably be performed with scrupulous regard to cleanliness. The instruments employed should be used for no other purpose, and if lancets are used, they should be cleaned with the greatest care after each use, and when several persons are to be vaccinated at once the instrument employed should be thoroughly sterilized after each operation. The use of a disinfecting solution for such purpose is desirable, such as a five-per-cent. solution of carbolic acid, or the flame of a spirit lamp.

Circumstances Calling for the Immediate Performance of Vaccination.—Under certain conditions it may be prudent to vaccinate at a very early age. When smallpox is prevalent in any locality, and especially when it exists in the same house where unvaccinated persons or such as have not been recently vaccinated are living, vaccination should be immediately performed. Repeatedly, for want of such precaution, have the lives of infants been sacrificed. The loss of a single day may sometimes prove to be the loss of a life.

Since the incubative period of vaccinia is shorter than that of smallpox by about three days, it is found that if vaccination is performed at any time within the first three days of exposure the vaccination will cause a certain degree of modification of the smallpox, and consequent protection. If it is postponed to a later day no protection is afforded. An illustration of the latter condition has come under the writer's observation. An unvaccinated child was exposed to smallpox on a certain day. Vaccination was delayed until ten days afterward. On the third day after the vaccination was performed, a well-marked eruption of smallpox appeared and the child died. Singularly enough the appearance of smallpox was attributed by some to the vaccine virus employed but two days previously.

The only safe rule under all such circumstances is to *vaccinate immediately*.

In all such cases it is of the utmost importance that accurate observations should be made and recorded as to the date of exposure, the date of vaccination, and also the date of the first symptoms of smallpox, should they occur.

Seaton also urges with propriety that the word "vaccinated" should not be used in certificates of death in which vaccination was merely attempted, but without any result. He also condemns in the strongest terms the practice of vaccinating after symptoms of smallpox have actually appeared in any given case presented for vaccination.

EXTENT TO WHICH VACCINATION IS NOW PRACTISED.—Jenner stated in 1801 that about six thousand persons had been inoculated with cowpox in England. In the previous year the practice of vaccination had been introduced into several other countries, and gradually won its way into public favor. At the present day a fair estimate of the annual number of vaccinations performed throughout the world (including re-vaccinations) may be stated to be at least thirty millions, which would amount to sixty per cent. of an estimated annual number of births of fifty millions. The ratio, however, has been constantly increasing, as the practice of vaccination has spread to countries where it had not been introduced.

In the accompanying table the statistics of vaccination of several countries are presented, as compiled from such official sources as are accessible. It is to be regretted that the relative figures in the statistics of Scotland, England, Austria, and India have so little relation to each other. This fact is due to the lack of uniformity in the methods of reporting such statistics in different countries.

The figures in the foregoing table are those of vaccinations performed by public officials only, and do not include many which are done by private practitioners. Such figures are obtainable only in countries where the value of such information is properly estimated. Unfortunately, in the United States, as a general rule careful records of vaccination are not kept, except in a few cities, and but little is known as to the number or the results of the vaccinations made in each year.

In every case the record should not be considered complete unless it contains at least the name and address of the person vaccinated, and the results of an inspection made within ten days afterward.

The blank form on the opposite page, simplified from those now used in England, gives the essential items necessary for a public record of vaccination.

In the following table are presented from official sources the numbers of vaccinations and revaccinations in several foreign cities mostly for the five years 1895-99.

VACCINATIONS IN LARGE CITIES, FIVE YEARS 1895-1899.

	Living births.	Primary vaccinations.	Re-vaccinations.	Total vaccinations.	Primary vaccinations. Per cent. of living births.
London[1] (1895-99)	668,012	400,502	....	400,502	59.9
Paris[2] (1895-99)	293,375	178,419	256,849	435,268	60.8
Vienna[3] (1895-99)	125,500	110,689	30,837	141,526	88.2
Budapest[4] (1895-98)	88,319	92,970	42,011	134,981	105.3
Milan[5] (1898-99)	24,896	18,069	41,240	59,309	72.6

[4] Statistisches Jahrbuch.
[5] Municipio di Milano. Dati Statistici, 1900.

The foregoing figures relate to official vaccinations performed and recorded by official vaccinators; except in Vienna, where vaccinations performed and reported by private physicians are also included.

After deducting those infants who died unvaccinated, there still remained in London and Paris a large unvaccinated infantile population.

In the figures for primary vaccinations in Budapest a considerable number of older persons appear to be included, so that the number of vaccinations exceeds that of living births.

The vaccinations in Paris are reported by the following authorities: By thirty-four hospitals and asylums, by bureaus of charity, by the Academy of Medicine, by the general sanitary inspection service, and by those having in charge infants supported at public cost.

Germany has at the present day the most thoroughly vaccinated population in the world, since the compulsory law of that country is the most efficiently enforced.

The following figures present the numbers of the vaccinated and revaccinated for the year 1900.[8]

Total number liable to vaccination..................	3,101,465
Total number liable to primary vaccination after excluding exempts....................	1,739,968
Total number liable to revaccination................	1,281,039
Total	3,021,007
Total number vaccinated (primary)................	1,518,510
Total number revaccinated.........................	1,246,268
	2,764,778

Of these 99.94 per cent. were vaccinated with calf lymph and only 0.05 of one per cent. were vaccinated with humanized lymph. Glycerinated calf lymph was used in 1,485,522 of the primary vaccinations and also in 1,218,243 of the revaccinations. (For further figures see table at the top of this page.)

England.—In England in 1899 the statistics were as follows:

Number of births....................................	929,189
Number successfully vaccinated.....................	617,113
Reported as insusceptible	5,379
Had smallpox.	4
Number in respect of whom certificates of conscientious objection have been received, under law of 1898.	33,573
Died unvaccinated	113,516
Vaccinations postponed	16,605
Remaining	142,909

The percentage of children not accounted for, as compared with the births, was 17.2, that of 1898 having been 21.5.

Japan.—The following table presents the number of vaccinations in Japan in 1897 (the latest publication of the Central Sanitary Bureau).[9]

TOTAL VACCINATIONS IN JAPAN IN 1897.

	Successful.	Unsuccessful.
Primary	1,259,796	411,869
Revaccinations	4,458,265	9,571,754
Total	5,718,061	9,983,623

The success ratio of primary vaccinations was 75.3, that of revaccinations 31.8 per cent.

RECORD OF VACCINATION.

To be filled on the day of Vaccination.

RECORD OF VACCINATION.

To be filled on the day of Inspection.

1. Number.	2. Date of Vaccination.	3. Name of Vaccinated Person.	4. In case of Revaccination at ages over ten years, of persons previously successfully vaccinated, mark R.	5. Age.		6. Residence. (Street and Number.)	7. Source of Lymph. Name of Producer.	8. Number of separate scarified areas or punctures made.	9. Initials of Vaccinator.	10. Date of Inspection.	11. Result.		12. These forms may be conveniently made into books of 100 or 200 in each, sufficient for 1,000 or 2,000 vaccinations. If made up in this manner, the columns should be wider than those shown in the sample, and a blank space of two inches should be left between columns nine and ten for the convenience of folding and binding, the fold being made at that point.

The whole number of primary vaccinations in Japan in the ten years 1887-96 was 11,726,601, and the revaccinations in the same time were 16,709,064, making a total of 28,435,665. The total number vaccinated in 1897 (15,701,684) was more than half as many as the sum of the vaccinations of the preceding ten years. This enormous number is accounted for in the official report as follows:

"The furious rage of smallpox, and the cheapness of the price of vaccine lymph sold by the government institutes encouraged vaccination, and the number of vaccinated persons was very numerous compared with that of preceding years."

Italy.—The following figures presenting the number of vaccinations in Italy in the five years 1889-93 are given in "La Legislation et l'administration sanitaire en Italie, Rome, 1894."

NUMBER OF VACCINATIONS IN ITALY, 1889-93.

1889	1,194,390	1892	1,997,114
1890	1,618,880	1893	2,353,716
1891	1,930,502		

In many of the United States, in consequence either of the entire absence of laws relative to vaccination or on account of the lax enforcement of such as exist, it is probable that the ratio of vaccinations to births is less than that of most of the countries of Europe, unless a few cities of the former may be excepted in which efficient boards of health have enforced annual vaccinations and revaccinations.

A general vaccination was made by the State Board of Health of Illinois in 1882, in which 233,340 vaccinations were performed in a population of over 3,000,000 people. Of these, 153,936 were primary vaccinations and 79,404 were revaccinations; the former being about double the annual number of births, the latter being estimated at 25 per 1,000 of the population.

A publication issued by the State Board of Health of Tennessee, April 1st, 1902, estimates the number of persons in that State who had been vaccinated in the previous three years as 753,617, or 41 per cent. of the total population. Of the white population 36 per cent. had been vaccinated, and of the colored population 50 per cent.

For the three years ended February 19th, 1902, there had also been in the same State 13,106 reported cases of smallpox, with a mortality of only 276 deaths, or 2 per cent.

The following statement occurs in the Report of the Surgeon-General of the United States Army for the year ended June 30th, 1899:

The population of Porto Rico is about 900,000. Smallpox was of frequent occurrence. It was decided to vaccinate all who had not recently had smallpox. This was carried out rapidly and efficiently; 786,290 persons were vaccinated.

By an order of January 27th, 1899, every resident "who has not had smallpox was ordered to be vaccinated, and hereafter all infants before reaching the age of six months."

The vaccine lymph was produced from heifers reared upon the island, and the cost of the work was $28,536.17.

THE PROTECTIVE POWER OF VACCINATION.—In order to consider this phase of the question intelligently, and to determine satisfactorily the protective value of vaccination and of revaccination against smallpox, it will be necessary to consider the subject: *first*, by a comparison of the period before, with the period following, the introduction of vaccination; *second* (since it may with reason be urged that epidemics of several infectious diseases have become less severe within a century or more), a comparison of different populations living under similar conditions, except that of vaccination; and *third*, a consideration of the effect of vaccination upon the age-distribution of smallpox.

1. *The Period Before and the Period After the Introduction of Vaccination.*—It will be necessary in this connec-

tion to review the history of smallpox, for a century or more, in different countries.

"At the present day," says Simon, "the very success of vaccination may have blinded people to its importance. It is very easy to be bold against an absent danger, to despise the antidote while one has no painful experience of the bane."

Smallpox is fatal to a large proportion of those whom it attacks; it is eminently infectious from person to person; it seizes, with very few exceptions, upon all unvaccinated persons who for the first time come within its range.

Although smallpox has been described with accuracy by early writers, notably by the Arabian physician Rhazes, its history previous to the eighteenth century must be regarded as in a great measure defective, in consequence of being confounded with measles and with other diseases.

It is known that not a decade passed in the seventeenth and eighteenth centuries without the occurrence of devastating epidemics of smallpox in Europe. In England from seven to nine per cent. of all deaths were attributable to smallpox. In London it averaged from four to eight per cent. of the total deaths. Capt. John Graunt, in his observations on the Bills of Mortality of London (published in 1665), gives the number of deaths from smallpox for twenty years (1629 to 1636, 1647 to 1658), as 10,576, out of a total mortality of 229,250. It was also the seventh in the order of destructiveness upon the population, consumption being first.

In Berlin, from 1783 to 1797, one-twelfth of all deaths, according to Casper, were from smallpox. M. de la Condamine estimates that one-tenth of all deaths in France, amounting to 30,000 annually, were from smallpox. Three and a half millions perished from it in Mexico in the sixeenth century. In 1734 nearly two-thirds of the population of Greenland were swept away by it. In Iceland 18,000, out of a population of 50,000, died of smallpox. Catlin, in his "Letters and Notes on the Manners and Customs of the North American Indians," says: "I would venture the assertion, from books that I have read and from other evidence, that of the numerous tribes that have already disappeared, and of those that have been traded with, quite to the Rocky Mountains, each one has had this exotic disease in their turn, and in a few months have lost one-half or more of their numbers."

Wernher says, in his recent work, "Zur Impffrage": "Before the introduction of vaccination smallpox had become a permanent disease which never entirely ceased in one year, and every three or five years became a great epidemic.

"In non-epidemic years one-tenth of all mortality was from variola, in epidemic years one-half. Very few men escaped smallpox till old age; almost every one sickened at least once in his life of this horrible, murderous disease.

"Countless mortals who escaped death were maimed by loss of sight. Of new-born children, one-third died of smallpox before their first year; one-half before their fifth year of life. There was no family which had not heavy losses to deplore. In the country the mortality was greater than it was in the city.

"Physicians and Government possessed no means against this abominable evil. Isolation was impracticable from the general, widespread nature of the disease. Men accepted the pest as an unavoidable fate.

"The loss which Europe suffered from this one disease amounted to many millions. It was a principal factor which deterred or kept the population from progress; and to lead us back to these conditions are the efforts of many ignorant mortals directed."

Comparing the present conditions with those just stated the author goes on to say:

"We now find no child mortality from smallpox among vaccinated children.

"Also, among adults, whenever vaccination and revaccination are maintained, mortality from smallpox is at an end."

The following familiar table is herewith quoted from the "Report of the Epidemiological Society of London," and contains very conclusive evidence of the decline of smallpox in different countries after the introduction of vaccination. Two series of facts are presented. (1) The number of persons per million of the population who died of smallpox annually *before* the introduction of vaccination; and (2) the number per million who died annually of the same disease after its introduction. The periods are not in all cases the same, but the statistics are those which it was possible to collect for the periods named.

Period relative to which data are given.	Country or city.	APPROXIMATE AVERAGE ANNUAL DEATH RATE BY SMALLPOX PER MILLION INHABITANTS.

In the accompanying chart (Fig. 4925) are also presented the data relative to the mortality from smallpox in Sweden before and after the introduction of vaccination, by which it appears that in the twenty-four years before the introduction of vaccination in 1801 the mortality from smallpox counted 2,050 victims annually out of each million of the population, and after the introduction of vaccination this mortality was reduced to 158 per million annually. The period anterior to 1773, included in the original, has been omitted, since the deaths from smallpox previous to that year were not separated from those from measles.

No complete statistics of American cities for the period before the introduction of vaccination can be obtained. The data contained in the accompanying table are compiled from the most reliable historical sources, with reference to the prevalence of smallpox in Boston.

After the settlement of the colony at Plymouth, in 1620, smallpox appeared frequently in Massachusetts, among both the Indian tribes and the English settlers. Such epidemics occurred in 1631, 1633, 1639, 1677, 1678 (from 700 to 800 died in this year), 1702 (213 died, which was about 4.4 per cent. of the population). In 1721, with a population of 11,000, there were in Boston 5,989 cases of smallpox, more than half the population taking the disease, of which number 850 died. In the words of the historian: "The disease ran riot over the town, feasting on all who were susceptible to its poison" (Dr. Toner, in publications of Mass. Med. Soc., 1866, vol. ii.).

In 1730, with a population of 15,000 people, 4,000 were sick, and about 500 died. A vessel from London, with smallpox on board, was wrecked in 1751 near Nahant, and spread the disease again, and there were 7,653 cases, and 545 deaths. It broke out in the American army at

Cambridge in 1776, and Dr. Waterhouse wrote: "There were scarcely enough men free from it, or not liable to take it, to keep guard at the different hospitals."

In 1792, 8,346 had smallpox. In this epidemic it is stated that, out of a population of 19,484, 10,655 had already had smallpox, and that only 221 persons escaped having it, the remainder having moved out of town.

So virulent did it at times become as to compel the legislature to hold its sessions in some other town (Report of State Sanitary Commission of 1850, pp. 64–70).

After the introduction of vaccination the mortality from smallpox in Boston was as follows, so far as the records can be obtained:

	Deaths.		Deaths.
From 1811 to 1820	6	From 1861 to 1870.....	500
From 1821 to 1830	8	From 1871 to 1880.....	1,094
From 1831 to 1840	214	From 1881 to 1890.....	24
From 1841 to 1850	534	From 1891 to 1900.....	32
From 1851 to 1860	732	For 1901 and 1902.....	267

By reference to the tables relative to the prevalence of smallpox, which for the eighteenth century present only the date of epidemic years, since other data are not to be had, it will be seen that the highest ratio of deaths from smallpox, in any epidemic year since the introduction of vaccination (2.95 per 1,000 of the living population), was much less than that of the lowest epidemic year before its introduction.

Among the few records as to the prevalence of smallpox before the general introduction of vaccination, one of the best is found in a recent paper by Dr. John C. McVail, of Kilmarnock, Scotland, published in 1882 (Fourteenth Report of Medical Officer of the Local Government Board of England, p. 39). It presents a most graphic picture of the prevalence of smallpox at that time. It appears that a schoolmaster of Kilmarnock,

SMALLPOX IN BOSTON BEFORE THE INTRODUCTION OF VACCINATION. EPIDEMIC YEARS ONLY.

who was considerably in advance of his times, kept a record of the mortality of his parish in a beautifully written volume. This schoolmaster, Robert Montgomerie, was also the session clerk. The record contains a statement of the name, date, age, and cause of death of all who died in the parish of Kilmarnock for the thirty-six years from March 1st, 1728, to March 1st, 1764.

The population of the town in question is estimated to have averaged 4,200 for the period under consideration. The total deaths for the thirty-six years were 3,860, which would indicate a death rate of 24.36 per 1,000 per annum. In the careful record of the schoolmaster, which is divided into groups of six years each, four causes are credited with fully two-thirds of the total deaths. These were decay, age, smallpox, and fevers. What is meant by decay it is not easy to state; that old age is not a necessary element is evident from the fact that deaths at the ages of one and two years are attributed to it. The term embraces nearly all chronic diseases causing emaciation and debility, among which, of course, consumption is chief. From such cause or causes there were 915 deaths. The second disease was age, with 625 deaths, which appears to have formed a convenient class for all persons who lived beyond seventy years, and for many between sixty and seventy years. Omitting smallpox, fevers were credited with 545 deaths. This term probably included scarlet fever, which is not mentioned elsewhere, and also, perhaps, pneumonia and other acute febrile diseases.

There can be no doubt, says Dr. McVail, that smallpox caused more deaths, by a long way, than any other disease in old Kilmarnock. The entire number of deaths from smallpox in this little parish for the thirty-six years was 622. There were in all nine epidemics in the thirty-six years, the average time between the epidemics being four years. They came with terrible regularity.

The following table presents the data of these epidemics of smallpox by years and by ages:

Year.	Total deaths.	AGE IN YEARS AT DEATH.							Age not stated.
		Under 1.	1.	2.	3.	4.	5.	6 and over.

Totals	622	118	139	136	101	62	24	27	9

In seven of these nine epidemics the death rate for the year was higher than the birth rate, in one year to the extent of seventy-two per cent. The statistics of these years are summed up in the following table:

EPIDEMIC YEARS IN WHICH THE TOTAL DEATHS EXCEEDED THE TOTAL BIRTHS.

Year.	Births.	Deaths from all causes.	Deaths from smallpox.	Excess of deaths over births.
1728-29	111	162	66	51
1736-37	135	147	66	12
1740-41	95	164	65	69
1749-50	134	149	79	15
1754-55	146	203	95	57
1757-58	125	132	37	7
1762-63	132	173	66	41
Total..........	878	1,130	474	252

It will prove instructive to compare the greatest epidemic of modern times, in the same town, with the greatest to be found in the old records. In the year 1874 there were 141 deaths from smallpox in Kilmarnock, which then had 24,000 inhabitants, or at the rate of 5.8 per 1,000 living. The old epidemic was, therefore, four times as severe as the modern one, and it should be remembered that while the former epidemic had only a period of four and a half years in which to collect its victims, no serious epidemic had occurred for more than thirty years previous to 1874. One can hardly conceive what would be said at the present day about an ordinary annual death rate as great as that of what we have learned to look upon as a terrible epidemic, and yet an annual epidemic equal to that of 1872–73 would do little more than represent the conditions which prevailed in the eighteenth century. Similar statistics for other English towns confirm these statements of Dr. McVail.

2. *Comparison of the Vaccinated with the Unvaccinated in Like Periods of Time.*—If, now, it shall be urged, as it is occasionally, with some degree of reason, that certain malignant diseases have almost disappeared, at least from among civilized nations, and that the disappearance, or comparative rarity, of smallpox is not a necessary consequence of vaccination, let us then examine the condition of the vaccinated, as compared with that of the unvaccinated, with reference to their immunity from smallpox, while living in a similar environment and at the same period of time.

Wherever extensive parallel observations are made upon large populations of the vaccinated and of the unvaccinated, as exposed to epidemics of smallpox, the protective power of vaccination is especially manifest.

In the accompanying table are given the statistics of different populations in which observations are made upon the comparative immunity from smallpox of the vaccinated and the unvaccinated. It will be noticed that in the majority of the instances noted, the mortality among the vaccinated was but one-fifth or one-sixth of that of the unvaccinated, and that the highest mortality among the vaccinated was less than the lowest among the unvaccinated.

Places and dates of observation.	Total number of cases observed.	DEATH RATE PER 100 CASES.	
		Among the unvaccinated.	Among the vaccinated.

[10] Report on Epidemic of Smallpox, Leicester, 1893.
[11] Dr. Barry's Report, 1889.
[12] The deaths of the unvaccinated children under five years of age were 46.7 per cent. of those attacked, while those of the vaccinated children were only one per cent.

One of the most valuable reports of modern times, bearing upon the subject of the value of vaccination, is the report of Dr. F. Barry, upon the epidemic of smallpox in Sheffield, in 1887–88. Dr. Barry, an inspector of the Local Government Board of England, was instructed to inquire into every influence which could possibly bear upon the epidemic of smallpox at Sheffield. After making a most thorough and searching investigation, as his report shows, no influence could be discovered beyond the single dominating one of vaccination.

Dr. Buchanan's introductory to this report sums up the results as follows:

	PER 1,000 OF EACH CLASS STATED.			
	Attack rate.		Death rate.	
	Vaccinated.	Unvaccinated.	Vaccinated.	Unvaccinated.
Up to ten years	5.0	101	0.09	44
Living in invaded houses	78.0	869	1.0	381
Over ten years	19.0	94	1.0	51
Living in invaded houses	281.0	686	14.0	371
All ages	15.5	97	.7	48
Living in invaded houses	230.0	750	11.0	372

In the foregoing table the figures represent the rates per thousand of the child population under ten years, of persons over ten years of age and of persons of all ages; first, as applying to the population of the borough generally, and secondly, as applying to the enumerated population of the invaded houses. In a brief summary Dr. Buchanan further says, "the vaccinated children had, as compared with the unvaccinated in the same town, a twentyfold immunity from attack by smallpox, and had a four hundred and eightyfold security against death by smallpox; that in the invaded houses the vaccinated children had, as compared with the unvaccinated, an elevenfold immunity from attack by smallpox, and a three hundred and eighty-onefold security against death by smallpox, and that as regards all ages the vaccinated among the population generally had, as compared with the unvaccinated, a sixfold immunity against attack, and a sixty-fourfold security against death."

The following table presents the deaths and death rates from smallpox in those countries from which reports could be obtained. It shows, in general, in the lower table of relative figures the lower death rates from smallpox in well- or comparatively well-vaccinated countries. The figures for several years are not accessible in the reports of Japan, Italy, Hungary, and Spain. (See p. 126.)

Evidence was presented, for example, before the British Commission that there was but little opposition to vaccination in Scotland and Ireland as compared with that which existed in England. The result is apparent in the table.

Surgeon-General Sir William Moore testifies that the large yearly ratio of vaccination in India has had a very marked effect in the reduction of smallpox in that country.[27]

He also states his experience in India before vaccination had been generally introduced. He says he marched during an epidemic of smallpox a distance of one thousand miles, surrounded by smallpox. "Those suffering from the disease in a minor degree were in the streets, generally children, occupied in their accustomed play; or if too ill, lying neglected on the ground; and these represented a portion of the whole suffering from smallpox, the remainder, unable to leave their dwellings, awaiting death in their houses. Any one cognizant of the aftereffects of smallpox will at once understand the amount of suffering which must occur among those recovering from the immediate disease. The consequent effects on the eyes, the ears, the skin, the limbs, the joints, and the general constitution, at least equal in gravity the direct consequences of the disease. Roughly speaking, from calculations based on observing the people passing through the streets of certain cities, ten per cent. had lost the sight of one or both eyes, and an equal number had permanent injury of some organ or member; and of these affections the great majority could be traced to smallpox. From special inquiry I found nearly eighty per cent. of the population were more or less marked with smallpox."

According to the *British Medical Journal* there were in the last epidemic of smallpox in Guatemala twenty-five thousand deaths from the disease. In that country there are no vaccination laws. Its population is about one-half as large as that of New England, in which there have not been so many smallpox deaths in the last seventy-five years combined. The *Journal* characterizes Guatemala as an "antivaccination paradise" (*British Medical Journal*, 2, 1891, p. 1135).

At the Tenth International Medical Congress in Berlin, in 1890, Dr. Victor Desguin, of Antwerp, said that the medical inspection of schools in that city had been organized in a very complete manner since 1882, at which time revaccination was ordered for all school children who were twelve years old. It is performed with lymph, under every possible condition of security. It is furnished by the Central Vaccinal Institute of Belgium, and before delivery of the lymph an autopsy is made upon the animal from which it has been taken, to determine its condition of health, none being issued if the animal is found to be diseased. So that there is no danger of communicating either syphilis or tuberculosis.

In nine years 15,259 children were vaccinated, of which 8,033, or 52 per cent., were successful. He says this ratio of success in revaccination is probably due to the fact that a considerable number of children enter the schools with false certificates of vaccination, either on account of inefficient performance or by reason of its omission.

Revaccination was not followed in any case by unusual results, beyond what could easily be controlled, the school registers giving the particulars as to absence in all cases.

Moreover, he says that revaccination was never followed by the development of scrofulous symptoms; a fact which he attributes to the plan adopted for strengthening feeble school children by proper medical means.

During this period of nine years there were in Antwerp 497 deaths from smallpox, only two of which were those of school children. They were children of seven and eight years, neither of whom had been revaccinated, and one had never been vaccinated. During this period there were, among an average annual school population of 13,506 children (subject to yearly renewals and changes), 53 cases of smallpox, none of which was among revaccinated children (Transactions of Tenth International Medical Congress at Berlin, vol. v., No. 15, p. 144).

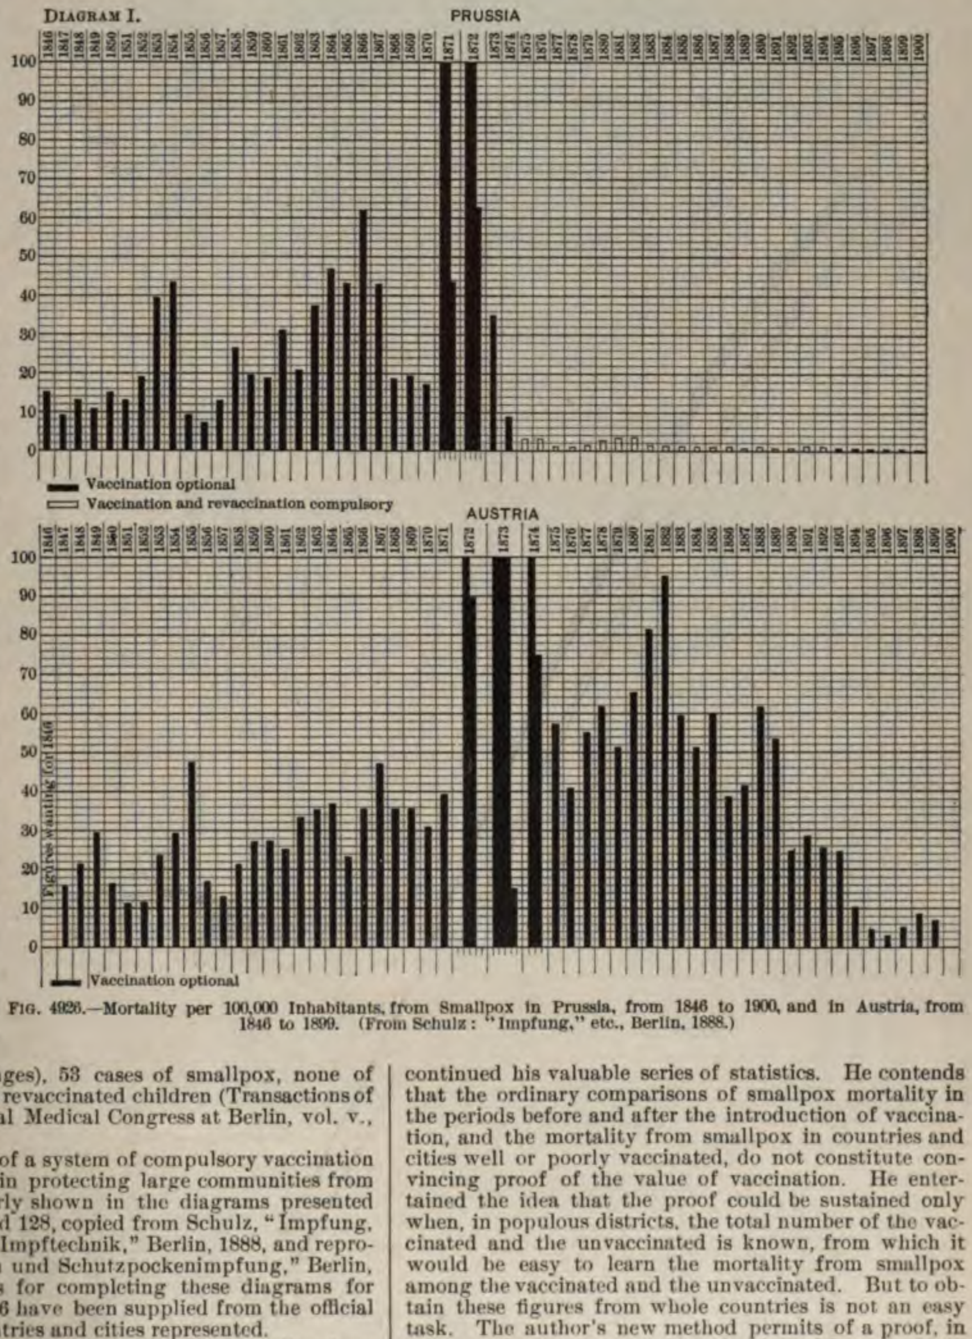

FIG. 4926.—Mortality per 100,000 Inhabitants, from Smallpox in Prussia, from 1846 to 1900, and in Austria, from 1846 to 1899. (From Schulz: "Impfung," etc., Berlin, 1888.)

The advantages of a system of compulsory vaccination and revaccination in protecting large communities from smallpox are clearly shown in the diagrams presented upon pages 127 and 128, copied from Schulz, "Impfung, Impfgeschäft und Impftechnik," Berlin, 1888, and reproduced in "Blattern und Schutzpockenimpfung," Berlin, 1896. The figures for completing these diagrams for the years since 1886 have been supplied from the official reports of the countries and cities represented.

Diagram I. presents the statistics of mortality from smallpox in Prussia and in Austria, showing the death rate per 100,000 from this cause in each country for a period of over fifty years, 1846 to 1900, in Prussia, and 1847 to 1899 in Austria. Vaccination was optional for the civil population in Austria for the whole period, while in Prussia it was compulsory after April 1st, 1875.

Diagrams II. and III. present the comparative mortality from smallpox of four German cities in which vaccination was compulsory after 1875, and that of four other large European cities in which it was either optional, or optional in the case of revaccination for the whole period (1861-1900), as it was in London.

The renowned statistician Körösi, of Budapest, has continued his valuable series of statistics. He contends that the ordinary comparisons of smallpox mortality in the periods before and after the introduction of vaccination, and the mortality from smallpox in countries and cities well or poorly vaccinated, do not constitute convincing proof of the value of vaccination. He entertained the idea that the proof could be sustained only when, in populous districts, the total number of the vaccinated and the unvaccinated is known, from which it would be easy to learn the mortality from smallpox among the vaccinated and the unvaccinated. But to obtain these figures from whole countries is not an easy task. The author's new method permits of a proof, in figures, of the influence of vaccination without a necessary knowledge of the number of the living vaccinated and unvaccinated. Until his inquiry was made, the vaccination question had been made to depend on the number sick or deceased from smallpox.

The tables which Körösi has published contain the number of persons treated for the most diverse diseases, and dying of the most diverse causes, their ages, and also whether vaccinated or unvaccinated. One table contains

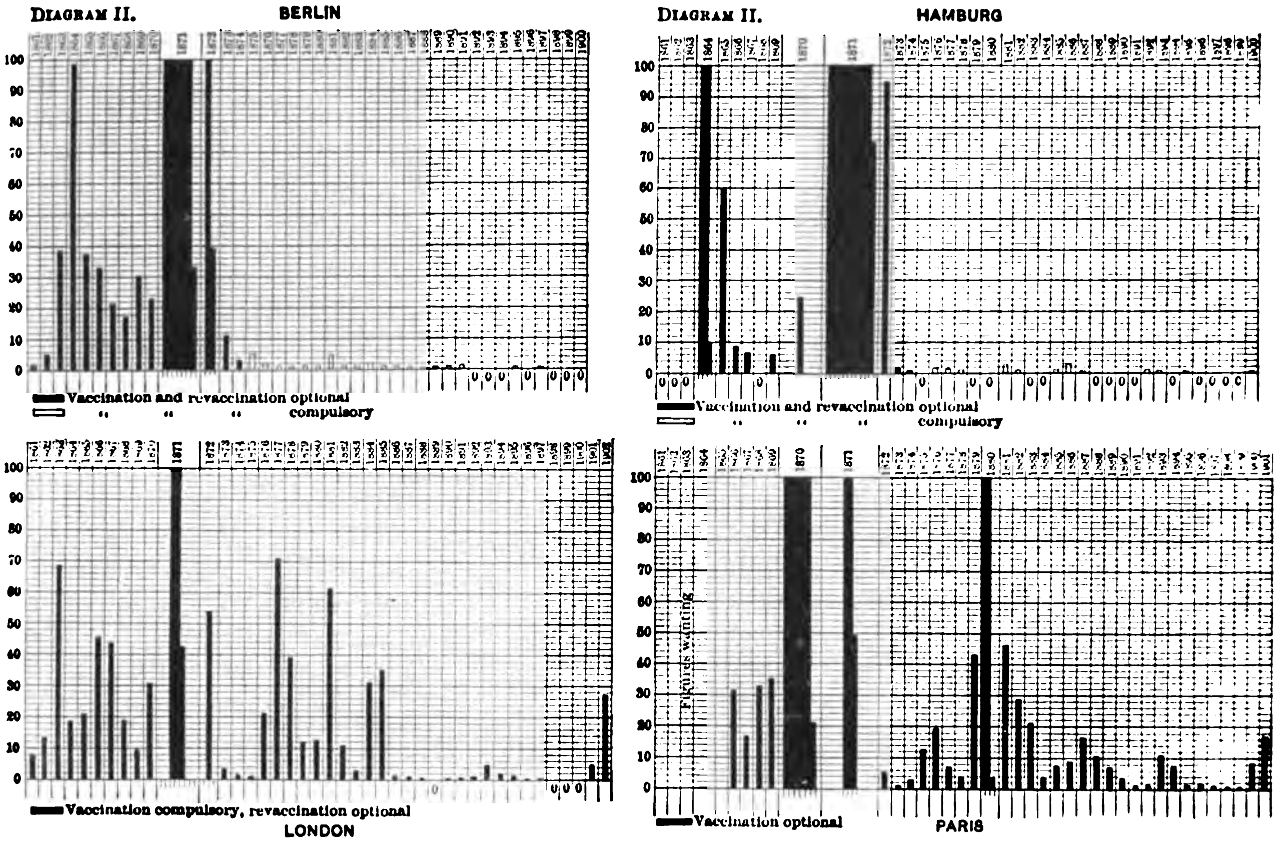

FIG. 4927.—Mortality from Smallpox in Several Large Cities per 100,000 Inhabitants. (From Schulz.)

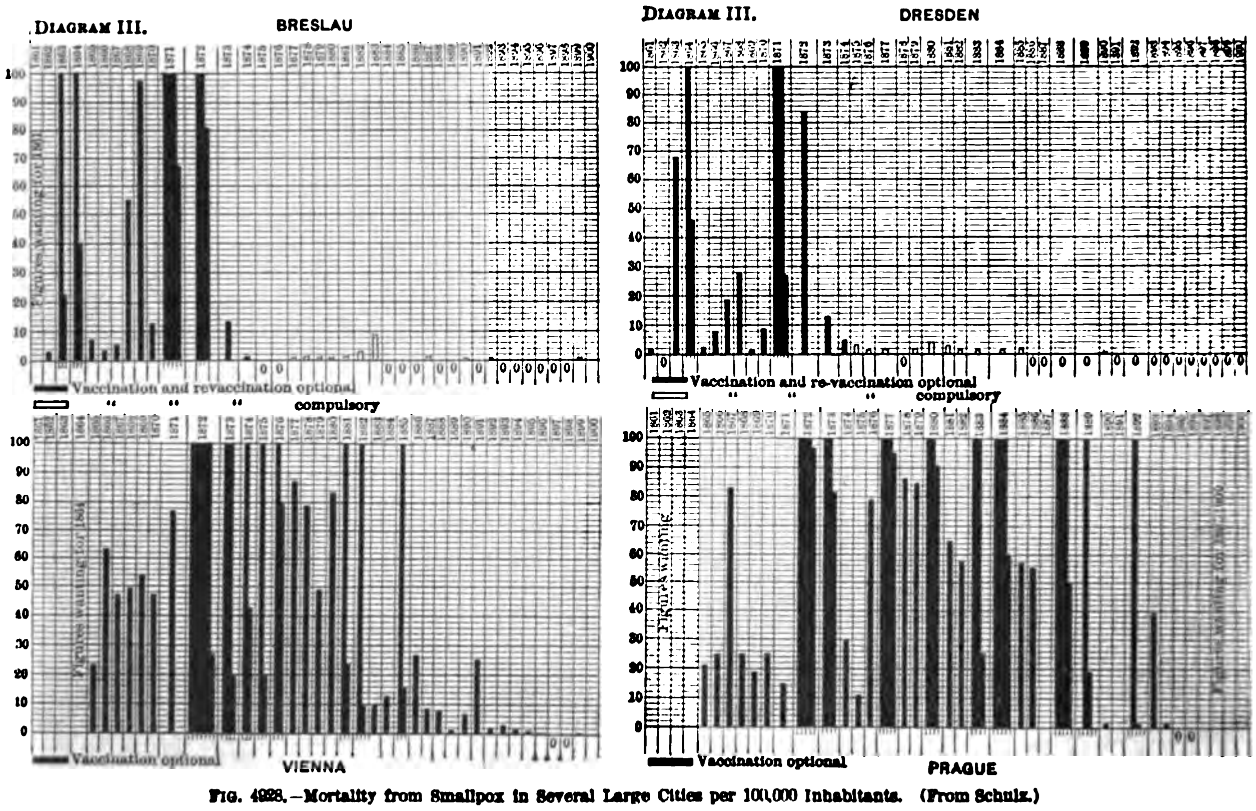

FIG. 4928.—Mortality from Smallpox in Several Large Cities per 100,000 Inhabitants. (From Schulz.)

the condition as to vaccination of 53,320 persons treated in 1886, 1887, and 1888, in 19 Hungarian hospitals. The second table presents the statistics of 5,518 deaths in the same hospitals and for the same period. A third table gives the statistics of 58,639 deaths in 10 Hungarian cities for the same years, from different causes.

Of the persons sick with different diseases in the hospitals, 11.75 per cent. were unvaccinated. If vaccination had no effect upon smallpox *morbidity*, then the unvaccinated would have shared to the rate of about 11.75 per cent. in the contemporaneous 1,912 cases of smallpox. In other words, there would have been 225 cases of smallpox among the unvaccinated. Instead of this the number of cases of smallpox among the unvaccinated was 726. The neglect of vaccination, therefore, increased the liability to smallpox three and one-fourthfold. In the same manner the author concludes that the danger of death from smallpox is six times as great among the unvaccinated.

He also estimates that skin diseases destroy two persons out of every million, while by vaccination two thousand are saved.

A severe epidemic of smallpox broke out in Montreal, in 1885, principally in the last half of the year, and destroyed 3,164, out of a population of 167,501. In the report of the local board of health for that year these are classified as follows:

	Population.	Deaths from smallpox.	Ratio per 1,000 of the population.
French Canadians	93,641	2,887	30.8
Other Catholics	29,627	181	6.1
Protestants	44,233	96	2.1

This classification was a fair index of the condition of the population of Montreal at the breaking out of the epidemic, the French Canadians being chiefly the unvaccinated portion, and the remainder the vaccinated.

"In the years 1873 and 1874, there died in the East Indies about 500,000, and in 1875 and in 1876 about 200,000 people from smallpox. On the other hand, among the European troops in the same country (120,000), there were only two deaths from smallpox. The immunity of the troops was attributed solely to the thorough and rigorous enforcement of vaccination" (Wernher, p. 263).

The contested points in regard to vaccination may be reduced to three:

1. Whether, in an equal number of vaccinated and unvaccinated, fewer of the former are attacked by smallpox than of the latter (a question of morbidity).

2. Whether, in an equal number of vaccinated and unvaccinated, fewer of the former die of smallpox (a question of mortality). To the question as to the ratio of the deaths from smallpox to the number of those taken sick with the disease, Körösi applies the term lethality.

3. Whether or not vaccination is of itself innocuous, and whether or not other diseases may not be introduced by vaccination (Körösi: "Neue Beobachtungen über den Einfluss der Schutzpockenimpfung auf Morbidität und Mortalität").

In summing up his observations upon the influence of vaccination upon the population of Buda-Pesth, Körösi collected the data of 20,574 cases of illness in four hospitals in Buda-Pesth and fifteen provincial hospitals of Hungary, subsequent to April 1st, 1886.

Excluding 223 children under one year of age, because many are not vaccinated in their first year, he found that out of 18,572 persons sick with different diseases, *exclusive of smallpox*, 16,135 were vaccinated, and 2,437 were not vaccinated. Of the 16,135 vaccinated, 1,306 died, or 8.1 per cent.; of 2,437 unvaccinated, 321 died, or 13.2 per cent. So that the lethality of the unvaccinated was 60 per cent. greater than that of the vaccinated, the disease, smallpox in this instance, being excluded from the calculation.

With reference to the effect of vaccination on the mortality from smallpox, he found that there were treated in all 1,113 persons over one year of age ill with smallpox. Of these 631 were vaccinated, of which number 42 died, or 6.66 per cent.; 468 were not vaccinated, of which number 231 died, or 49.68 per cent.

There were 17 doubtful cases, of which number 3 died. So that, with reference to smallpox, the lethality of the unvaccinated was 800 per cent. greater than that of the vaccinated. Körösi admits fairly that not quite the whole of this difference can be attributed to neglect of vaccination, since from all other diseases upon which neglect of vaccination has no effect there died 160 unvaccinated to 100 vaccinated. Taking this into account, we may still predict that under like conditions the unvaccinated will have nearly a sixfold greater liability to death when stricken with smallpox than the vaccinated.

Dr. Buchanan, the medical officer of the Local Government Board, gives the following summary of death rates from smallpox among the vaccinated and the unvaccinated for the year ending May 29th, 1881:

Death rate of people of subjoined ages.	Per million of each age of the vaccinated class.	Per million of each age of the unvaccinated class.
All ages	90	3,350
Under twenty years	61	4,520
Under five years	40½	5,950

At the date of the British census of 1881 the number of children under ten years of age in London was 916,784, which was divided into about 55,000 unvaccinated and 861,000 vaccinated. In the same year the deaths from smallpox were as follows: 782 among the 55,000 unvaccinated, and 125 among the 861,000 vaccinated, or 1 in 70 of the former to 1 in 6,968 of the latter, a difference of nearly one hundredfold in favor of the vaccinated class.

The difference in these two methods of inquiry should be noticed, since Dr. Buchanan considers the effect of vaccination upon the population at large, while Körösi considers the effect of vaccination upon the mortality from smallpox as compared with the number of cases.

From all these observations, and from many more of the same character which might be quoted, we find that the *mortality among the unvaccinated* (without reference to the question of age distribution, or to the quality of the vaccination performed) *is from five to seven times as great as it is among the vaccinated.*

When, however, the conditions of the latter class are more carefully examined, it is found that *among vaccinated persons infected with smallpox* the danger of the disease is chiefly determined by the character or quality of the vaccination.

Mr. Marson, who first observed and made known the value of this principle, stated that, if the vaccinated are divided into two classes—(1) those who have been vaccinated in the best-known manner, and (2) those who have been badly vaccinated—the fatality from smallpox, if it infects the former, is but 5 per 1,000, and among the latter 150 per 1,000.

Classification of cases according to the character of vaccination.	Mortality rate in each class. Per cent.
1. Unvaccinated	35.00
2. Said to have been vaccinated, but having no cicatrix	23.57
3. Vaccinated:	
(*a*) Having one vaccine cicatrix	6.80
(*b*) Having two vaccine cicatrices	4.70
(*c*) Having three vaccine cicatrices	1.95
(*d*) Having four or more cicatrices	.55
(*e*) Having well-marked cicatrices	2.52
(*f*) Having badly marked cicatrices	8.82
4. Having previously had smallpox	19.00

Mr. Marson's observations further established the fact that the *degree of modifying power is in the exact ratio of* *the excellence and completeness of the vaccination as shown by the cicatrices.* This principle was shown by observations upon 15,000 cases of smallpox which came under his observation in the course of thirty years.

The preceding well-known table is introduced in support of the statement.

From these observations it appears that the average of vaccinated persons, if they contract smallpox, have about one-sixth of the chance of dying from this disease which is incurred by those who have never been vaccinated; some of them, on account of the poor quality of the vaccination, incur one-third of that risk, while, on the other hand, others, thoroughly vaccinated, incur less than one-seventieth part of it. As to the prognosis of any case of smallpox, then, the question is not merely whether the patient has been vaccinated or not, but also *how* he has been vaccinated (Seaton, in "Reynolds' System," vol. i.).

In the examination of nearly a half-million children in England, with reference to the quality of the vaccination, the following causes of imperfection were noticed:

(1) The frequency with which practitioners, instead of attempting fully to infect the system, had been satisfied with insertions of lymph sufficient to produce only one, two, or three ordinary vesicles; (2) the want of due attention to the selection of the lymph used in vaccinating; (3) carelessness and clumsiness in the performance of the vaccination, so that, if the operation did not wholly fail, it very frequently resulted in a less degree of effect than it had been the aim of the operator to produce; and (4) the great and unnecessary extent to which the use of preserved and conveyed lymph was substituted for the vaccination with fresh lymph.

These observations were made upon children, most of whom had been vaccinated by public vaccinators, but a large number of whom had been vaccinated by private practitioners; and it was the impression of the observer that the latter were not so well vaccinated as the former. This observation has been substantiated by more recent inquiries (Report of the Local Government Board, 1884). This report, in commenting upon the variable quality of vaccination, and upon the inquiries of Dr. Stevens upon this subject, says: "The 125 children under ten years of age who died of smallpox after an alleged vaccination, must be reduced to 117 by deduction of those who were discovered, on his personal inquiry, not to have been vaccinated at all, or to have been 'unsuccessfully' vaccinated; and this number 117 divides into 82 vaccinated by private practitioners, and 35 by public vaccinators. Now, the number of vaccinated children under ten years of age, in London, is made up in about equal numbers of those vaccinated by private practitioners, and of those vaccinated at the public expense. Among the privately vaccinated there were 82 deaths, and among the publicly vaccinated there were but 35.

"From these figures we may deduce the fact that public vaccination in London protects against smallpox much more than private vaccination.

"Children privately vaccinated comprise most of the children of the upper classes, who certainly run less risk of smallpox infection than those of the poor. The comparatively large mortality among those privately vaccinated, therefore, becomes the more striking. And, undoubtedly, there are medical men to be found who, having formed some opinion of their own about the sufficiency of one vesicle, cannot be induced to set aside that opinion in deference to the indisputable evidence to the contrary that every smallpox hospital holds up to them."

In the Prussian army there has not been a single death from smallpox since 1874.

In Germany smallpox has diminished, since the enactment of the law of 1874, to a degree never before known, so far as records reach, while in the neighboring countries it prevails. It is for this reason that the German Government publishes an annual statement in which the condition of cities in neighboring countries in regard to smallpox is compared with those of Germany. The following table presents the figures of 1896 as published in the annual German report upon smallpox[10].

DEATHS FROM SMALLPOX, 1896.

	Number of inhabitants.	Deaths from smallpox in 1896.	Proportion per 1,000 inhabitants.
In the German Empire.........	52,612,568	10	0.02
In 265 German cities...........	14,125,027	2	.01
In 57 Austrian cities............	3,619,109	64	1.77
In 15 greater cities of Switzerland	600,259	1	.17
In 70 Belgian cities.............	2,107,594	12	.57
In 108 greater cities of France..	8,149,348	958	11.76
In 33 greater English cities.....	10,846,971	25	.23
In 12 greater cities of Holland..	1,362,056	20	1.47

Under the title of "the balance of vaccination," Körösi discusses the advantage secured as contrasted with the infinitesimal dangers of the practice. He says: "There died in Buda-Pesth 153 children from skin diseases in six years, of which number 30 had been vaccinated. If the chances of death increased thirteen per cent. with the chances of disease, then instead of these 30 cases in the course of six years, there would have been 34 cases; accordingly 4 cases would have been charged to vaccination; in other words, for each year 4 to 6 cases, in a population of about 350,000, and for 100,000 inhabitants and one year, about one-fifth of a case. Therefore, in a city of one million inhabitants there would die, of skin diseases as a result of vaccination, at most two children more, while, on the other hand, 2,000 would be saved from the smallpox. The balance gives a gain of 1,998 lives. In whatever light the case may be considered, cowpox vaccination will continue to produce many hundred times more good than evil. So, although the great blessings of vaccination are not bought for nothing, still they are bought at a very trifling cost. And we may say boldly that vaccination is one of the grandest preservative forces for lowering mortality, and raising the average length of life." (This testimony comes from a layman, and one of the highest living authorities upon the interpretation of vital statistics.)

3. *The Effect of Vaccination upon the Age Distribution of the Mortality from Smallpox.*—Smallpox, when it occurs unmodified by vaccination, as in the eighteenth century, is essentially a disease of childhood; it might almost be said, of infancy. M. Marc d'Espine says of it: "The elective age of smallpox is childhood and infancy." Some of the names of this disease in different languages, which have come to us from ante-vaccination periods, are indicative of this characteristic, as Kinderpocken, Barnkopper, and possibly the English name smallpox, *i.e.*, pox of *the small.* It is as essentially a disease of children as scarlet fever or measles. In the latter disease a regular declining series is presented when successive ages are considered. For these diseases no method of prevention is known, and hence the statistics of mortality express unmodified natural affinities of such diseases for the earliest periods of life. For smallpox, since the introduction of vaccination, this declining series is interrupted in a most remarkable manner. The interruption is purely artificial, and is the expression of the effect of vaccination in postponing the greater mortality to a later period of life; and hence the necessity of revaccination, a subject which will receive further consideration.

The adjoining table expresses in four series of figures what may be taken as the expression (at least approximately) of the natural affinity of certain diseases. The population under five is a minority of the population (seldom more than fifteen per cent.), but it furnishes by far the majority of deaths from the diseases named—two-thirds of all deaths by scarlet fever, four-fifths of all deaths by unmodified smallpox, and a still greater proportion of deaths by measles and whooping-cough. In a word, these are all distinctively infantile diseases; and the obviousness of this fact represents three conditions: First, that the susceptibility to those diseases develops itself very early in life; secondly, that the susceptibility, when once acted upon by its corresponding exterior cause, becomes exhausted more or less absolutely for the remainder of life; thirdly, that the exterior cause or infection has been of sufficiently frequent recurrence among the population for those relations of susceptibility to show themselves.

For the meaning of the diseases being infantile is, not that any insusceptibility to contract them is acquired in the mere act of growing up, but that, because the susceptibility develops itself at the commencement of life, and because the exterior influence which acts upon that susceptibility is seldom absent, therefore all who have outlived the first years of childhood have commonly had each susceptibility exhausted by suffering the disease to which it relates. Hence if all occurring cases of any such disease be classified according to the ages at which they happen, the resulting series of figures must necessarily have its maximum at that age when the special susceptibility is first fully developed. From this point it must undergo a more or less rapid and uninterrupted decline; the *uninterruptedness* being determined by the fact that at each succeeding age there will be fewer and fewer susceptible persons, the *rapidity* being graduated by the frequency or constancy with which the exterior cause is in operation.

PROPORTIONATE DISTRIBUTION BY AGE OF 1,000 DEATHS IN GENEVA BY SMALLPOX (1580-1760), BEFORE THE DISCOVERY OF VACCINATION, AND OF THE SAME NUMBER OF DEATHS BY WHOOPING-COUGH, MEASLES, AND SCARLET FEVER, AS OBSERVED IN 1847.

Ages.	Smallpox.	Whooping-cough.	Measles.	Scarlet fever.
0- 1	202½	404½	155½	63¼
1- 2	191½	275	346¾	145
2- 3	190	138½	201½	171¼
3- 4	132¼	77¾	117	153
4- 5	88¾	47¼	68	123½
0- 5	805	943	883¾	656
5-10	155½	52½	91¾	254½
10-15	18¾	2¼	13½	54¼
15-25	13¾	½	7	12¾
Above 25	7	1½	4	22½
At all ages	1,000	1,000	1,000	1,000

A report of the German Vaccination Commission shows that during the ten years following the enactment of its compulsory law of 1874, Germany not only had a smaller death rate from smallpox than ever before, but even passed from a position of inferiority to England to one of distinct superiority in regard to its immunity from smallpox. Smallpox mortality in the cities of Germany has become a trivial matter, while in London, Paris, and Vienna there have been quite appreciable epidemics, having their principal incidence upon the younger adult class of the population.

The following statistics as to the incidence of smallpox at certain ages are from the Report of the Medical Officer of the Local Government Board of England for 1884. While the 86 deaths among children under ten, stated in the column headed "Vaccinated community," contrast strongly with the 612 in the preceding column of the unvaccinated, there is no doubt, as the medical officer states, that even this number 86 is far too high, and is indicative of *sham* vaccination.

A comparison of the mortality from smallpox of children under one year of age living under the provisions of different laws, some of which are vigorously enforced, others optional or partially enforced, and also of populations entirely without vaccination, as was the case in the eighteenth century, is very instructive. Dr. Robertson, of Edinburgh, made such a comparison, and found that under the optional system in practice in Scotland from 1855 to 1864, the number of deaths from smallpox of children under six months of age was about equal to that of children whose ages were six to twelve months.

When vaccination became compulsory this ratio was greatly changed, and the number in the second six months was about one-fourth as large as that of the first six months. It was inferred that vaccination made the difference. A third fact, however, strengthened this inference, and that was the ratio existing before vaccination was known. This was to be found in the carefully kept statistics of the Kilmarnock register already quoted.

RATIO OF DEATHS FROM SMALLPOX BETWEEN SIX AND TWELVE MONTHS OF AGE, TO ONE HUNDRED DEATHS FROM SMALLPOX UNDER SIX MONTHS, IN THREE SELECTED PERIODS.

Age.	1728-1763. Kilmarnock. Vaccination unknown.	1855-1864. Scotland. Vaccination optional.	1865-1879. Scotland. Vaccination compulsory.
Under 6 months	100	100	100
From 6 to 12 months	491	103	26

The first ratio may be taken as the normal one of natural smallpox. It is a disease nearly five times as fatal in the second as in the first six months of life. But when modified by optional vaccination in the second six months, the mortality is reduced from 491 to 103. And when vaccination becomes compulsory, as in the third period, the 103 is further reduced to 26.

The question may be asked, How far is this decrease in smallpox mortality to be attributed to causes other than vaccination? Improved hygiene and treatment may have exercised considerable effect upon the mortality, but they can have but little bearing upon the facts quoted in the last table. Such an enormous improvement, at the rate of nearly 20 to 1, could never have been due to mere measures of sanitation. Let the following table of the rate of improvement of certain infectious diseases illustrate this:

RATE PER ONE THOUSAND PER YEAR OF DEATHS FROM CERTAIN INFECTIOUS DISEASES IN KILMARNOCK IN 1728-64, AND IN ENGLAND AND WALES IN DIFFERENT PERIODS.

Disease.	Rate in Kilmarnock. 1728-64.	Rate in England.	Rate of decrease.
Measles	0.615	(1861-71) 0.4399	100 to 70
Whooping-cough	.7671	" .5273	100 to 68
Fever (including scarlatina)	3.4722	" 1.8474	100 to 53
Smallpox	4.1071	(1854-79) .208	100 to 5

Deaths from smallpox have therefore decreased 14 times more than those from measles, 13 times more than those from whooping-cough, and 10 times more than those from fever.

From the instructive comparison given by Dr. Vail, the following conclusions are drawn:

1. Smallpox was epidemic every four and one-quarter years (1728-64).

2. Its death rate per 1,000 per year was nearly 20 times as great as it now is. 3. Its death rate under five years of age was 35 times as great as it now is.

4. The mean age at death from smallpox was two and one-half years in the last century, and is now nearly twenty years.

5. The death rate from smallpox in the second half-year of life is now only a fourth of that in the first half-year, while formerly in the second half-year it was nearly 5 times as great as in the first half-year. 6. The smallpox death rate has improved about 12 times as fast as the death rate from measles, whooping-cough, and fever.

The fact that smallpox when allowed to pursue its natural course, unmodified by vaccination, is essentially a disease of childhood, is illustrated in a most forcible manner in the sketch of smallpox in Kilmarnock in the last century, already quoted.

Of the 622 persons who died of smallpox in that town between 1728 and 1764, 586, or 94.2 per cent., were five years of age and under. Seven only were over ten years of age, and the oldest was but twenty-six.

In the different epidemics which fell upon that community, the time from the height of the first epidemic to that of the second was but four years and eight months, and of the 45 children who succumbed in 1733, 44 were less than four years and eight months of age, the remaining one being seven years of age. Thus only one child that died in the epidemic of 1733, had been alive previous to the height of that of 1728. The disease had to secure its victims almost wholly from the population that had come into existence since its last visitation. One epidemic left almost no victims for its successors: in the same way, hardly any had been left to it by its predecessors. It called at every door, and nearly all who were not disease-proof came within its grasp.

Epidemic years.	Interval since height of former epidemic.	Total deaths, smallpox.	Deaths of children born since height of former epidemic.	Deaths among children who had passed safely through one epidemic.	Deaths among persons who had passed through more than one epidemic.
1728-29	Unknown	66			
1733	4 years 5 months.	45	44	1	
1736	3 years 5 months.	66	58	7	1
1740	3 years 7 months.	66	60	5	1
1744-45	4 years 8 months.	74	67	6	1
1749-50	5 years	84	79	4	1
1754	4 years 6 months.	95	84	11	
1757-58	3 years 2 months.	45	39	6	
1762	4 years 8 months.	66	53	11	2
Cases occurring between epidemics.		14	8	5	1
Total		621	492	56	7
Percentage		....	88.6	10.00	1.2

The principal point shown in this table is that, on an average, over eighty-eight per cent. of those who died in one epidemic had been born since the previous one; that ten per cent. who died had passed safely through one epidemic; and that only one per cent. had lived through more than one outbreak.

The next table shows that these epidemics, to nearly nine-tenths of their extent, did not practically occur in a

SECTION OF POPULATION BORN SINCE FORMER EPIDEMIC.

Height of epidemic.	Born since height of former epidemic.	Died of various diseases, excluding smallpox.	Remaining to form a field for new epidemic.
May, 1733	614	90	524
October, 1736	476	82	394
May, 1740	501	89	412
January, 1745	506	68	438
January, 1750	634	107	527
July, 1754	648	131	517
September, 1757	445	41	404
May, 1762	690	110	580
Totals	4,514	718	3,796
Averages	564	89	475

population of 4,200, but in a population of 475 people. And the average number of deaths in this population was 60, or at the very high rate of 126 per 1,000 living in each epidemic year. Now the number of attacks in unvaccinated children under five years of age is two for every death. As many die as recover. Therefore, of every 100 children born in Kilmarnock, no less than 25 were seized with smallpox at the very first epidemic after their birth.

"These two tables show that, as regards smallpox, there were, in fact, three Kilmarnocks. One, a Kilmarnock of 3,700 persons, had no fear of its attacks. These had already met and battled with the disease fiend. On many were to be seen the marks of the conflict. Some were blind, some had lost their hearing, many were permanently injured in constitution, and very many were scarred and disfigured for life; and, for every one that conquered, another had fallen, never to rise again. There was indeed a second Kilmarnock under the green sod of the kirkyard. The Kilmarnock which had reason to dread the epidemic's approach was a Kilmarnock the least able to meet it. It consisted of a band of little children, numbering less than five hundred in all. Every such group that came into existence had to face, within four or five years of its birth, the most terrible physical enemy that it would ever meet; and, having fought the battle, some were added to the maimed and distorted who formed so large a portion of the population, and others were laid beside those who had been destroyed by former epidemics. One can barely imagine what must have been the feelings of a mother regarding these fearful visitations. Even where the town was free from the pestilence, there would be the constant foreboding of its all too certain coming; and when at last the first case occurred—when the doctor was called in, and pronounced the disease to be the dreaded pox—his words would be heard as a sentence of death to some member of almost every family containing little ones; and, as the news spread from house to house, with what a despairing clutch would each mother press her darling to her breast, and beg Almighty God to command the destroying angel to pass by her door! After the lapse of a hundred and fifty years, one can have little conception of the real meaning of a smallpox epidemic. But the old parish register has enabled us to apprehend something of its horror, and I venture to say that, if the antivaccinationists had their will, we would ere many years be again experiencing somewhat of the awful visitations which were so familiar in old Kilmarnock."

The following figures and diagrams show in a conclusive manner the fact that smallpox in the eighteenth century was beyond question a disease almost exclusively of young children. They also show in quite as conclusive a manner the modifying effect which vaccination has had upon the age incidence of smallpox mortality.

The figures for the smallpox diagram (eighteenth century) were made from an average of the records of several English and continental towns which are given in the foregoing pages. This average was as follows: Out of each 1,000 deaths from smallpox 805.5 were those of children under five years, 155.5 were those of children from five to ten years old, 26.5 from ten to twenty years, 10 from twenty to thirty years, 2.5 from thirty to forty years, and 25 over forty years. (See lower left-hand diagram in Fig. 4929. In these four diagrams the inci-

Dr. Tissot, writing about the middle of the eighteenth century, said of smallpox:

"Smallpox is the most frequent, the most extensive of all diseases. Out of 100 persons there are not more than 4 or 5 exempted from it. *People generally take the smallpox in their infancy or in their childhood.*" ("Advice to the People with Respect to their Health," 1762, p. 156.)

The Duration of the Protective Power of Vaccination.—Gerstäcker, as quoted by Wolffberg, states (*Centralblatt für allg. Gesundh.*, 1888, p. 182) that the cardinal principle of the duration and efficiency of the protection afforded by vaccination depends essentially upon the intensity of the preceding vaccination, and upon those changes which—independent of every attempt at protection—the natural individual predisposition to smallpox undergoes in the course of life, although reduced to a definite lower standard by vaccination.

The Comparative Protection Afforded by Vaccination and by Smallpox.—Both Marson and Simon expressed the opinion, before the Parliamentary Committee of 1871, that the protection afforded by an attack of smallpox against a subsequent attack was greater than that afforded by vaccination (Replies 3,517-3,521; 4,220-4,224).

In the early years of vaccination it was quite a common practice to expose vaccinated people to the smallpox either by contact or by inoculation, for the purpose of testing the efficacy of the practice. The town of Milton, Mass., in September, 1809, voted to test the question upon twelve children who had been vaccinated in July of the same year. Twelve vaccinated children were therefore selected and inoculated with smallpox lymph. They were quarantined during fifteen days at a hospital provided for the purpose, and the following certificate was issued on their release:

> MILTON, October 25th, 1809.
>
> The twelve children whose names are written on the back of this card were vaccinated at the town inoculation in July last; they were tested by smallpox inoculation on the 10th instant, and discharged this day from the hospital, after offering to the world, in the presence of most respectable witnesses, who honored Milton with their attendance on that occasion, an additional evidence of the never-failing power of that mild preventive, the cowpox, against smallpox infection; a blessing great as it is singular in its kind, whereby the hearts of men should be elevated in praise to the Almighty Giver.
>
> AMOS HOLBROOK,
> *Physician.*
>
> OLIVER HOUGHTON,
> *Chairman of the Committee for Vaccination.*

[Card in possession of Massachusetts State Board of Health.]

As compared with the earlier practice of inoculation with smallpox lymph, vaccination has the great advantage over the latter that its protection is afforded without risk to life, without disfiguring the features, without causing loss of sight or of hearing, and without the risk of propagating a highly infectious, loathsome, and deadly disease among the community.

BOVINE VACCINATION.—The term bovine, or animal, vaccination is applied to that which is practised by the aid of vaccine lymph cultivated in bovine animals. Warlomont very truly says that the term *animal vaccination* is purely conventional; the vaccine lymph from an infant is just as much an animal product as is that from a heifer.

With reference to the origin of the practice, Dr. Warlomont states that an aged physician had, in his youth, seen his father, the village doctor, inoculate the teats of a cow with human vaccine, preserved through the winter in order to renew the stock of fresh lymph at the commencement of each vaccinating season. Such was a common practice, and it has been carried out for years in Germany, and especially in Bavaria. This method of practice has been called retrovaccination. It has also been practised to a considerable extent in the United States. Supplies of vaccine virus were largely obtained for use in the army by this method during the latter part of the Civil War (1861–65), and while this method has been vehemently opposed by some, it is also true that no evidence has been adduced to show that such vaccination, when properly transmitted from a healthy infant to the heifer, and thence, after one or more successive transmissions from animal to animal, is again transmitted to the human species, is less protective against smallpox than that which has never been cultivated upon other soil than that of the cow. The German Government takes this ground and sanctions its employment in its instructions upon this subject.

That method to which is now given the term animal or bovine vaccination is of later origin, and also has a more restricted application. Warlomont defines animal vaccination as "the product of natural horsepox or cowpox which has been cultivated upon heifers," and has never quitted that place (or medium) of cultivation ("n'ayant jamais quitté ce lieu de culture"). This method was practised in a limited degree as early as 1800, by Duquenelle, at Rheims, and by Valentine, at Nancy. It was introduced into Naples in 1810 by Galbiati, and continued by his pupil, Negri. Both of these early experimenters occasionally resorted to retrovaccination, but Negri finally began a series of continuous vaccinations, for which he obtained his original supplies, on two different occasions, from animals found to be affected with natural cowpox.

In 1864 M. Lanoix, a French physician, visited Naples to study this method of vaccination, and thence introduced the practice into Paris in the same year. A commission was appointed by the Government in 1866, whose report favored the practice of animal vaccination, and the first virus employed by them was that which had been obtained from Naples. A new source was soon found at Beaugency, in France, in 1866, and still later another at St. Mandé, near Paris. Other cases of natural cowpox may be found detailed in an article in the *Revue d'Hygiène* (July, 1888) by Dr. A. Layet, entitled "Les Sources naturelles du Vaccin." Dr. Seaton, in his report on animal vaccination to the Local Government Board of England, made after a visit to Paris and other parts of the Continent in 1869, states that Drs. Lanoix and Chambon, who had introduced animal vaccination into Paris, "saw no advantage in keeping these *two lymphs* distinct, and the virus which they have employed since 1866 is a mixture of the two natural sources discovered at Beaugency and at St. Mandé."

Dr. Seaton had made an unfavorable report upon Bovine Vaccination, urging, in the *first* place, the difficulty of transmitting the virus from one animal to another successively; *second*, the great risk of failure in transmitting it from the calf to the human subject; *third*, the inferior preservative quality of bovine lymph.

In reply to this it may be said:

First. With reference to the facility of infecting calves or heifers continuously with vaccine lymph, Dr. Cory states, in his report to the Local Government Board in 1886, that 153 calves were vaccinated with lymph of one hundred and twenty hours' growth, and all of them proved susceptible to vaccination; 8,600 insertions were made, resulting in 8,242 vesicles (an insertion success rate of 95.8 per cent.); 94 calves were vaccinated with lymph of ninety-six hours' growth, producing 5,440 vesicles out of 5,631 insertions (an insertion success rate of 96.6 per cent.); 3 other calves were vaccinated with lymph of one hundred and sixty hours' growth in 144 places, producing 142 vesicles.

In the writer's experience not more than five per cent. of bovine animals of different ages prove refractory to vaccination, and the operation of transmitting the vaccine infection successfully from animal to animal is not, in the hands of an expert, attended with difficulty. The reasons for the comparative insusceptibility of adult animals are given elsewhere.

Second. As to the transmission of the infection from the bovine animal to the human subject (under like conditions as to the quality and freshness of the lymph used), the operation is quite as successful as with humanized lymph, and by some authorities the percentages of success are reputed as greater than with humanized lymph.

In Illinois, in 1882, out of 138,488 primary vaccinations with bovine lymph, 82.7 per cent. were typical, and out of 15,448 performed with humanized lymph, 76.9 per cent. were typical. Dr. Cory vaccinated 4,688 persons, and of these 4,212 were successful in five places, 238 in four places, 92 in three places, 51 in two, 37 in one, and 17 were unsuccessful in the first trial. Excluding a very few who did not return for inspection, Dr. Cory's insertion success rate was 96.5 per cent., Mr. Murphy's 99.9, Mr. Stott's 90.6.

Dr. Pissin, of Berlin, in 1882, reported that he had made 12,679 vaccinations from 18 calves, with a ratio of success of 98.1 per cent. in primary vaccinations, and 91.3 per cent. in revaccinations, using scarifications only. Pfeiffer, of Weimar, obtained a success of 98.6 per cent.; Rissel, 97.8 per cent.; Reissner, 98.6 per cent., and Voigt, 99.4 per cent.

At the Hamburg vaccine establishment the ratios of reported success were as follows: In 1878, 69 per cent.; in 1879, 82 per cent.; in 1880, 73 per cent.; in 1881, 82 per cent.; in 1882, 85.4 per cent.

Weiler, on the contrary, found the humanized lymph to give better results, obtaining 97.3 per cent. in primary vaccinations with humanized lymph, and 86.8 per cent. with bovine lymph.

Third. As to the preservation of animal lymph as compared with that of humanized lymph.

1. As to its use upon calves. Dr. Cory, in the report already alluded to, made careful observations as to the preservation of lymph stored in tubes, and established the possibility of such preservation for a period of two years. His results were as follows: The lymph referred to in these observations was partly of ninety-six and partly of one hundred and twenty hours' growth, none being taken later than one hundred and twenty hours after insertion. He also states that lymph taken at a later period deteriorates more rapidly, and is apt to produce spurious results, just as happens occasionally with humanized lymph taken at a later date than the eighth day.

Number of days during which lymph was preserved in tubes before using.	Number of insertions with it on calves.	Successful insertions on calves.	Insertion success rate per cent.
2	3,998	3,390	84.7
4	1,438	1,139	74.2
6 to 8	255	184	72.1
9	431	309	71.6
11 to 12	337	273	70.6
14	263	214	81.3
16	288	207	71.9
17 to 46	639	472	73.8
53 to 93	445	332	74.6
100 to 200	388	258	66.5
200 to 500	104	17	16.3
500 to 600	135	45	33.3
600 to 700	82	24	35.0
816 to 858	72	4	5.5

2. As to its use upon the human subject. Like the former, this lymph was also of one hundred and twenty and of ninety-six hours' growth, in about equal proportions. A part was stored in tubes and a part upon ivory points, in regard to which Dr. Cory says that within four months of storage there is an advantage in points over tubes as a method of storage, and a period of one hundred and fifty-four days appears to be the longest interval that should be allowed to elapse between the taking of calf lymph on points and its use on children. For longer periods the lymph in tubes retained its powers better than that preserved upon points.

The three tables on the opposite page were the results of Dr. Cory's observations on this point.

From Italy and from France the practice of bovine vaccination extended to other countries. In February, 1865, it was introduced into Brussels by Dr. Warlomont, who employed successively lymph from the Neapolitan source, afterward from the Beaugency source, and finally from a third source obtained at Esneux. A state vaccinal institute was finally established at Brussels under his charge, where the practice of bovine vaccination has

been carried out with the greatest care, for the gratuitous distribution of lymph both of humanized and of bovine stock. The institute was established on condition that both sorts of lymph should be distributed from it. Dr. Warlomont, by the thorough character of his work as well as by his published writings upon the subject, has accomplished very much toward the general introduction of bovine vaccination.

Bovine vaccination was introduced into Berlin in 1865 by M. Pissin, and is still conducted there, and also at Vienna; the amount of bovine lymph used, as compared with the humanized, having increased rapidly from year to year since its introduction. Establishments for the production of animal lymph are now in operation at Berlin, Halle, Kiel, Kassel, Munich, Nuremberg, Dresden, Bautzen, Leipsic, Frankenberg, Stuttgart, Cannstadt, Karlsruhe, Darmstadt, Schwerin, Weimar, Bamberg, Lubeck, Hamburg, Bremen, Strassburg, and Metz. This practice has gradually made its way into other countries of Europe, and now nearly every large city has its vaccine institute or establishment for the propagation of bovine lymph. It is also in use under the auspices of the British Government in India. It was introduced into Bombay in 1881, and into Madras and Bengal in 1882, and was introduced into Japan in 1874.

The following table illustrates the rapidity with which bovine lymph has taken the place of humanized lymph in Germany since 1879:

PERCENTAGE OF BOVINE LYMPH IN USE IN GERMANY. 1879-1900.

	Per cent.		Per cent.
1879	2.6	1890	89.0
1880	3.3	1891	96.8
1881	4.0	1892	98.5
1882	7.1	1893	98.9
1883	11.2	1894	98.9
1884	19.1	1895	99.85
1885	33.1	1896	99.88
1886	54.2	1897	99.96
1887	68.4	1898	99.96
1888	...	1899	99.72
1889	77.4	1900	99.94

The foregoing figures for the years 1879–87 are from the "Arbeiten aus dem Kais. Gesundheitsamte" and for the years 1889–1900 from the "Mittheilungen."

England was slow to adopt the new method of vaccination; Dr. Seaton's unfavorable report in 1869 undoubtedly delayed its introduction. This report, however, contained much valuable information upon the subject, which led to its careful consideration, and finally to its introduction under the direction of the Local Government Board in 1881, the use of either humanized or bovine lymph being optional. The experiments of Dr. Cory, establishing the possibility of the transmission of syphilis by humanized virus, even under the most rigorous conditions, undoubtedly strengthened the position of the board in introducing the bovine virus.

"As the result, however, of the findings of the Royal Commission on Vaccination," says Dr. Copeman,[12] "legislative measures have now been introduced by which arm-to-arm vaccination will be entirely superseded, in public work at any rate, by animal vaccination, and the adoption of the use of preserved glycerinated calf lymph having been determined on, the necessity for stational attendance will disappear, except in so far as may appear desirable for purposes of control, or in order to provide facilities for teaching."

By the term "stational attendance" the writer refers to certain definite places and times, when and where facilities were provided for the work of arm-to-arm vaccination from healthy infants. Opportunities for vaccination upon the old arm-to-arm method were usually furnished weekly in the large cities, and about once in three months in the country districts.

In the United States bovine vaccination had been attempted on various occasions previous to its more general introduction in 1870–71. Dr. John Yale, of Ware, Mass., writes to me that in 1855, his cow "had the cowpox, a single umbilicated vesicle on the udder adjoining the teat; I took the crust, and vaccinated with it, used the matter upon calves, and so kept up a supply for years." He also stated that in 1844 he had observed cowpox in a herd of thirty cows belonging to Mr. Truman Curtis, of Torringford, Conn. The milkmaids and some of the men servants contracted vaccinia upon their hands from this herd.

In March, 1865, Dr. E. Cutter, of Woburn, Mass., detected kinepox in at least two instances in the town of Lexington, where the disease was more or less prevalent, and at times very troublesome at dairy farms. From two of these cases he vaccinated two cows, and obtained a succession of lymph, which was used to a considerable extent in the vaccination of soldiers in the Army of the Potomac, in the spring of 1865. A report was made upon these cases by Surgeon J. J. Milhau, U. S. A. (dated March 29th, 1865), who visited and personally inspected twelve of the animals thus vaccinated ("Medical and Surgical History of the War of the Rebellion," Medical Volume, part iii.).

Previous to the date referred to (March, 1865) Dr. Cutter, as stated in his report of 1872, had employed retrovaccination quite largely, and with excellent success, and in this respect had followed very much the same method which had formerly been employed by Negri, at Naples.

In 1870 Dr. Henry A. Martin, of Roxbury, Mass., imported lymph of French origin, and organized a well-equipped vaccine establishment at which a constant succession of heifers has been vaccinated since that time, the work having been continued after his death by his

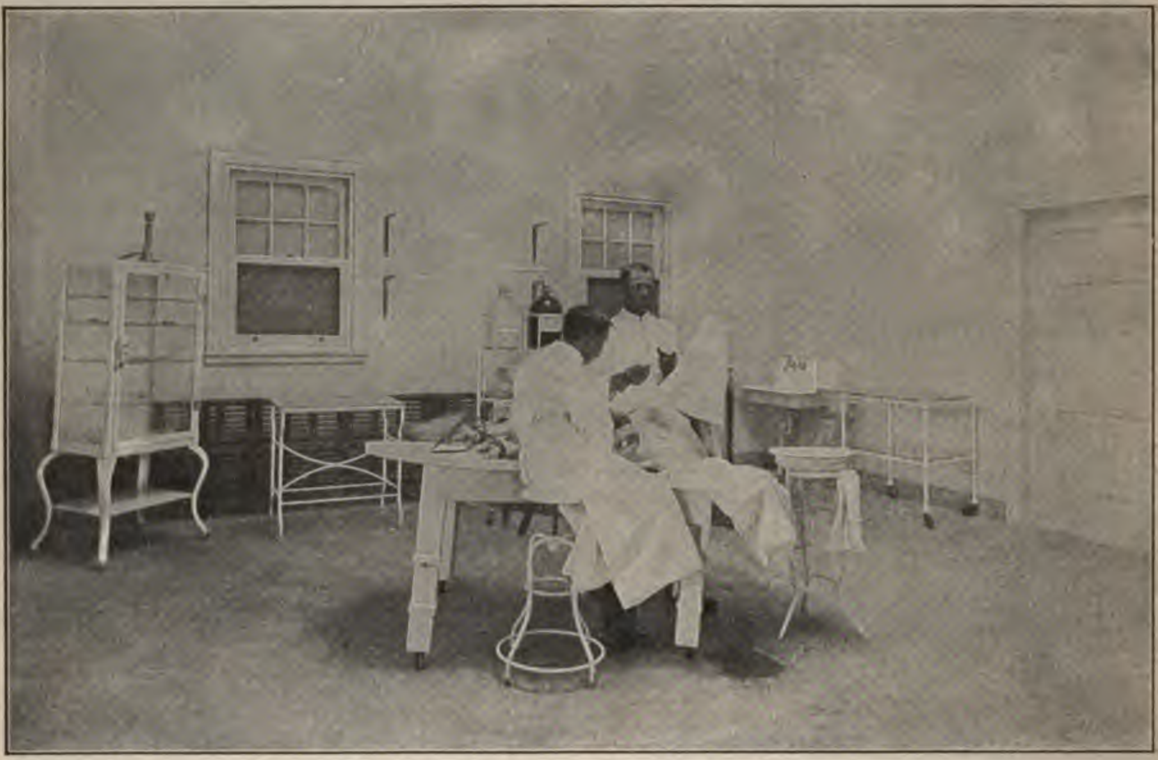

FIG. 4930.—Vaccinating a Calf. (By permission of the H. K. Mulford Company.)

sons. To him the work of successfully bringing bovine vaccination to popular notice in the United States, as a substitute for humanized vaccination, was largely due. Dr. Martin also obtained lymph from cases observed in the neighborhood of Boston, which was also successfully transmitted to a succession of heifers. Others soon followed him in different parts of the United States, especially Dr. Frank P. Foster, of New York, and Dr. E. L. Griffin, of Fond Du Lac, in Wisconsin.

The production of vaccine material in the United States is now (1903) mainly in the hands of a few private producers, who furnish most of the vaccine lymph used in the country. The principal producers are the H. K. Mulford Company, of Philadelphia, Parke, Davis & Co. of Detroit, Mich., and the National Vaccine Company of Washington. All of these are equipped with establishments of ample size, furnished with modern appliances, including excellent bacteriological laboratories and capable of producing vaccine material ample in quantity and reliable in quality for general use. Considerable quantities are also exported abroad for use in other countries.

At present it is safe to say that practically all of the lymph used for vaccination in the United States is of direct bovine origin—produced by artificial propagation.

There are certain advantages in the employment of animal lymph which may be detailed as follows:

The avoidance of the transmission of certain diseases common to mankind, which it has been conclusively proven may be transmitted by the process of vaccination; for while it is undoubtedly true that millions are annually vaccinated without the occurrence of a single case of such transmission, it is also true that a sufficient number of cases are on record to establish the possibility of such transmission.

The French Academy of Medicine had, as long ago as 1830, proclaimed, almost in dogmatic terms: "Vaccinate without fear, for the vaccine virus taken from subjects afflicted with complaints susceptible of communication by contagion, such as syphilis, does not convey such germs, in any case, and gives rise only to vaccinia."

The question was again fully discussed in 1864, by the same body, and it was finally admitted by the Academy that vaccinal syphilis was an incontestable fact, and while it was of very rare occurrence its possibility could not be doubted. Ricord said of it: "I at first denied the possibility of the transmission of syphilis by vaccination, but facts repeating themselves, and becoming more and more confirmatory, I admitted with reserve, and even with repugnance this mode of transmission. To-day I do not hesitate to state it as a fact."

Proofs of the occurrence of vaccinal syphilis are to be found in the writings of Depaul, of Viennois, and others, where about three hundred cases are given in detail. The reported cases are mainly of French and Italian origin, those detailed by Professor Cerioli and the Rivalta cases constituting a large part of the number. While the earlier English writers have been slow to accept the possibility of such transmission, some recent experiments have apparently settled the question conclusively that the danger exists, so far as vaccination with humanized lymph is concerned, although the transmission is of extremely rare occurrence.

It is certain that hundreds of thousands of vaccinations were made every year without the occurrence of the accident in question, and hundreds of busy practitioners passed through the period of active practice, during which they were called upon to make frequent vaccinations, without meeting a single case.

Three methods have been detailed as possible for the occurrence of vaccinal syphilis:

(1) By the mixture of vaccine lymph with the products of a syphilitic skin eruption.

(2) By mixture with the blood of a syphilitic person.

(3) By the use of the clear lymph of a vaccine vesicle existing on the person of a syphilitic.

With reference to the question of the transmission of syphilis by inoculating the blood of a syphilitic upon a healthy person, there can be but little question. The question has been proven, both by observation and by experiment.

With reference to the transmission of syphilis through the medium of the clear vaccine lymph containing no blood, the experiments of Dr. R. Cory, an officer of the Local Government Board of England, established the possibility of such communication. These experiments were witnessed by a committee of experts comprising the noted surgeon, Jonathan Hutchinson, together with Drs. Bristowe, Humphrey, and Ballard (see Twelfth Report of Medical Officer of the Local Government Board of England, p. 46).

Since the introduction of animal vaccination generally into different countries, the reports of such cases have become comparatively rare, and consequently the discussion of this question has now lost much of its practical importance.

When it is remembered that at least five hundred millions of persons have undoubtedly been vaccinated since the introduction of vaccination by Jenner, the ratio of these cases of transmitted syphilis to the whole number is surprisingly small.

Another reason for the use of bovine virus lies in the facility with which an abundant supply of lymph may thus be secured for use at short notice. The occasional advent of smallpox among the crowded populations of large cities renders the production of large quantities of vaccine lymph in a brief space of time an absolute necessity.

The amount of vaccine lymph which may be obtained from one animal, as compared with the paucity of material which it is practicable to obtain from a healthy infant, is very large.

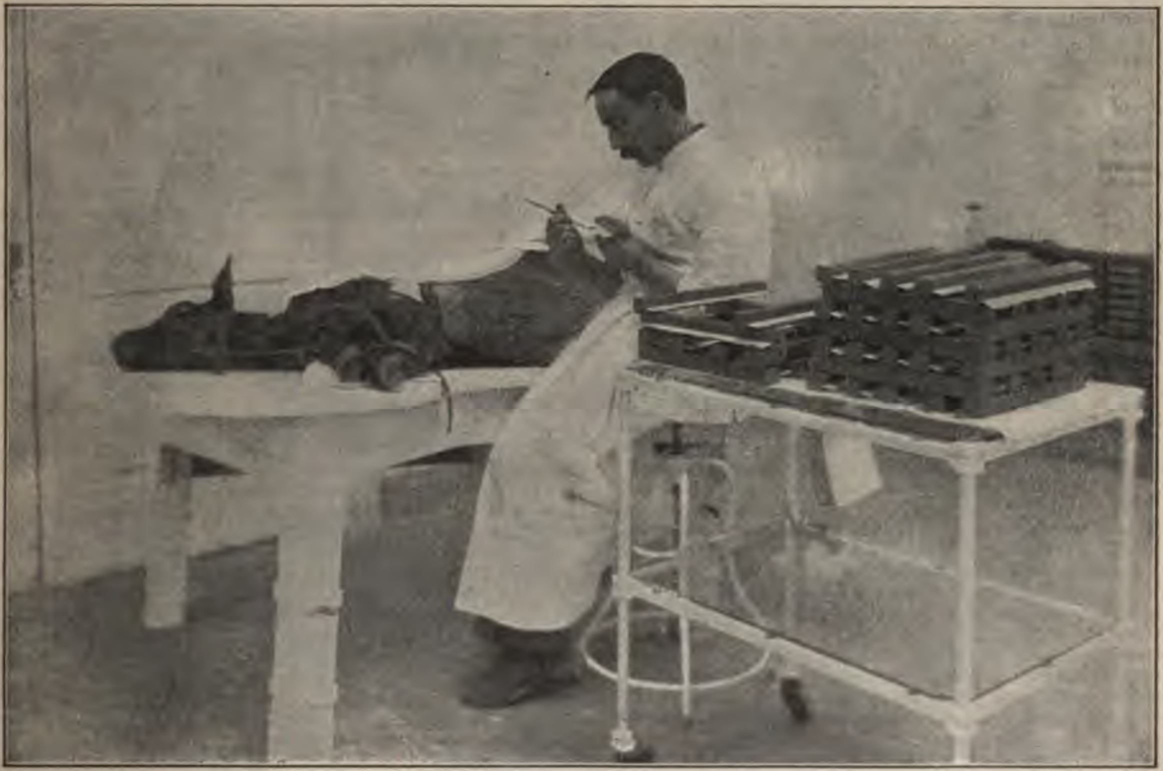

FIG. 4931.—Charging Ivory Points. (By permission of the H. K. Mulford Company.)

From two thousand to ten thousand charges of effective lymph upon ivory points is not an unusual quantity to be taken from a single heifer, and nearly equal quantities can be procured under modern methods in which the vaccine material is finally mixed with glycerin. It is, therefore, a decided advantage to be able to resort to the cow, and thus to avoid the objections which may be raised against the taking of supplies of lymph from infants. It is especially desirable, when lymph is supplied by the authorities of state and city governments, that such lymph should be of the best quality. Such authorities are under moral obligation to furnish to the people a vaccine lymph which is beyond all suspicion in the matter of freedom from contamination of disease.

These two faults, the possibility of contamination with syphilis and the relative paucity of lymph, were especially the faults of the Jennerian method of vaccination —and in animal vaccination may be found a method wherein lies the remedy for both; that is, the avoidance of syphilitic contamination and the capability of indefinite multiplication of vaccine material.

The possibility has been suggested of communication of bovine disease other than vaccinia, especially of tuberculosis of the cow. Tuberculosis is known to be inoculable, as demonstrated by Villemin, and more recently by the experiments of Koch and many other experimenters. Inoculated tuberculosis starts from the point of its insertion, as shown by experimentation upon the guinea-pig, rabbit, and other animals. It may be transmitted by means of the tubercle bacilli present in a tubercle itself, in the blood of an infected animal, or in the air exhaled from a diseased lung. Upon this point Dr. Warlomont says: "The importance of these facts as related to bovine, as well as to humanized vaccination, is worthy of consideration, and one fact should be stated at the outset, that it is impossible to inoculate tubercle by means of *superficial insertion* of bacilli which is the usual method of the insertion of vaccine lymph. The latter develop very slowly, and cannot, like those of splenic blood, rapidly infect a small wound. If we desire to make an animal tuberculous, we must carry the bacilli deeply into the tissues. Thus it is explained why it is that no one has been infected while making autopsies of tuberculous subjects. Thus, *a fortiori*, is it explained why no one has ever been infected with tuberculosis through vaccination. . . . So much for theory; now for the practice. Let them show, among the millions of subjects vaccinated in the past twenty-four years, either with humanized or with bovine lymph, a single case that has exhibited, at the spot of insertion of vaccine lymph, anything that resembled a tubercle. Nothing of the kind has ever happened, although it is probable that, among so large a number of inoculated persons, some must have received vaccine from tuberculous vacciniferś."

With reference to transmission of diseases of the "charbon" type, Dr. Warlomont states that "it has been completely demonstrated that laudable vaccine vesicles would never develop in animals affected with charbon. These affections are not common in animals sold at markets or elsewhere for purposes of vaccination."

All of these difficulties, if they are worthy the name of difficulties, may be avoided by the method adopted in the best establishments at present, which consists in delivering or using the lymph from any animal for the purpose of vaccination only after such animal has been proven by autopsy to have been absolutely healthy.

Government Production of Vaccine.—The production of vaccine lymph for the use of sanitary authorities in foreign countries is very generally conducted by the governments of these countries, or under their direct supervision.

In Sweden, a central establishment at Stockholm, under the direction of the Council of Health, furnishes vaccine for the whole kingdom. In Germany all the establishments are under the general supervision of the Imperial Board of Health.

In England an establishment is maintained at London under the direction of the medical officer of the Local Government Board. In Italy there is maintained at Rome a national establishment which distributes lymph to any province which desires it. But the provinces may establish their own plants, or obtain supplies from private parties under careful restrictions.

In France vaccine is supplied by private parties, but the work has the strong support of the Academy of Medicine.

In Austria the supply is partly from public and partly from private sources.

The cities of New York and Chicago maintain vaccine plants for the public use of these cities. There can be no reasonable objection to the establishment of such plants either by a country, State, or large city. In fact, the objections which are always liable to arise in consequence of the sharp competition of private producers are thus avoided. There is also the advantage that a State in which no private establishments exist may produce its own vaccine, under its own control, and in such place as may be readily accessible in times of emergency.

The Question of the Degeneration of Vaccine.—The question whether vaccinia, in its transmission from the cow through a series of human beings year after year, loses any of its primary efficiency has been a subject of discussion since the earlier years of the present century.

Jenner did not admit such a possibility, although frequent applications were made to him, within two or three years after his discovery, for lymph "as recent from the cow as possible." A further experience of twenty years satisfied him that the hypothesis of such degeneration was groundless. He was, however, careful to require that the successive transmissions of lymph should be made through healthy subjects. In 1816 he stated that "the matter may undergo a change that may render it unfit for further use by passing even from one individual to another, and this is as likely to happen in the first year of vaccination as in the twentieth." But that with proper care and attention lymph underwent no change he considered to be proven, by the fact that the vesicles he was then producing were "in every respect as perfect and correct in size, shape, color, state of the lymph, period of the appearance and disappearance of the areola, its tint, and, finally, the compact texture of the crust, as they were in the first year of vaccination; and to the best of my knowledge, the matter from which they were derived was that taken from a cow about sixteen years ago."

The argument as thus stated was, that if lymph could undergo eight hundred or nine hundred transmissions through men without giving evidence of change, it should also remain equally unchanged after an indefinite number of such transmissions, and many observers after forty years declared the same opinion.

The National Vaccine Board of England, in their annual report for 1854, declared "that the vaccine lymph does not lose any of its prophylactic power by a continued transit through successive subjects."

Seaton confirms the truth of this statement in his "Handbook," page 203.

In the United States one of the most noted instances of long-continued transmission of humanized lymph is that recorded by Dr. E. M. Snow, superintendent of health of Providence, R. I., and his successors. In a report published by Dr. C. V. Chapin in 1886 he said: "The record of the vaccine now used in the public vaccinations in this city may be traced from arm to arm by name and date continuously back to February 29th, 1868; a date fully two years before the importation of the famous Beaugency stock of animal virus, from which the country has since been so largely supplied." He states, furthermore, that "all the traditions concerning the matter are to the effect that the virus then in use was of the stock sent to this country to Dr. Waterhouse, of Cambridge, by Dr. Jenner in the spring of 1801, with the statement that it was from his original stock."

The theory that vaccine lymph has suffered degeneration by successive transmissions through the human species is chiefly of continental origin. Many French authorities have affirmed this principle as a reason for frequently resorting to the cow for a renewed supply of lymph. Kinglake also, in England, as early as 1814, had advanced the theory of degeneration.

The Royal Academy of Sciences of France in 1838 offered a prize of ten thousand francs for the best essay on this subject, thus indicating the importance which was attached to the problem at that early day. It was not till 1845 that a report was made on the thirty-five essays received. The prize was divided between Bousquet, Fiard, and Steinbrenner, each of whom answered the question affirmatively. The Sanitary Commission of the Grand Duchy of Baden in 1817 reported in favor of a frequent resort to the cow, in consequence of the degeneration of lymph.

THE TECHNIQUE OF BOVINE VACCINATION.—The best animals for use in bovine vaccination are calves and heifers, from the age of one month to two years. Warlomont says "they should weigh at least 100 kgm. (220 lbs.), and be in good health."

The recent German regulations state that calves of "five weeks and upward are to be preferred." (Dr. Voigt, of Hamburg, employs calves from three to four months old.)

Vaillard prefers calves from two and a half to three months old, and gives as a reason the consequent avoiding of tuberculous stock. M. Leclerc, the chief inspector at Lyons, had met but five tuberculous calves out of about four hundred thousand slaughtered animals.

The stock selected for the purpose of vaccine propagation should be in perfect health, and if fatigued by long travel on the railroad, or affected with diarrhœa from improper feeding, they should be allowed to rest for a day or two until they are in good condition, before being submitted to vaccination.

The stable should be well ventilated and kept at a medium temperature. For young animals the feed should be mainly of milk, and for older animals hay and the lighter meals may be used. In Holland, the feed of calves at vaccinating establishments consists of ten litres of milk, and from two to four eggs daily, for each calf.

Older animals are often used for the propagation of lymph with good success, and milch cows have not infrequently been employed for the purpose, such animals yielding an abundant supply of lymph, the process of vaccination apparently having no effect upon the quantity or the quality of the milk. Such animals, however, present the disadvantage of large size and consequent difficulty of management. If a large yield of lymph is not called for they may be vaccinated, and the collection of lymph may be made without laying the animal upon the vaccinating table. Another disadvantage presents itself in the fact that a small percentage of milk-giving cows, and especially of the older animals as found in farms, have usually suffered with cowpox at some period of their lives. It is useless to attempt to vaccinate such animals.

With reference to the effect of vaccination upon the value of the animal, either alive or as slaughtered for beef, the following statement from Dr. Warlomont should be received as authority. "We must, indeed, not forget that, at the latest, the animal should yield all its harvest in the course of the sixth day, and that it may be killed on the seventh, before the possible development of suppurative fever. As a matter of fact, it does not suffer in consequence of vaccination, however numerous the insertions may be. It may suffer from the fatigues and ill-treatment of the journey, from the management of the dealer, from change of stable, or from its separation from the mother, but vaccination of itself is by no means the cause of any depreciation in the animal. This may be laid down as an axiom in the matter of responsibility."

In Berlin such calves after collection of the lymph are sold to the Jewish rabbi to be slaughtered as food. A larger price is paid for them than for ordinary calves, owing to the fact that they are in excellent condition as a result of good feeding while at the vaccine station.[12]

Animals vaccinated upon the abdomen may injure the vesicles by abrasion against the floor, an accident which may be prevented by the use of Tegmin bandages. These have been introduced at some of the German establishments in recent years. Their use, however, does not appear to be universally satisfactory.

The vaccination of animals should be conducted under conditions of scientific cleanliness, such as are presented for example in Dr. Copeman's description of the plant at Cologne. These conditions apply to: 1. The construction and administration of the stabling for the calves. 2. The means for washing or bathing calves before their vaccination. 3. The construction and cleansing of the operating rooms. 4. The cleansing of the vaccinated surface of the calf with germicidal preparations and sterilized cloths before collection of lymph. 5. The use of clean sterilized outer garments by all officials concerned in the processes carried out. 6. The sterilization of all instruments employed. 7. The carrying out of the process of admixture of the lymph material or pulp with glycerin, as also its preparation and storage under conditions of laboratory freedom from extraneous organisms.

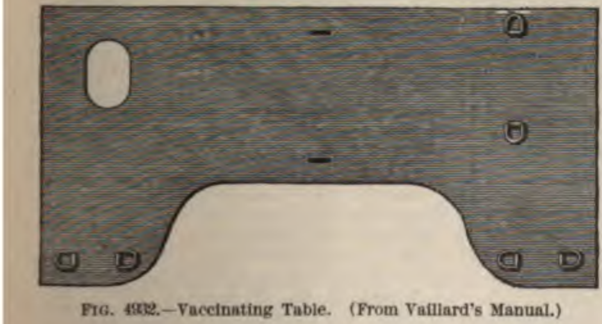

FIG. 4932.—Vaccinating Table. (From Vaillard's Manual.)

Region to be Selected for Inoculation.—Since the days of Negri, who introduced bovine vaccination, most of the continental vaccinators have chosen the inguinal region as the point of election. Lanoix, Depaul, and Ciaudo preferred this region, including a space from 6 to 8 in. (15 to 20 cm.) square. Warlomont defines the region of election as about as large as "the crown of a man's hat," and lying between the inguino-mammary region and the umbilicus.

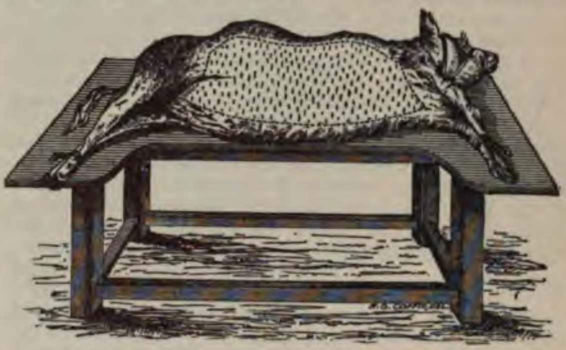

FIG. 4933.—Calf upon the Vaccinating Table. (From Vaillard.)

Chambon and Vaillard define a much larger region for use, namely, the entire surface bounded by the axillary fold in front, the inguino-crural fold behind, an antero-posterior line running near the umbilicus below, and above by a horizontal line connecting the middle of the axillary fold with a corresponding point behind. Upon this broad rectangular surface may be made from one hundred and fifty to two hundred insertions of lymph.

Typical vesicles are often raised upon the escutcheon, or milk mirror, of adult animals, the disadvantage of this region lying in the risk of soiling.

For the fixation of the animal in a convenient position for the requisite operations, a tilting table will be found to be useful for all animals weighing less than 300 lbs. (140 kgm. or less). This table should be constructed of two-inch plank, strongly fastened together and provided with rings for securing the straps or thongs used for fastening the animal; one broad strap will be found useful to encircle the body. The table should be secured to the framework by four strong strap hinges. To place the animal upon it, it should be led alongside the table, secured to it firmly, and then the table should be tilted into a horizontal position and the animal more securely fastened in place. The region for vaccination is thus exposed for the necessary manipulations preliminary to vaccination. To free the animal it is only necessary to tilt the table back to the vertical position, loosening first the fetters and then the large abdominal band or surcingle. An improved table may be made by covering the plank with metal.

Other forms of tables are in use in the German establishments, some of which are made of metallic bars, having a slightly trough-shaped arrangement. In one American establishment a V-shaped trough is used for young calves, the sides being made of thick plates of glass, which may be easily cleansed. The calves are placed in this trough with their legs upward.

The shaving of the animal is a laborious task; it is usually accomplished by the use of the scissors in the first place, although the operation may be facilitated by the use of a clipper such as is used for shearing horses, if it is a good one. The parts should then be lathered with soap and warm water and carefully shaved with a razor, an operation which is by no means easy, especially if the animal be restless.

Insertion of lymph may be made by various methods, by puncture, or by scarification by a sharp lancet, or by slight incisions. In Berlin and several other German establishments long, shallow, parallel incisions are made, into which the lymph is rubbed with a spatula.

Warlomont gives careful details as to the method of securing the animal to the table, for which purpose he employs five assistants, the duties of each being carefully defined.

Two of the forceps in common use are shown in the accompanying cuts. Fig. 4934 is that of Chambon, and Fig. 4935 that of Warlomont.

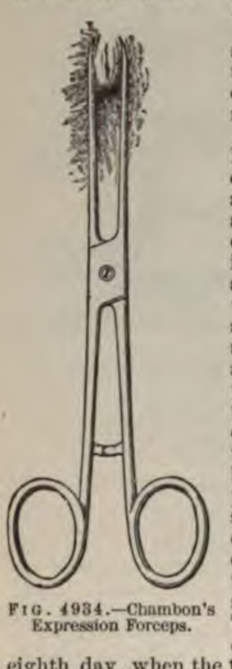

FIG. 4934.—Chambon's Expression Forceps.

A slight pressure only is necessary to hold the vesicle and facilitate the flow of lymph, and it often happens that no forceps are necessary.

The Development of the Vesicle.—If the inoculation is successful, each incision will begin to show a light red border at the end of about forty-eight hours; at the end of another day a slight swelling appears, increasing in size; and by the end of the fifth day a well-formed vesicle will be seen at the seat of each successful insertion. These vesicles are shaped according to the method of insertion. In the case of punctures they are circular, and in the case of incisions they are shaped like the half of an "elongated coffee-berry," having a cicatricial depression, surrounded by a zone of silvery white, and encircled by an outer zone of a reddish hue, the distinctness of color varying with the amount of pigmentation of the skin at the places of insertion. The swelling of the vesicle increases until about the seventh or eighth day, when the transparent zone becomes yellowish in color, and in the following days the vesicle becomes purulent, dries up, and is converted into a brown crust, which falls off from the fourteenth to the twentieth day.

According to Warlomont, if the modes of insertion by incision and by puncture be practised on the same animal, the eruption will be developed twenty-four hours later in the latter, a circumstance which may prove of advantage, by having two stages of development in the same animal, and by the consequent possibility of collecting mature lymph on two successive days if necessary.

The proper time for the collection of lymph is a period of about twenty-four hours in length, and in order to obtain lymph of the best and most efficient quality, the opportune moment for collection should be carefully studied. This moment is not of necessity the time when the most abundant flow takes place, but an earlier period. For greater clearness of expression, it is best to state the period in hours, since the expressions, third, fourth, fifth day, etc., are differently interpreted by different writers.

Negri often made use of the vesicles of three times twenty-four hours. Throughout the continent, it is common to make the collection of lymph either at the termination of three, four, five, or six times twenty-four hours. At Cologne it is the practice to vaccinate on Tuesdays and collect lymph on Fridays. The more common custom in the United States was, previous to 1890, to collect lymph at the end of seven times twenty-four hours, or on the same day of the week with its insertion; or, if the collection required several hours, to complete the operation at that time, after the method employed by Lanoix. In most United States establishments, however, lymph is now collected at an earlier date.

Collection of Vaccine Lymph.—The vesicles propagated upon bovine animals usually require more pressure, in order to obtain a supply of lymph, than is necessary in the collection of humanized virus, especially from the arms of infants, in whom the skin is tender. From these the lymph usually flows readily at the slightest puncture or incision. In bovine animals, however, having a skin of greater thickness, considerable pressure is usually required to cause a free flow of lymph (see further statement in description of the establishment at Cologne).

Delivery of the Lymph.—A careful record is kept at each establishment of the date of sending, quantity, recipient, and other important items. By far the greater quantities were furnished in the months of May and June. The recipients were classified into public vaccinators, private physicians, and military physicians. The former class used by far the greatest quantity of lymph.

Sending and Packing of the Lymph.—The usual mode of sending lymph from the stations in the German cities is by mail in capillary tubes, usually containing about enough for five vaccinations, and in large glass tubes containing fifty or one hundred such portions. These are securely packed in wooden or pasteboard boxes, with directions for use accompanying them.

In most of the cities, test vaccinations were made upon calves for the purpose of proving the efficiency of the lymph before forwarding it. In times of unusual demand, however, this practice was omitted.

The Efficiency of the Vaccinations.—The results are stated with great care, both as to the number of persons vaccinated, and as to the number of insertions or separate scarifications made.

In Leipsic observations were made upon 22,158 primary vaccinations, in which the successful vaccinations amounted to 21,982, or 99.21 per cent.; partially successful, 145, or 0.65 of one per cent.; and unsuccessful, 31, or 0.14 of one per cent. Of the revaccinations, 15,115 out of 16,706, or 90.48 per cent., were successful.

In Hamburg, in a series of ten years the success rate of primary vaccinations was fully 99 per cent.

In the entire German Empire the success rate of primary vaccinations in 1899 was 96.1, or 1,446,914 successful vaccinations out of a total of 1,505,698.

Duration of Efficiency.—Lymph, when carefully preserved at an even and low temperature, retained its efficiency for from two to four months, and even longer.

Lymph used at stations was usually quite fresh, but private physicians often found it efficient at the age of several months. Tests were made at Stettin of lymph, 46, 81, 102, 138, 153, 175, 178, 229, and 249 days old, and in each case it was found to be efficient. The lymph was preserved in glass tubes.

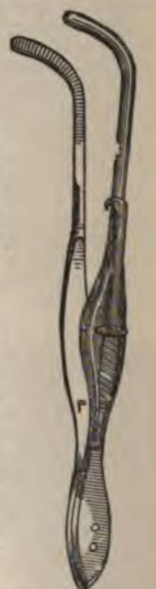

FIG. 4935.—Warlomont's Expression Forceps.

Some lymph was sent to Madras from Berlin, February 17th, 1891, and a calf vaccinated with this lymph on the 17th of March, had one hundred and one good vesicles out of one hundred and twenty-one insertions. This was also successfully transmitted from this calf to others. In some cases lymph sent to places in hot climates proved without effect.

Diseases Following Vaccination.—Vaccine physicians are instructed to make special observations upon this point. Out of the immense number of vaccinated persons in Germany, but very few cases of erysipelatous eruptions, swelling of the axillary glands, and slight skin eruptions of a temporary character were recorded, and no cases of syphilis were mentioned.

Preparation of Lymph.—The following account of the method of preparing vaccine lymph at Berlin is given by Prof. Albert Guttstadt, in an article entitled "Das Impfwesen in Preussen in 1887-88," in the *Zeitschrift des Königl. Preuss. Statistisch. Bureaus*, 1890."

The skin of the calf is first washed with warm soap and water. The incisions then show clearly, and the lymph is taken out with a sharp spoon, shaped like a potato borer.

The lymph was at first mixed with glycerin in a porcelain mortar, but afterward a machine was employed which was designed by the assistant, Dr. H. Döring.

This apparatus, the "Döring lymph mill" (Fig. 4936), is the result of several trials, and consists of an iron frame fastened to an iron plate, supporting four cylinders of porcelain having roughened surfaces. These cylinders are removable, and may be sterilized.

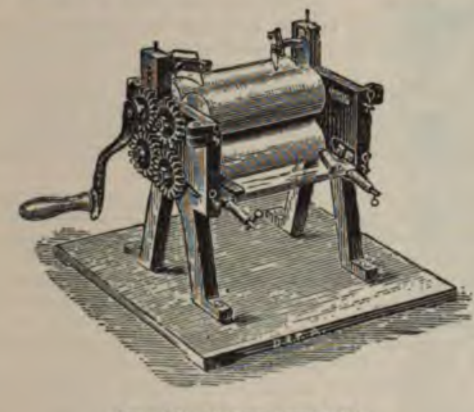

FIG. 4936.—Döring Lymph Mill.

The lymph is first mixed by light stirring with one-third of its weight of glycerin, and is then placed on the line of contact between the cylinders, a little at a time, while an assistant turns the handle. In a few moments the finely mixed lymph mass is scraped off from the last cylinder by the glass shield and caught in the dish below. After the whole mass has passed through the apparatus it is stirred with a glass rod, with the addition of more glycerin, and is passed through the mill again. It is advisable, after emptying the lymph upon the cylinders, to scrape the dish to avoid loss. The lymph is then ready for use. The loss is at the utmost 0.5 per gram. From 20 and 25 gm. of raw lymph may thus be easily prepared for use in thirty-five minutes.

The apparatus, exclusive of the plate on which it stands, is about 20 cm. (8 in.) in each dimension. Accompanying each apparatus are two rectangular dishes and glass scrapers, a spatula to collect lymph, a clamp, screwdriver, and oil can. The apparatus is sold by Julius Schober, Adalbert Street, 39, Berlin.

Another machine employed for the same purpose is that devised by Dr. Chalybäus, of Dresden. It consists of a vertical spindle revolving in a cylinder, the material for trituration being fed through a funnel at the top.

Vaccination in Japan.—Vaccination has made rapid progress in Japan since its introduction there. It appears from the government reports that calf lymph is now very largely used. The vaccine farm was at first under control of the Government, but was finally entrusted to a private association. February 16th, 1888, a commission was appointed to investigate the subject of the preservation of lymph, so that it could be distributed to distant places and still be used with efficiency.

1. *Vaccine Lymph in the Dry Condition.*—(*a*) On ivory points. The points in use in the United States at present are of a pretty uniform size, being about 37 mm. in length, 6 mm. in width, and about ⅛ mm. in thickness. By far the greater number are produced at several establishments in Connecticut, where bone points of the same size and shape are also made for the same purpose, at less cost. Larger and smaller sizes have also had a limited use. One end of the point is usually made square and the other end pointed, and the rounded edges near the point are often bevelled, this device having been adopted for the purpose of allowing the point to be used as a lancet (Fig. 4923).

In order to charge the points, they should be applied to the lymph exuding from the vesicle, first upon one side of the point and then upon the other, until they are quite uniformly coated with the lymph for a distance of from 1 to 2 cm. from the point. In the case of some propagators, it is customary to allow the points to dry, and to recharge them with lymph, either from the same or from another animal. The points should be carefully laid to dry upon the edge of any convenient place, where the charged portion may project in such a manner as to allow of its drying readily. Ivory vaccine points are adapted to use in connection with the method by scarification, rather than by puncture. As ordinarily prepared, the lymph upon ivory points will usually retain its activity, when the points are kept at an even, cool temperature of 40° to 60° F. (4° to 15° C.), for two months or more. They have been known, however, frequently to retain their activity for very much longer periods, ten months or more having been reported. Points are also charged with glycerinated lymph, and are then coated with paraffin, or protected by a shield of glass or other material.

An ingenious device was brought to notice by Dr. F. Kimball, of Andover, Mass., in 1880, for the purpose of facilitating the rapid application of lymph to ivory points when considerable quantities are required at once (see Fig. 4937). It consists of two pieces of pine wood glued together in such a manner as to allow the points to be held firmly in position while the lymph is applied. A thin shaving of uniform width is removed from one of the pieces of wood, not quite as thick as the points. Similar devices are now in use in some of the larger American establishments.

Various methods are employed for packing charged points for transportation. Those methods are best which most efficiently protect the points from the air, from moisture, and from changes of temperature. In the method employed by Dr. Martin the points are first wrapped with clean absorbent cotton, then with thin white paper, and finally are wrapped in an outer coating of thin sheet gutta-percha, which is easily made perfectly tight by a very moderate degree of heat.

(*b*) *Crusts.*—This method of using vaccine material has, fortunately, gone out of use in places where bovine lymph can be obtained, and it should be abandoned altogether, as relating both to bovine and to humanized lymph, since the crust consists of the products of the vaccine vesicle which have passed the period of maturity, when the clear transparent lymph has advanced to the purulent stage and the vesicle has become a pustule.

A few years since, bovine crusts were offered for sale in the shape of masses, or cones, which consisted of powdered crusts, formed into shape by the aid of pressure and other means; examination showed that these masses contained a considerable quantity of foreign material, such as might be expected to be found in the crusts formed upon animals which had not been carefully kept. Serious results following the use of these devices soon put an end to their use.[13]

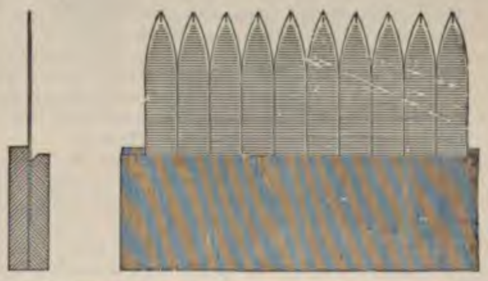

FIG. 4937.—Kimball's Device for the Rapid Collection of Lymph.

It is hardly necessary to allude to the fact that crusts, like other organic material, undergo rapid putrefactive changes in the presence of heat and moisture. Instances are on record of serious injury from so-called vaccinations made by the use of crusts kept dissolved in water for a considerable period.

Other methods employed in the early part of the nineteenth century were the use of bits of thread or silk saturated with vaccine lymph, and these were drawn under the skin and allowed to remain till infection took place.

Bits of goose quill were also sharpened like a pen and then charged with lymph. These were often used for vaccinating by puncture.

(*c*) *Dried Vaccine Lymph in the Form of Powder.*—This method of using vaccine lymph has been employed to some extent, but has not come into general use. M. Ciaudo says he has obtained good results with dried vesicles after from one hundred and ten to one hundred and thirty days. Warlomont experimented with vesicles cut into small fragments and rapidly dried in a drying apparatus. These fragments at the end of two or three days were reduced to a fine powder and preserved in tubes closed only with cotton. When the powder was used in this condition the vaccinations were not very successful; but if the powder was allowed to macerate in glycerin and water for twenty-four hours (thus allowing the vaccine microbes to pass from a latent state to one of active life) and was then used, good results were obtained, even though the powder was more than three months old.

2. *Vaccine Lymph in the Moist Condition—Pulp.*—This method, first introduced by Ciaudo, of Milan, consists in excising the vesicles, freeing them from all detritus, making a homogeneous paste, and adding to each vesicle 0.5 gm. of chemically pure glycerin; this is placed in a small glass vial, and covered with more glycerin to exclude the air.

Vaccine material thus prepared preserves its activity for a long period, and is very efficient. Its effects are, however, occasionally quite irritant. A similar mode is adopted in Holland, the pulp being preserved between glass plates.

In Germany it is customary to employ capillary tubes for single vaccinations, but when large quantities are required, the glycerinated emulsion is put into small vials holding enough for twenty-five to fifty or one hundred vaccinations in each. Glass plates, slightly excavated and fitted with tight covers, are also in use.

Capillary Tubes.—These were first brought to public notice by Dr. Husband, of Edinburgh. Their essential characteristics were stated to be as follows: (1) They should be so slender as to admit of ready sealing in the flame of a lamp; (2) they should be large enough to contain lymph sufficient at least for one vaccination; (3) they should be long enough to admit of sealing without subjecting their contents to the heat of the flame; (4) they should be strong enough to admit of handling without breakage. Dr. Husband advised the following dimensions: Average length, $2\frac{3}{4}$–3 in. (about 7–8 cm.); diameter, $\frac{1}{25}$ in. (about 1 mm.). Another form is made with an enlargement at the centre of the tube. Tubes are sometimes made with closed ends, that the interior may be kept clean until ready for use. When required for use the ends should be broken off, a small rubber bulb applied, and the lymph should be blown out upon a glass plate, from which it may be conveyed with the lancet to the scarifications. Tubes should be used only for the preservation or storage of glycerinated lymph.

Glycerinated Lymph.—As early as 1850 Mr. R. Cheyne[14] had called attention to the superiority of vaccine lymph which has been treated with glycerin. Curschman, however, credits Müller of Berlin with this discovery. Warlomont of Brussels refers to the subject in his "Traité de la Vaccine" and had patented a process of such mixture in 1882.

The German Government also recognizes this process in the regulations issued April 28th, 1887.

Chambon, Menard and Straus,[15] of Paris, also by means of experiment, arrived at similar conclusions. So also did Leoni, Klein, Kitasato, and others.

Dr. Copeman[12] sums up the advantages of glycerinated lymph as follows:

1. By employing the method of glycerination of lymph pulp great increase in quantity can be obtained without any consequent deterioration in quality, the percentage of insertion success following in its use being equal to that obtained with perfectly active fresh lymph.

2. Glycerinated lymph does not dry up rapidly, as does unglycerinated lymph, thus simplifying the process of vaccination.

3. Glycerinated lymph does not coagulate, so that it never becomes necessary to discard a tube on this account.

4. Glycerinated lymph can be produced absolutely free from the various streptococci and staphylococci which are usually to be found in untreated calf lymph, and which are, under certain circumstances, liable to occasion suppuration.

5. In like manner the streptococcus of erysipelas, in the event of its having been orignally present in the lymph material, is rapidly killed out by the germicidal action of the glycerin.

6. The tubercle bacillus is effectually destroyed even when large quantities of virulent cultures have been purposely added to the lymph.

7. The possibility of inoculation of syphilis is eliminated, as the calf is not subject to this disease.

8. The necessity for collecting children together, with the attendant risk of spread of infectious diseases, or of transporting a calf from place to place, is obviated, while the danger of "late" erysipelas in the child is diminished by reason of there being no necessity to open the mature vesicles for the purpose of obtaining lymph.

9. The bacteriological purity and clinical activity of large quantities of lymph can be readily tested prior to distribution.

10. By reason of the possibility of keeping large stocks of glycerinated lymph on hand for considerable periods of time without appreciable deterioration, any sudden demand, such as is likely to arise on the outbreak of epidemic smallpox, can be promptly met.

11. The expense of producing glycerinated lymph is proportionally small, since the amount obtainable from each calf is enormously increased.

With reference to the question of quantity Dr. Copeman further observes: "It is no unusual thing abroad to provide from a single calf an amount of glycerinated lymph that shall serve for four thousand and six thousand vaccinations, and in Berlin we were assured that the glycerinated lymph which was prepared in our presence from one calf, would suffice for no less than fifteen thousand vaccinations" (p. 192).[12]

Upon the subject of the duration of activity of glycerinated lymph Dr. Copeman also states: "Glycerinated calf lymph can be prepared which becomes freed from extraneous organisms, is available for a large number of vaccinations, at least five thousand from an average calf, and retains full activity for eight months, and will, under favorable circumstances, continue to do so in all probability for still longer periods if necessary" (p. 186).

DESCRIPTION OF THE VACCINE ESTABLISHMENT AT COLOGNE.—This new vaccine plant, erected about 1895, was built as a matter of convenience near the new cattle and slaughtering establishment of Cologne.

In building the new establishment the provision of a suitable annex for the production of lymph was borne in mind from the very first; and so the present institution originated, which meets all the demands of hygiene, and may justly be regarded as the prototype of such institutions.

The building is very solidly built, but undercellared only, and to the smallest extent on the eastern side. As, however, the whole of the ground was filled in, and only absolutely dry and permeable material employed, there is no fear of any dampness of the rooms.

On the ground floor of the building are the corridor, collecting-room, calf stable, slaughter-room, doctor's room, office, and a closet.

On the upper floor, which is reached from the collecting-room by a convenient winding staircase, is the laboratory, adjoining which, on both sides, is a large garret. The calves are driven into the station through the doorway of the slaughtering-room, which lies at the opposite end of the building. (See Fig. 4938.)

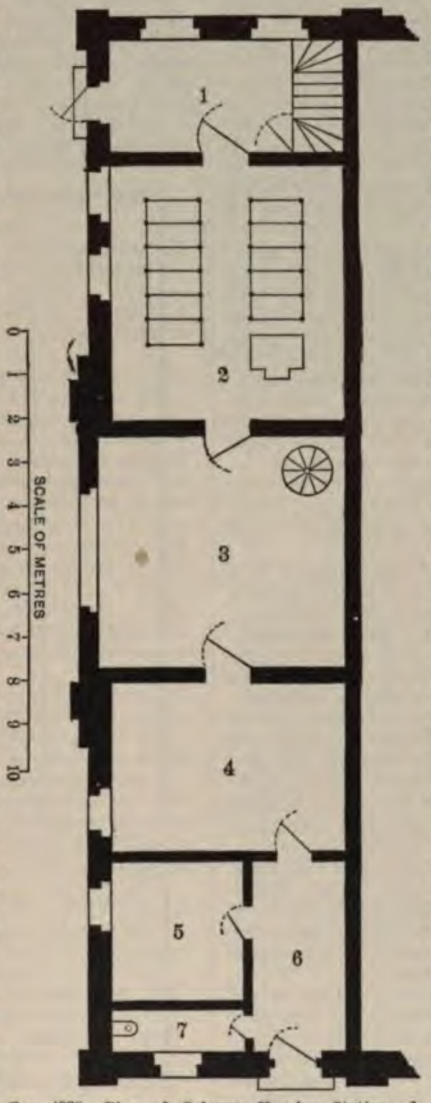

FIG. 4938.—Plan of Cologne Vaccine Station. 1, Slaughtering-room; 2, calf stable; 3, vaccinating-room; 4, medical director's room; 5, clerk's room; 6, entrance hall; 7, closet. (From *Centralblatt für allgemeine Gesundheitspflege.*)

While the floors of the slaughtering-room, calf stable, collecting room, and laboratory are of concrete, the doctor's room and the office have inlaid wooden floors (parquetry); the corridor and closets are laid with "Mettlacher" tiles; and, finally, the rooms in the roof (garrets at the sides of the laboratory) are laid with floor boards. In the calf stable, slaughtering-room, and collecting-room the floor is slightly sloped in one direction, and at the lowest point there is a drainage outlet which is shut off by a small intercepting trap. The collecting-room, calf stable, and closet are lined, to the height of 1.5 metres from the floor, on all four sides, with white opaque glass tiles; the slaughtering-room on three sides (the door side is excluded) to the same height with white glazed tiles. The remaining part of the walls of these rooms is painted with white porcelain enamel. The walls in the doctor's room and the office are papered. In the laboratory and corridor the walls are painted with oil paint. The collecting-room is brightly lighted by a window 4 metres wide by 3 metres high. The light entering becomes strongly reflected by the brilliant white walls. The laboratory has three windows, the calf stable two, and the doctor's room and office one large window each. The closet and slaughtering-room have each one small window. All the rooms are, therefore, amply lighted.

The calf stable contains eleven stalls for the reception of calves. Upon the space which would correspond to the twelfth stall a weigh-bridge is sunk, enclosed with the above-described iron work; this machine allows of the calf being weighed while being taken through. The hollow in which the weigh-bridge stands has also a smell preventing arrangement. The ventilation of the stable is obtained by a large tube which passes through the garret above. The doors, padding, and air draught isolate the collecting-room both from smell and from noise. Between the calf stable and the collecting-room there is an arrangement of double doors, one of which is thickly padded. Water is supplied by the city main, and in every room a sink is provided. The lighting is by electricity; in the laboratory, however, the "Auèrches Glühlicht" (a form of incandescent light) has been found preferable.

The heating is effected by means of American stoves. Large gas stoves serve for the heating of the water and milk. For the storage of considerable quantities of lymph a sufficiently large room is reserved in the refrigerating house of the city cattle establishment.

The laboratory is completely fitted for bacteriological investigations, containing all sterilization apparatus—thermostats, an excellent microtome, microscopes, centrifuge, etc.

The extent of the lymph production may be understood from the following figures: In the year 1894 about 356,000 portions of lymph were issued, and in this year (1895) about 400,000.

Calves.—The calves range usually from about six to eight weeks old. They are purchased in the meat market which immediately adjoins the establishment. The calves required for the current week are bought on Monday, and they are sold on the following Saturday, after their slaughter and the collection of lymph on the previous day; so that the stable is always empty from Saturday to the following Monday. The calves are kept under observation in the stable for twenty-four hours after their reception, and are vaccinated on Tuesday. *Only three complete days* are allowed for the progress of the local results of vaccination. On Friday the animal is slaughtered in a small slaughter-house opening off from the stable, and immediately it is dead the carcass is brought into the collection-room on a trolley, the abdomen washed, and the epithelial pulp of the vaccination area is removed by means of a sharp spoon.

Vaccination of Calves.—The process of vaccinating the calves is carried out in a fashion similar to that employed at the Berlin and Dresden stations, namely, by long parallel incisions over which glycerinated lymph is rubbed by means of a spatula or other flat-bladed instrument. The lymph employed for vaccination of calves is always kept for a period of at last six weeks after glycerination, in order to insure that it shall be as free as possible from extraneous organisms before it is used to vaccinate the calves.

After collection of the lymph pulp, and while it is being prepared for use, the carcass of the calf is taken back to the slaughter-room, where it is skinned and opened. The internal organs are removed and brought in on trays to be examined by the veterinary surgeon. In the event of his forming an opinion that any of the organs presented any condition indicative of disease, the lymph derived from the animal in question would be at once destroyed.

In view of this precautionary measure it is not deemed necessary to test the calves by the injection of tuberculin prior to their vaccination.

Collection and Preparation of Lymph.—The greatest amount of vaccine is collected during the months of March, April, and May, when from six to eight calves are employed every week. For the remainder of the year the weekly vaccination of one or two calves is found to be sufficient to supply all the lymph required for human vaccination and revaccinations in the Cologne district.

In the preparation of lymph material the epithelial pulp from the vaccinated area is removed by scraping with a Volkmann's spoon, and is received in a small glass dish. In this it is weighed, after which it is turned out into a mortar and thoroughly triturated; at first, without any addition of water or glycerin; later, small quantities of water are gradually added to the extent of five times the weight of pulp. The mixture having been ground up still further, double the quantity of glycerin is finally incorporated. Thus, at the time of our visit, 10 gm. of pulp having been collected from one calf, the composition of the finished emulsion was as follows: Pulp, 10 gm.; water, 33.5 gm.; glycerin, 66.5 gm. Dr. Vanselow informed us that this quantity would suffice for the vaccination of five thousand children.

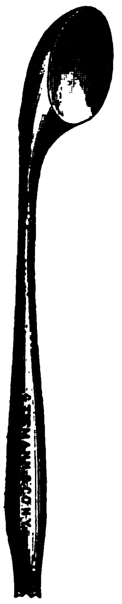

FIG. 4939.—Volkmann's Spoon.

The emulsion is afterward forced into small bottles and tubes by means of a machine actuated by water power. This machine, which is manufactured by a Vienna firm, appears to be decidedly useful and convenient, and is capable of being worked in connection with any form of pressure apparatus.

The small bottles are of different sizes, and contain lymph sufficient for fifty, for one hundred, and for one hundred and fifty vaccinations respectively. The bottles and their corks are all of them sterilized prior to use.

We were struck with the numerous precautions which are taken in this institution to insure thorough asepsis throughout the various stages of lymph production. Thus, in the collecting-room the flooring is of cement concrete, the walls are lined internally for about half their height with opaque glass tiles, the upper half being of Parian cement.

On the first floor of the building is a bacteriological laboratory, which is reached from the collecting-room by an iron spiral staircase. It is fitted up with an autoclave, incubators, etc. But owing to the director being engaged in private practice, he has no time to work in this laboratory, which is, therefore, used only when it is desired to sterilize cloths, instruments, or glassware. With the lymph and pulp material collected and glycerinated in our presence on January 16th, 1897, Dr. Cory vaccinated 34 children on January 19th, with an insertion success of 98.8 per cent., and 21 children on February 11th, with an insertion success of 93.3 per cent. (Copeman's Lectures, pp. 225–228).

Plan of Model Vaccine Establishment.—The following plan of a model vaccine establishment is shown in Delobel and Cozette's "Vaccine et Vaccination," Paris, 1899. The general plan is that of an open court surrounded by apartments, stables, etc., suitable for the purposes of producing vaccine material from animals.

This establishment is about 77 feet wide by 155 in length, and may be made much smaller by the omission of the two large director's rooms (intended in the original plan as a living-room) and the horse stable and carriage-house, as circumstances may require. Rooms 8 and 9 are found to be convenient in those cities where vaccination with fresh lymph is practised at the establishment as one of the functions of such a plant, a practice which was carried out for many years at the government station managed by Dr. Cory in London. (Fig. 4940.)

THE BACTERIOLOGY OF VACCINIA.—As early as 1809 Sacco[16] noticed the presence of granules in vaccine lymph. For a half century no further progress appears to have been made. As late as 1863 Eiselt of Prague described vaccine lymph as a contagious fluid devoid of cells. In 1866 Beale[17] drew attention to particles of germinal or living matter invading the tissues from the blood, which he identified as the virus contagium, or *materies morbi* of contagious diseases, and applied this principle especially to vaccine lymph. Hallier and Zurn,[18] of Jena, claim priority, and described in 1867 an abundance of micrococci as occurring in vaccine lymph. They also indicated the necessity for cultivation experiments to determine whether or no these micrococci stand in a causal relation to vaccinia.

Keber,[19] of Danzig, in 1868 also described micrococci in vaccine lymph. Cohn[20] in 1872 confirmed Keber's observations and distinguished the micrococci from the spores of moulds, and also differentiated them from bacilli. Cohn was not able to establish a difference between vaccine and variolous lymph.

It then became necessary to determine whether this particulate matter was essential to its specific action. Chauveau[21] attacked this question, and showed that the leucocytes in lymph are not essential to its specific action, since, after dilution, the supernatant fluid, free from leucocytes, was found to produce normal vesicles of vaccinia. On the other hand, by a carefully conducted experiment, he proved that if distilled water be cautiously floated on the surface of lymph in a small cylindrical vessel the soluble elements of the plasma will diffuse in the water, but the granular corpuscles remain in the lymph. The upper layers of the liquid, which have imbibed by diffusion the soluble albuminous matter of the lymph, are nevertheless totally inactive and incapable of

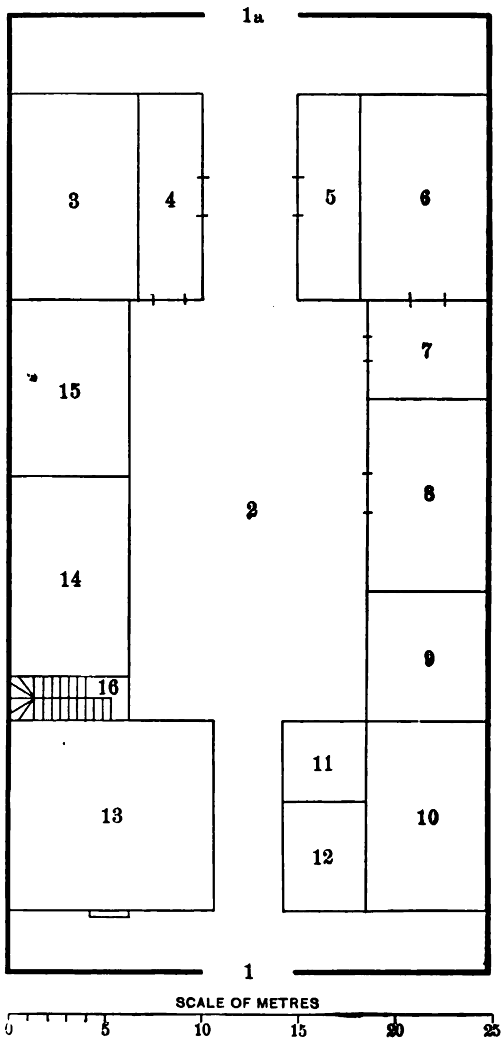

FIG. 4940.—Plan of Proposed Plant for Animal Vaccine Production. 1, 1*a*, Gates, one at each end. 1, Public entrance; 1*a*, entrance for animals; 2, open court; 3, stable for ten animals; 4, room for preparing the calves, shaving, etc., sufficient for one or two animals; 5, vaccinating-room, provided with one or two vaccinating-tables; 6, room for the vaccinated animals; 7, room for collecting the lymph; 8, vaccinating-room, for those who come to the establishment to be vaccinated; 9, waiting room; 10, laboratory; 11, packing-room; 12, clerical room, records and correspondence; 13, director's room; 14, carriage house; 15, horse stable; 16, stairway leading to the granary and room of employees.

producing vaccinia. He therefore concluded that the active principle of the lymph resides, neither in the leucocytes nor in the soluble albuminous material, but in the suspended granular corpuscles of the lymph, that is, that the contagium is particulate. He showed further that lymph can be greatly diluted, and yet retain the contagium unimpaired, provided the greater the dilution the more extensive the absorbing surface. With a lymph diluted with about fifty volumes of neutral fluid a large proportion of vaccinations may fail totally; but in those which "take" the vesicles will not show any sign of attenuation or diminished virulence of the infective matter, but will be as large and as characteristic as those produced by undiluted lymph.

Sanderson[22] in 1870, in his report to the Privy Council, confirmed the experiment of Chauveau.

Copeman[16] has recently performed the experiment of filtering lymph through a Kitasato porcelain filter under pressure. The filtrate was absolutely sterile.

The hypothesis, therefore, that the active principle of vaccine lymph resides in its particulate elements rests on a very high degree of probability.

The flora of the lymph of vaccinia and variola have been thoroughly studied by Crookshank, Copeman, Blaxall, Buist, Fremlin, and others in England, by Cohn, Kleps, Koch, Pfeiffer in Germany, and by many others, and many micro-organisms have been isolated, several of which have been claimed to be specifically pathogenic, but no organism appears to have been discovered which has been proven to be the specific contagium of vaccine lymph. Of the various micro-organisms that have been discovered in lymph by different observers, the three most common are *Staphylococcus albus*, *S. pyogenes aureus*, and *S. cereus flavus*, which probably correspond to Buist's white, orange, and yellow vaccine. According to Copeman, one or another of these is to be found almost universally in every specimen of lymph examined.

Parallel with and in harmony with these investigations are the various experiments which have led to the adoption of glycerin for the purpose of preserving and diluting vaccine lymph, and of rendering it sterile, so far as concerns the presence of aërobic extraneous bacteria.

Cheyne[14] in 1850 and 1853 first demonstrated the fact that the activity of vaccine-lymph could be preserved for at least six months by the use of glycerin, and that its activity appeared to be increased rather than diminished by this means.

Müller,[23] director of the Berlin vaccine institution in 1866, confirmed Cheyne's experiments, and showed that such dilutions could be transmitted to distant countries and tropical climates without impairing their activity.

Copeman[24] again confirmed these experiments in 1891. In 1892 Chambon and Menard[15] found that while fresh glycerinated vaccine pulp gave only moderate results, the same emulsion kept for a fortnight caused a fair eruption, and at the end of forty, fifty, or sixty days produced a crop of typical vesicles.

Copeman found that a sample of glycerinated calf lymph forty-two weeks old gave in Dr. Cory's hands an insertion success, based on fifty insertions, of one hundred per cent.

Farrar[16] therefore concludes that prolonged glycerination secures the gradual extinction of all extraneous saprophytic microbes, that whatever be the nature of the contagium of vaccinia it is not an organism which can be cultivated by aërobic methods in ordinary laboratory media, and that no microbe isolated down to the year 1892 had any claim to be considered specific.

Crookshank[24] indorses this opinion, and says that no evidence is to be obtained by present methods as to the bacterial nature of calf lymph. He therefore suggests that a different line of inquiry may throw more light on the subject.

Other Theories.—Protozoa.—Renaut[25] in 1881 noticed certain highly refractile bodies in vesicles produced by inoculating the corneæ of rabbits and guinea-pigs with vaccine lymph.

Guarnieri[26] in 1892 described these bodies and called them *Cytoryctes vacciniæ vel variolæ*, classified them as Rhizopoda, and claimed for them a specific action in vaccinia and variola. They are capable of reproduction. Monti,[26] of Pavia, identified the same bodies, and drew the same conclusions. Ruffer and Plimmer[27] independently examined the same bodies and established a close correspondence between them. The Pfeiffers,[28] of Jena, and Weimar,[29] Clarke,[30] and others also described these so-called parasites more carefully, confirming Guarnieri's hypothesis. It cannot be denied that by their delicate and careful work, they have made out a strong *prima-facie* case for the protozoon theory, which also derives much support from the analogy of malaria. But the malarial parasite is much more definite in shape and size, its developmental changes follow a regular and well-defined cycle, and the evidence of its being the specific etiological agent of malaria has been well established.

Ferroni and Massari[31] maintained, *per contra*, that bodies indistinguishable from the so-called parasites of Guarnieri could be identified in the epithelial cells after mere mechanical or chemical irritation, and that those bodies are either altered leucocytes or derivatives of the nuclei of the epithelial cells.

Salmon[32] examined these alleged protozoa and pronounced them to be merely chromatic masses derived from the migratory cells.

Attempts to cultivate protozoa have not met with success. Shattock and Ballance[33] in 1895 made many careful attempts at cultivation, but the results of all their experiments were negative. In 1892 a fresh impetus was given to the bacterial hypothesis by Klein,[34] who suggested that a bacterial organism might exist in vaccine and in variolous lymph latent in spore form.

Certain considerations favor this hypothesis: First. The action of glycerin appears to be germicidal only for cocci and sporeless bacilli, and is not inimical to the preservation of the spores.

Second. Lymph when dried after its collection from the vesicle preserves its efficacy for a long time, as well as or better than pure lymph stored in the fluid state. This fact suggests that active vaccine matter exists in the form of spores, since non-spore-bearing bacteria rarely retain their vitality when preserved for a long time in a thoroughly dry state.

Third. Lymph taken from the calf on the fifth, sixth, or seventh day, or from the human arm on the seventh, eighth, or ninth day, that is, when the vesicles are mature, retains its efficacy better than lymph taken at an earlier date, although such earlier lymph used directly from calf to calf or calf to arm is fully efficacious.

These facts are consistent with the existence of spores in the lymph taken at that particular date, and a microbe yielding spores as the last phase of its life history would be present in the earlier stages of vaccinia chiefly as a non-spore-bearing form, and in such form would withstand drying less well.

The earlier, therefore, we obtain lymph from the nascent vesicle the more likely we are to obtain the hypothetical microbe free from spores. By a special technique Klein succeeded in isolating a small bacillus, staining with difficulty, which there is fair ground for presuming to be the pathogenic organism of vaccinia.

Klein's method consists in prolonged staining with alcoholic gentian violet, by which he isolates a bacillus which he describes as occurring in cylindrical rods, fairly uniform in length, single, and occasionally in dumb-bells, 0.4 μ–0.8 μ in length, and one-third of this measurement in thickness. They are generally thicker at the ends than in the middle, and often include a spherical and slightly oval clear globule. They are to be found sparingly in lymph of the fifth or sixth day, more abundantly in that of the fourth day, and almost as a pure culture in lymph of the third day. Preparations of lymph taken from the calf seventy-two hours after vaccination contain bacilli chiefly in groups which look as though they came from an artificial culture. The later the lymph is taken the less numerous are the bacilli found. Klein made many attempts to cultivate this bacillus in artificial media, but all attempts failed. This proves that the bacilli though constant in the lymph do not belong to the saprophytes that are occasionally present in lymph and are easily cultivable. Until this microbe can with certainty be cultivated, it cannot be submitted to the test of Koch's postulates, and its pathogenicity cannot, of course, be conclusively proven. Meanwhile, it would appear that there is a high degree of probability that it will turn out to be the specific agent in variola and vaccinia. This bacillus was also found in clear lymph from the vesicles of confluent smallpox of the fourth day.

Copeman claims to have cultivated the same or a similar bacillus by incubating for a long period—about a month—in eggs, and by inoculation of this upon calves he obtained a strain of lymph which was successfully used in the vaccination of calves and afterward of children.

After Chauveau had demonstrated that subcutaneous injection of vaccine lymph into the tissues is protective against subsequent vaccination (vaccinia sine exanthemate) Beclere, Chambon, and Menard[35] in 1896 proved that the serum of calves rendered immune by vaccination, and withdrawn several days or weeks after desiccation of the pustules, and inoculated into other calves in sufficient quantities (say 1,500 c.c.), renders these calves, if not absolutely, at any rate relatively, immune in a high degree to vaccination with lymph of proved potency.

Finally, Dr. Farrar concludes that the pathogenic identity of vaccinia and variola has been proved by the experiments of several workers. Klein's work on this subject is convincing. He showed that lymph originally derived from the vesicles of human variola and transmitted through calves would produce typical vaccine vesicles in calves and typical vaccinia in the human subject, the result being constant through several removes, and the calves so treated being insusceptible to vaccination with current calf lymph.

In the discussion which followed the reading of Dr. Farrar's paper Tavel,[16] of Berne, expressed the opinion that of all organisms hitherto found Guarnieri's *cytoryctes* would most probably be shown to be the specific etiological agent in vaccinia. He believed that the alleged discovery of a *sporidium vaccinale* by Funck, and the finding of certain protozoa by other experimenters were due to erroneous methods.

A new stimulus was given to the study of this most interesting question by the offer of a prize of £1,000 by the Worshipful Company of Grocers of London, in 1883. The problem being stated as follows: "To discover a method by which the vaccine contagion may be cultivated apart from the animal body in some medium or media not otherwise zymotic; the method to be such that the contagion may, by means of it, be multiplied to an indefinite extent in successive generations, and that the product, after any number of such generations, shall (so far as can within the time be tested) prove itself of identical potency with standard vaccine lymph."

The great importance of such an inquiry can scarcely be overestimated, since certain great advantages would thus be secured. On the one hand, the ability to produce unlimited quantities of vaccine material for immediate use in the face of an epidemic of smallpox, and, on the other hand, the ability to overcome the objections urged against animal virus of either sort, humanized or nonhumanized, namely, the possibility of transmission of disease, however slight the foundation of such objections might be.

Experiments were conducted in this direction by Quist of Finland, by Dougall, and by S. C. Martin of Boston, but no practical conclusions appear to have been reached.

In harmony with this line of investigation are the investigations of Drs. Councilman, Magrath, Brinckerhoff, and Tyzzer. At a meeting of the Boston Society of Medical Sciences April 28th, 1903, Dr. Councilman announced the discovery of the etiology of smallpox, and at the same time gave his opinion as to the identity of the disease with vaccinia.

He stated that smallpox passes though certain perfectly definite stages in its development on the clinical side, to which correspond equally definite changes in the form of the causative organism; that these changes in form consist first in the appearance in the cell protoplasm of small, homogeneously staining, structureless bodies, about 1 μ in diameter, not staining so deeply as nuclei, which gradually increase in size, coincidently with the degeneration of the cells in which they lie; that with this increase in size the character of these bodies changes, small granules surrounded by circles appear in them, the general outline becomes irregular, with increasing resemblance to an amœba; that a process resembling sporulation takes place with the breaking up of the amœboid forms into smaller, sporelike bodies; and that this constitutes the first cycle in the life of the organism. Up to this period the nuclei of the epithelial cells show no changes whatever, but the following alterations in these structures now appear: penetration of nuclei by the small sporelike bodies before spoken of, with the disappearance of such bodies from the cell protoplasm; small ring-shaped bodies become apparent in the nuclei; they also increase in size; the ring shape is at first preserved, which is soon surrounded by a spongelike body. This whole structure grows, fills, and finally destroys the nuclei, and the bodies become free; the bodies again become more homogeneous; ring-shaped bodies again become evident; finally each ring appears to have a central dot. These final bodies are regarded as the infecting agent of the disease. Two cycles of the organism, corresponding in general to what we know of the protozoa, have therefore been demonstrated: the first—extranuclear—simple, and the second—intranuclear—very probably sexual.

It also appears to be demonstrated by this work that vaccinia represents the extranuclear phase of the organism, but that the production of true smallpox is dependent upon the invasion of the nuclei—the intranuclear cycle. Vaccinia may be produced by inoculation, for example, in the calf or the rabbit; variola under similar conditions is produced in the monkey. This, also, Dr. Councilman and his colleagues have shown. The organism was found in the blood in one case. The difficulties of study are very greatly increased by the extreme rapidity with which the entire process takes place and by the ease with which the organisms are destroyed; the life history is completed with the formation of the vesicle, hence the absolute necessity of securing early and perfectly fresh material. The rôle of bacteria is regarded as entirely subordinate to that of the organism described, though the influence, particularly of streptococci, must be taken into consideration in the development of the disease.

Dr. Councilman expressed the opinion with confidence that the organism which he described as belonging to the protozoa was the essential etiological factor in the production of smallpox.

Proposed Investigations Relative to Vaccination.—The offer of a prize by the Grocers' Guild of London amounting to £1,000 has already been referred to, the object of this prize being to stimulate investigation in the direction of some possible medium of vaccine culture outside the living organism, either of man or of the lower animals.

A new line of investigation is also suggested by the Report of the German Board of Health of 1900, in which it is stated by the vaccine authorities of Hamburg, that they have reason to believe from the experience which they have had in the culture of vaccine lymph that it is possible to secure a much longer period of immunity from smallpox than has hitherto been possible by the employment of any vaccine lymph in ordinary use. They had arrived at this conclusion in consequence of certain observations relative to the percentage of failures in the revaccination of school-children in that city. It was observed that, for some reason, in 1894 the percentage of successful vaccinations among the revaccinated children in Hamburg suddenly fell off from an average of about 85 per cent. in the nine years 1885–93 to an average of only 67 per cent. in the six following years, 1894–99. That this decline in the percentage of successful revaccinations was not due to any deterioration of the lymph in use appears to have been proven by the fact that the high percentage of success among primary vaccinations conducted with the same lymph (an average of fully 98.5 to 99.5 per cent.) continued throughout the entire period. The only explanation offered for this fact was that in consequence of employing a lymph of unusual strength in the earlier primary vaccinations, these children were rendered immune for a longer period than they would have been had ordinary lymph been employed, so that when they arrived at the legal age for revaccination the percentage of successful results was greatly diminished.[8]

This fact opens up a very interesting field of investigation with the view of strengthening the quality of vaccine lymph to such a degree as to prolong its immunizing power.

The following figures illustrate this singular fact in the experience of the Hamburg vaccine district:

RESULTS OF VACCINATION AND REVACCINATION IN HAMBURG DURING THE YEARS 1885–1901.—PERCENTAGE OF SUCCESSFUL RESULTS.

Years.	Primary vaccinations.	Revaccinations.	Years.	Primary vaccinations.	Revaccinations.
1885........	99.8	85.8	1894.........	98.8	69.3
1886........	95.4	78.9	1895.........	99.7	66.5
1887........	98.9	80.2	1896.........	99.3	59.7
1888........	99.8	83.4	1897.........	99.4	66.8
1889........	99.8	87.7	1898.........	99.5	69.6
1890........	99.7	90.1	1899.........	97.7	69.5
1891........	99.4	89.3	1900.........	99.4	74.8
1892........	99.0	87.3	1901.	99.7	93.6
1893........	99.6	82.9			

LAWS OF DIFFERENT COUNTRIES RELATIVE TO VACCINATION.—Herewith are presented the essential features of the vaccination laws of different countries in which vaccination has been introduced.

England.—The following are the essential provisions of the vaccination act of England as amended by further acts of 1871, 1874, and 1898:

(I) 1. The period within which the parent or other person having the custody of a child shall cause the child to be vaccinated shall be six months from the birth of the child, instead of the period of three months mentioned in § 16 of the vaccination act of 1867, and so much of that section as requires the child to be taken to a public vaccinator to be vaccinated shall be repealed.

2. The public vaccinator of the district shall, if the parent or other person having the custody of the child so requires, visit the home of the child for the purpose of vaccinating the child.

3. If a child is not vaccinated within four months after its birth, the public vaccinator of the district, after at least twenty-four hours' notice to the parent, shall visit the home of the child, and shall offer to vaccinate the child with glycerinated calf lymph, or such other lymph as may be issued by the local government board.

4. The public vaccinator shall not vaccinate a child if, in his opinion, the condition of the house in which it resides is such, or there is or has been such a recent prevalence of infectious disease in the district, that it cannot be safely vaccinated, and in that case shall give a certificate (under § 18 of the vaccination act of 1867) of postponement of vaccination, and shall forthwith give notice of any such certificate to the medical officer of health for the district.

5. Notwithstanding any regulation of any lying-in-hospital or infirmary, or other similar institution, the parent of any child born in any institution shall not be compelled under such regulation or otherwise to cause or permit the child to be vaccinated at any time earlier than the expiration of six months from its birth.

(II) 1. No parent or other person shall be liable to any penalty under § 29 or § 31 of the vaccination act of 1867, if within four months from the birth of the child he *satisfies two justices*, or a stipendiary, or metropolitan police magistrate, in petty sessions, *that he conscientiously believes that vaccination would be prejudicial to the child*, and within seven days thereafter delivers to the vaccination officer for the district a certificate by such justices or magistrate, of such conscientious objection.

2. This section shall come into operation on the passing of this act, but in its application to a child born before the passing of this act there shall be substituted for the period of four months from the birth of the child the period of four months from the passing of this act.

3. An order under § 31 of the vaccination act of 1867, directing that a child be vaccinated, shall not be made on any person who has previously been convicted of non-compliance with a similar order relating to the same child.

4. No proceedings under § 31 of the vaccination act of 1867 shall be taken against any parent or person who has been convicted under § 29 of the said act on account of the same child, until it has reached the age of four years.

5. Persons committed to prison on account of non-compliance with any order or non-payment of fines or costs under the vaccination acts shall be treated in the same way as first-class misdemeanants.

Italy.—Italy supports fourteen vaccine establishments, at Bologna, Milan, Genoa, Ancona, Venice (two), Bergamo, Arezzo, Verona, Vicenza, Rome, Modena, Ravenna, and Rimini.

A law of January 1st, 1892, provides for the production and preservation of vaccine lymph.

All children must now be vaccinated within the half-year succeeding their birth. Certain exemptions are specified—children who have had smallpox, etc.

Persons who have not been revaccinated since they were eight years old are excluded from schools and workshops until they are revaccinated.

Norway.—In Norway, vaccination was made obligatory by law in 1811.

In *Austria*, *Roumania*, *Turkey*, and in *Greece* the Government assumes the right to vaccinate all the unvaccinated, and in some of these countries to revaccinate all who have not been vaccinated within seven years. Vaccination is not compulsory in *Belgium* and in *Spain*.

In Vienna, Dr. Weyl attributes the low mortality from smallpox in the last years of the century to the introduction of the vaccination of school-children, to the active efforts of officials to arouse an interest in public vaccination, to the introduction of animal vaccine lymph, and to the establishment of a state institution for this purpose. ("Die Assanierung von Wien," 1902, p. 173.)

France.—After a century of failures to enact a compulsory vaccination law France has finally fallen into line by the enactment of a law which became operative in February, 1903. This act constitutes a portion of the new "law for the protection of the public health" of February 19th, 1902. It provides: (§ 6) that vaccination shall be obligatory during the first year of life, and also that revaccination shall be performed during the eleventh and twenty-first years. Parents and guardians are made responsible for the execution of this measure. A public regulation made after consultation with the Academy of Medicine and the Consulting Committee of Public Health will establish the necessary measures for carrying out the provisions of this act. By Article 23 the prefect of police is charged with the duty of enforcing the provisions of the act so far as penalties are concerned.[36]

Vaccination of all new recruits in the French army is obligatory, and to this regulation is undoubtedly due the comparative immunity of the army from smallpox as compared with the people at large.

Holland.—In Holland vaccination is not compulsory, and for many years it was the custom to delay vaccination until the child was more than two years of age.

There are at present four vaccine establishments, at Rotterdam, Amsterdam, The Hague, and Utrecht, and three temporary establishments at other places. Bovine lymph is mainly used at these.

Germany.—In Germany every child must be vaccinated in the year following the year of its birth. All scholars in public and private schools must be revaccinated in the twelfth year, if they have not already had the smallpox. When the vaccination and revaccination are not successful, they should be repeated in the two following years.

Only attested physicians may vaccinate. The special control of vaccination is left to the separate States. The public vaccinations are free to all. The cost is paid from the public treasury. Humanized lymph, retrovaccine lymph, and animal lymph may be employed indifferently. Humanized lymph is now scarcely ever used.

Dr. Wernher makes the just comment upon the age limit for vaccination that it is delayed too long for children, since children born in January may become twenty months old before their vaccination is obligatory.

Denmark.—Vaccination was established by law both in Denmark and in the Faroë Islands, at the beginning of the present century. By the laws of Denmark no child can be admitted to school, or present itself for confirmation, until a certificate of vaccination is produced. Revaccination is also enjoined for soldiers, and seamen in the navy.

In *Iceland*, which was subject to devastating epidemics of smallpox in the eighteenth century, one country physician and eight district physicians are appointed for the control of vaccination, and every clergyman, after having received the necessary instruction of these physicians, shall be the vaccinator *ex officio* of his parish and keep a register of those who are vaccinated. The district physicians provide a supply of vaccine virus from Copenhagen.

Sweden.—The law in Sweden prescribes, as a general rule, that children shall be vaccinated before the age of two years, and in case of epidemic smallpox vaccination is recommended in the first months of life. Revaccination is generally *recommended* at the age of fifteen years, and is *prescribed* for recruits in the army and navy.

Japan.—Vaccination was introduced into Japan in 1849 by Dr. Monnik, a Dutch physician at Nagasaki, and vaccinating offices were afterward opened; but the results were not at first satisfactory, in consequence of the want of a regular supply of good lymph and its deterioration, or on account of the imperfect performance of the operation. In June, 1874, a central office was opened for the purpose of collecting vaccine lymph from calves and distributing the same to the local authorities throughout the empire in the spring and autumn, and wherever smallpox should be prevalent.

In December of the same year (1874), vaccination was made compulsory, and regulations were issued for its performance and for the collecting of statistics relative to vaccination and revaccination.

Prof. E. S. Morse, who has been a keen observer of all matters of public interest in Japan, says: "It is gratifying to know that smallpox, which was formerly endemic, is now coming under control by the Government taking active measures to insure vaccination. The frightful scourges of smallpox in past times are seen in the sadly scarred faces of many of the people, and in the number of blind persons one encounters."

United States.—The following résumé contains the essential points of the vaccination laws of the principal States of the Union.

The following order of the Secretary of the Treasury relates to the vaccination of immigrants:

"Steerage passengers and crew, coming from districts where smallpox prevails in epidemic form, or who have been exposed to smallpox, shall be vaccinated before embarkation, unless they show evidence of immunity to smallpox by previous attack or recent successful vaccination."

In Alabama the county health officer is required from time to time to obtain necessary supplies of reliable vaccine matter which, without charge, he must, on application, furnish to the practising physicians of the county; and when prepared, vaccinate without charge all indigent persons of the county applying at his office.

Arkansas has no State law as to vaccination.

In California the law forbids the attendance of unvaccinated children at school, and it is provided that "any practising physicians may certify that the child or person has used due diligence and cannot be vaccinated so as to produce a successful vaccination, whereupon such child or person shall be exempted from the operation of the act" (Law of 1889).

In Colorado the local sanitary authority may provide for vaccination during the prevalence of smallpox, and even then only as an alternative to isolation.

In Connecticut the town boards of health may adopt such measures for the vaccination of the inhabitants of their respective towns as they deem necessary. Every person who refuses to be vaccinated, or prevents any one under his control from being vaccinated, on application of a member of a board of health, or of a physician employed by the board for such purpose (unless in the opinion of another physician it would not be prudent on account of illness), shall forfeit five dollars to the town.

The Board of School Visitors of any town has authority to require every child to be vaccinated before such child is permitted to attend a public school. The expense of vaccination is to be paid from the town treasury, when necessary.

In Delaware the school authorities are required to enforce the vaccination of all school-children, unless they are previously protected either by vaccination or by smallpox. A copy of the law must be posted for two weeks at the door of every school-house.

Florida.—By a law of 1889 the State Board of Health was authorized to make regulations. They made it the duty (by § 11 of the Sanitary Code) of city and town authorities to "provide for the vaccination and revaccination of the citizens residing in their several cities and towns." Every parent or guardian of a child is made responsible for its vaccination; exceptions were made in the case of sparsely settled districts when not threatened with smallpox, and in the case of a certificate from a reputable physician that vaccination would be "dangerous to the health of the person required to be vaccinated."

By §§ 12 and 13 superintendents of schools in towns having more than two thousand people, and owners or managers of factories are not to admit unvaccinated persons.

Illinois has no state law relative to vaccination. The State Board of Health has issued an order excluding unvaccinated children from the public schools and defines what it deems to be a "proper and successful vaccination."

Indiana has no state law as to vaccination. The State Board of Health has issued certain rules especially applicable to epidemic seasons. It has also ordered that bovine virus should be used for vaccination, with certain exceptions.

In Iowa the attendance of unvaccinated children at school is forbidden.

In Kansas there is no state law as to vaccination.

In Kentucky the law requires that all unvaccinated persons over twenty-one years of age shall procure their own vaccination. Parents and guardians must have their children and wards vaccinated within twelve months after their birth. The secretary of the State Board of Health is required to furnish vaccine virus to local boards of health for the gratuitous vaccination of the poor.

Louisiana has no state law as to vaccination. A city ordinance relative to school attendance is enforced in New Orleans.

In Maine the city or town authorities are required annually, or oftener if they deem it prudent, to provide for "free vaccination with the cowpox" of all inhabitants over two years of age, to be done under the care of skilled practising physicians, under such circumstances and restrictions as the authorities may adopt. School committees may, if they deem it expedient, exclude unvaccinated children from the public schools.

A law was enacted in Maine in 1889 providing for the exclusion of all unvaccinated persons from paper mills, where domestic or foreign rags are used, under penalty of fifty dollars or less.

In Maryland, a state vaccine agency is established which is required to keep a supply of fresh vaccine virus for the use of physicians. The governor is required to appoint a vaccine agent with prescribed powers and duties. Physicians are authorized to vaccinate children born in their practice. A penalty is provided for the use of virus of bad quality. Parents are charged with the duty of having their children vaccinated within twelve months after their birth. Unvaccinated children are not to be admitted to the public schools. Small fruit-growers, canners, truck farmers, and fish-packers must not employ persons who do not show written proof of vaccination of more recent date than July, 1898. Penalty, $50 to $500 (order of State Board of Health of March 6th, 1899).

In Massachusetts the law provides that parents and guardians shall cause their children and wards to be vaccinated before they attain the age of two years, and revaccinated whenever the town authorities shall, after five years from the last vaccination, require it. The town authorities shall also require and enforce the vaccination and revaccination of all inhabitants when the public health requires it. The penalty for neglecting to comply with these provisions is $5. Towns shall furnish means for vaccination to those who cannot pay for it. Incorporated manufacturing companies and superintendents of public institutions are required to see that the inmates of such institutions are vaccinated. Towns may make further provisions for vaccination, under the direction of the Board of Health, or of a committee chosen for the purpose. School committees are required to exclude unvaccinated children from the public schools, except "any child who presents a certificate signed by a registered physician designated by the parent or guardian, that the physician has at the time of giving the certificate personally examined the child, and that he is of the opinion that the physical condition of the child is such that his health will be endangered by vaccination, shall not, while such condition continues, be subject to the provisions of" the vaccination acts (chap. 190, Mass. Acts of 1902).

In Michigan townships may make suitable provision for the "inoculation of the inhabitants with the cowpox," under the direction of the Board of Health, or of the health officer. The Board of Health of each municipality may at any time direct its health officer or physician to offer vaccination with bovine vaccine virus to every child not previously vaccinated, and to all other persons not vaccinated within the preceding five years. Any health officer is also authorized to order the prompt vaccination or isolation of persons who have been exposed to smallpox.

In Minnesota parents and guardians are charged with the duty of having minors vaccinated.

Missouri has no state law as to vaccination.

In New Hampshire the law is permissive as to the appointment of agents for the vaccination of towns. Unvaccinated children are excluded from the schools.

In New Jersey the school authorities may prohibit the attendance of unvaccinated children who have not had the smallpox, and may decide whether revaccination shall be required when smallpox occurs in any city or district. In the enrollment of children by the school authorities, inquiry must be made as to the fact of vaccination, and if the parents desire, children are to be vaccinated by a regularly licensed physician. The State Board of Health may prohibit the manufacture and sale of impure vaccine virus, antitoxin, or other animal product (Law of 1895).

In New York it is the duty of local boards of health to provide at stated intervals supplies of vaccine virus, of a quality and from a source approved by the State Board of Health. During an epidemic, local boards of health are to obtain fresh supplies of virus, at intervals not exceeding one week, and at all times to provide thorough and safe vaccination for all persons who may need it.

In North Carolina cities, towns, and counties may make rules requiring vaccination (Law of 1893).

In Ohio local boards of health may take measures, supply agents, and afford inducements and facilities for gratuitous vaccination. They may also make and enforce such rules and regulations to secure the vaccination of school-children as in their opinion the safety and interests of the people require.

In Pennsylvania by a law of 1895 the Bureau of Health may issue an order requiring all persons in a city, or any part thereof, to be vaccinated within such time as the Bureau shall prescribe. Penalty, $5 to $20.

Unvaccinated children may be refused admission to school.

In Rhode Island the town councils shall provide annually for the gratuitous vaccination of the inhabitants. They shall also contract with and provide physicians to vaccinate. Such physicians are to record the names and ages of persons vaccinated. Unvaccinated children are excluded from the public schools. The maximum fine for violation of the law is $50, or imprisonment for thirty days.

In South Carolina the State Board of Health may order vaccination (Chap. 77, Laws of 1899).

In Tennessee the State Board of Health has power to prescribe rules to prevent the introduction of epidemic diseases.

In Vermont, by a law of 1892, the local board of health must provide, whenever it is deemed necessary by the State Board of Health, a suitable supply of vaccine virus of a quality and from a source approved by said State Board of Health; and during the existence of an actual outbreak of smallpox in any town or city, the local board of health shall at all times provide thorough and safe vaccination for all persons within its jurisdiction who may need the same.

In Virginia unvaccinated children are excluded from the public schools. The governor is required to appoint an agent annually, who must furnish, by mail or otherwise, to every citizen of the State who applies for it, genuine vaccine virus, free of charge, with directions how to use it. The agent must advertise that he is ready to furnish such virus. The town and city authorities may cause the inhabitants to be vaccinated, and may enforce obedience by fixing fines and penalties for violation.

West Virginia also had a statute requiring the appointment of a vaccine agent, but this has recently been repealed.

In Wisconsin the following remarkable decision of the courts is published:

"Compulsory vaccination as a condition precedent to school attendance cannot be sustained as an exercise of police powers by the Board of Health in the absence of a statutory provision requiring it.

"If the Board of Health possessed the power to make a rule excluding children from the public schools without a certificate of vaccination, it is void as unreasonable when no epidemic, and but a few scattered cases of smallpox exist in the State where the rule is adopted, and but one case in the city where adopted, and that quarantined" (Adams v. Burdge, 95, 390, Wisconsin).

ANTIVACCINATION. — Vaccination, like almost every important discovery which has ever been made, has had its opponents from the very outset.

The literature of antivaccination is quite considerable, and consists of many pamphlets in English, the principal writers being Messrs. Gibbs, Tebb, Taylor, Young, Wilkinson, and Prof. A. R. Wallace. Several journals devoted to the same cause are published in English, the *Vaccination Inquirer* being the organ of the first-named society.

There are also many continental pamphlets upon the same subject, chiefly in French, German, and Swedish.

The most decided resistance to the vaccination acts in England has been for several years in the county of Leicester, where the number of unvaccinated children has increased during the past few years, until, in the returns for 1896, it appears that the neglect of vaccination amounted to 79 per cent. of the births, and in the city it amounted to 82.1 per cent.

The following figures show the increasing neglect in regard to vaccination, both in London and in the whole country:

PROPORTION NOT FINALLY ACCOUNTED FOR IN REGARD TO VACCINATION.

Year.	London.	Rest of England.	Year.	London.	Rest of England.
1887........	9.0	6.7	1894.........	20.6	19.0
1888........	10.3	8.2	1895.........	24.9	19.8
1889........	11.6	9.6	1896.........	28.4	22.3
1890........	13.9	10.9	1897.........	29.1	21.6
1891........	16.4	12.9	1898.........	33.0	19.6
1892........	18.4	14.3	1899.........	27.7	15.4
1893........	18.2	15.7			

Dr. Arnould, in his treatise on "Public Hygiene," recognizing the fact that an unvaccinated person is a constant menace to the public safety, reasonably inquires whether the *liberty* of those who do not wish to have the smallpox is not as worthy of respect as the *liberty* of those who do not desire to be vaccinated.

In France, the opponents of compulsory vaccination succeeded in preventing the enactment of the bill proposed by Dr. Liouville, in 1881; and in Switzerland a similar organized opposition secured the repeal of compulsory acts in 1882, the effect of which action very soon became evident in a decided increase of smallpox in that country.

The opposition to vaccination is based mainly upon the following objections:

1. Alleged infringement of personal liberty. Upon this subject, Dr. J. M. Toner, of Washington, makes the following excellent comments:

"The question of the prophylactic power and safety of vaccination is so well settled that the individual who fails to protect himself against variola by it should be looked upon by the community with aversion, and treated as a nuisance (as he really is, so far as the social interests are concerned), and be compelled to submit to vaccination for his own safety and the protection of the public.

"Parents and guardians have no more right to withhold or neglect to provide vaccination for the children under their protection than they have to jeopardize the lives of their helpless infants by not furnishing them with food or clothing. It is criminal to neglect either, as death may be the consequence; but the failure to provide protection against smallpox seems to be more maliciously wicked than to neglect either food or clothing, as the former may not only cause the death of the child, but may be the means of spreading disease and death among many others; while the evil which arises from the latter ceases with the death of the victim."

2. As to the claim that vaccination does not protect from smallpox.

The amount of protection afforded by the process of vaccination, when properly performed, has been quite fully discussed in the earlier portion of this article. At the present day, but very few authorities claim that the protection afforded by a single vaccination is absolute. Not even smallpox itself is protective in all cases against a second attack. The amount of protection afforded is quite well shown by the statistics of epidemics. Dr. Buchanan, medical officer of the Local Government Board of England, showed that the smallpox death rate among adult persons vaccinated was 90 to the million; among the unvaccinated it was 3,350 per million. Among vaccinated children under five years age it was 40.5 per million; among unvaccinated children of the same age it was 5,950 per million.

3. As to the claim that vaccination introduces other diseases besides vaccinia. As has already been stated, the fact that such cases have occurred is not denied. It is also true that cases of such injury are exceedingly rare. So far as the introduction of diseases of human origin is concerned, this objection is entirely overcome by the employment of bovine virus; and with reference to the possibility of introducing any of the diseases common to the cow and to man, the question has been sufficiently answered by the quotations already given.

With reference to the various incidents which occasionally follow vaccination, very much has been attributed to the operation which does not belong to it, on the entirely erroneous principle of *post hoc, ergo propter hoc.* The mortality from all causes among children is large, and in a large number of annual vaccinations, as for example, among the two millions or more of the German Government, it is not remarkable that a considerable number of deaths should occur within a short period of vaccination, and cases of harm are attributed to the operation which actually have no connection with it, in the line of cause and effect.

4. A singular argument often urged by the opponents of vaccination is, that smallpox is not caused by contagion, but by filth, and hence its proper preventive treatment should be accomplished simply by sanitary measures, without vaccination. Undoubtedly, filth and bad hygienic conditions promote the spread of smallpox, but that they directly cause the disease in the absence of a previous case of smallpox has never been proven. On the other hand, the disease has been shown to be contagious and inoculable in the highest degree.

With reference to the theory of the origin of smallpox from filth, Dr. Carpenter says: "As regards smallpox, there is not any difference of opinion on this point. It certainly requires the introduction from without of some form of particulate contagion (a germ or living organism), however much meteorological states and personal diet may promote its growth; and if the contagion be absent, smallpox cannot arise."

5. Displacement of mortality (Carnot's doctrine). This theory was proposed by M. Carnot, a French artillery officer. He alleged that, while certain diseases, such as smallpox, measles, convulsions, and croup, were decreasing, other diseases, such as cholera, typhoid fever, and dysentery, were increasing; that the births were tending to become less in number than the deaths; that the depopulation of France was an imminent danger; and that vaccination was the cause of all this disturbance. Mr. Simon comments upon this remarkable theory as follows: "Supposing Carnot's statistics to be correct, does he give any sufficient reason for ascribing to vaccination that deteriorated state of adult life which he professes to have discovered? So little does he this, that in any of the sentences where damnatory conclusions are drawn, if there were substituted at hazard for his word *vaccination*, the mention of any other historical event belonging to about the same period of time as Jenner's discovery, M. Carnot's logic would scarcely suffer by the change, or his new conclusion be less warrantable than his first. *Post ergo propter* was never more whimsically illustrated. For the argument goes simply to claim as the *effect* of vaccination whatever evils have occurred since its discovery; and M. Carnot's moderation may be praised, that, with the infinite resources of this proof, he did not also convict Jenner of causing last year's inundation of the Rhone."

M. Charles Dupin, in 1848, and Dr. Bertillon, in 1854, also exposed the fallacy of Carnot's proposition. It was shown that, whether his arithmetic were right or wrong, his medical conclusions were wholly untenable. His evidence was purely local and applied to France, in which there were, it is true, certain facts of an unfavorable character relative to the growth or movement of the population; and yet these same observations were not applicable to England, nor to Sweden, nor to Russia, nor to any other countries in which vaccination was practised as well as in France.

Has Vaccination Increased the Liability to Other Diseases, and has it Increased the General Death Rate?—

Both of these propositions have been advanced by the opponents of vaccination. Let it first be inquired what is meant by these propositions.

"A child whose liability to smallpox has just been extinguished by well-performed vaccination," says Simon, "may to-morrow, like an unvaccinated child, be run over, or be drowned, or become sick of measles, or suffer with teething, or be struck with any other of the numberless shafts of death. And the vaccinated subject, advancing to adolescence, to middle life, or to old age, must encounter, like the unvaccinated, the several risks of each period of life. And obviously, if vaccination on a given day, in England, secures a thousand lives from death by smallpox, sooner or later those lives will be subject to the inevitable lot; sooner or later the thousand deaths will be written against the names of other diseases than smallpox; and such diseases may then be said to have been rendered more frequent by vaccination. In the same sense every life that is snatched from fire, or flood, or poison counts at last as a death from some other cause; and to say *in this sense* that such causes are more fatal than before vaccination, is but another form of saying, what Jenner would most have wished to hear, that smallpox is less fatal than it was."

Dr. W. Channing relates a case of a young mother who desired to have her child vaccinated, but hesitated and declined to have it performed. In a few days the child was covered with a loathsome eruption. Had vaccination been performed, the disease would undoubtedly have been attributed to the operation (*Boston Medical and Surgical Journal*, March 1st, 1860).

THE BRITISH PARLIAMENTARY COMMISSION OF 1889. —From the very beginning of the introduction of vaccination opposition has been manifested to its practice, the degree of resistance differing much in different countries. In England several parliamentary inquiries have been held upon the subject, the general result of which has been a confirmation and strengthening of existing laws upon vaccination. The last Parliamentary Commission appointed to consider this subject was that of 1889. The commission consisted of fifteen members, of which Lord Herschel was chairman. Several voluminous reports of this Commission were published containing an enormous amount of evidence together with many appendices containing valuable information, covering about 3,300 folio pages of closely printed matter. Many witnesses were examined by this commission, including such noted experts as Sir John Simon, Dr. Ogle, of the Registrar-General's Office, Dr. Buchanan, Dr. Thorne Thorne, Dr. Cory, Dr. Barry, and other officials of the Local Government Board of England. The principal advocates of repeal of the compulsory laws were Alfred Russell Wallace, LL.D., Messrs. Alexander Wheeler, William Tebb, and others.

The points which this commission was charged to consider were the following:

1. The effect of vaccination in reducing the prevalence of, and mortality from, smallpox.

2. What means, other than vaccination, can be used for diminishing the prevalence of smallpox, and how far such means could be relied on in place of vaccination.

3. The objections made to vaccination on the ground of injurious effects alleged to result therefrom; and the nature and extent of any injurious effects which do, in fact, so result.

4. Whether any, and if so, what means should be adopted for preventing or lessening the ill effects, if any, resulting from vaccination; and whether, and if so, by what means, vaccination with animal vaccine should be further facilitated as a part of public vaccination.

5. Whether any alterations should be made in the arrangements and proceedings for securing the performance of vaccination, and, in particular, in the provisions of the Vaccination Acts with respect to prosecutions for non-compliance with the law.

The commission made an interim report April 21st, 1892, at which time it had held ninety meetings and examined one hundred and thirty-five witnesses. The final report was not made until 1896. The two recommendations which the commission made in its interim report were substantially as follows:

1. It appears that the courts had so construed the laws as to warrant repeated orders in respect to the non-vaccination of a child and the imposition of a penalty for the disobedience of each of such orders, notwithstanding that previous penalties have been inflicted. The commission agreed that the imposition of repeated penalties in respect to the non-vaccination of the same child should no longer be possible. They arrived at this conclusion independently of the question whether vaccination should continue to be compulsorily enforced.

Those who favored the view that vaccination ought not to be compulsory were naturally opposed to repeated convictions; while those who inclined to the opposite view believed that any advantage which could arise from the tendency of repeated convictions to increase the number of the vaccinated, is more than counterbalanced by the resentment and active opposition to vaccination which they engender.

2. The question having arisen whether a person committed to prison on account of failure to pay the penalty imposed under the Vaccination Laws, should be treated as a criminal or not, the commission expressed its opinion that such persons "should no longer be subjected to the same treatment as criminals. Many of the victims of such imprisonment regard the practice of vaccination as likely to be injurious to the health of their children, and are well-conducted and in other respects law-abiding citizens. Even those who consider that the course which such persons adopt is a mistaken one may nevertheless well be of the opinion that they ought not, during their imprisonment, to be subjected to the treatment awarded to criminals, such a proceding not being calculated to secure obedience to the law or to add to the numbers of the vaccinated."

Dr. Alfred Russell Wallace appeared before the Royal Vaccination Commission, in 1890, as a convert to the principles of anti-vaccination, and was hailed by the opponents of vaccination with great triumph. Dr. Wallace confidently expected to demolish the arguments in favor of vaccination upon scientific principles, and appeared before the commission with a long array of tables of statistics and diagrams which fill many pages in the third report of the commission. The principal part of these statistics relates to vaccination in the departments of France for a period of about twenty years. The data presented for each department are the number of births, number of vaccinations, and number of deaths from smallpox for each year, the object being to show that vaccination increases smallpox.

These tables were taken up and carefully considered by the commission, and, so far as Dr. Wallace's hasty conclusions were concerned, they were found to be worthless. This witness finally admitted, after retreating step by step, that his tables were "not perfect," that "the imperfection is very great and irregular." He also admitted that, if his entry of "no deaths" often meant nothing more than that there had been "no returns" (which was actually the case), "then, of course, the whole thing is imperfect," and that in view of such a defect, which was vitally important, "the whole thing is valueless."

Criticism followed upon criticism, and at last Dr. Wallace asked that he might make a few personal concluding remarks, the pith of which had to do with suggestions from the commission that he must have "taken up this subject and written upon it without full and accurate information befitting a man of science." And, in making the personal explanation, the previous declarations as to the absolute need for a scientific accuracy such as had controlled the labors of Darwin seems to have been forgotten, and in their place came the frank admission, "My answer is that I did not take it up as a question of pure science."

Thus ended the "absolute test and demonstration" held out at the previous session of the commission, and the result is that the opponents of vaccination still lack a scientific statistician as an exponent of their views (editorial in *Practitioner*, 1891, vol. xlvi., p. 465).

The smallpox statistics of Prussia, which Dr. Wallace presented to the commission, were brought down to the year 1874, and there discontinued. The compulsory law of Prussia was enacted in 1874, and Dr. Wallace admitted that "he had heard of it," but had not seen any evidence that it made any important difference.

On the contrary, there are nowhere to be found any statistics so absolutely conclusive of the value of vaccination as the comparative statistics of Prussia for the two periods before and after the enactment of the compulsory vaccination law of 1874.

The London *Lancet*, in commenting upon the testimony of this witness, says that Dr. Wallace's theory was based upon "blunders that would hardly be expected of a school boy," and in a concluding paragraph upon the same subject affirms, "if this is all that science can do for the antivaccinationists, the scientific value of vaccination stands more than ever confirmed." But, notwithstanding the exposure of his errors, the philosopher obstinately adheres to his position that "vaccination is a delusion" ("The Wonderful Century," New York, 1899). In this paper he quotes largely from the experience of English towns in which vaccination is only partially enforced, and utterly ignores the greatest and best example of modern times—the German nation. He also quoted the experience of Leicester, England, but takes special pains to omit all reference to the difference between the smallpox mortality of the vaccinated and the unvaccinated in that city, as shown so clearly by its medical officer, Dr. Priestly, in his report of the epidemic of 1892–93. Out of a total of twenty-one deaths from smallpox in that city nineteen were those of unvaccinated persons, one had been vaccinated and the facts in regard to the remaining one were unknown.

The principal modern opponents of vaccination who have published their views upon the subject are Prof. E. M. Crookshank, Dr. Charles Creighton, Professor Wallace, Mr. William Tebb, Prof. A. Vogt, of Berne, and Lorinser, of Vienna.

The final outcome of this legislative farce was the enactment of the "conscientious objector" clause already quoted. The practical operation of such a law is sufficiently illustrated in the following report of the first case which came to trial January 27th, 1899:

THE FIRST APPEAL UNDER THE VACCINATION ACT, 1899. REGINA V. WELBY, EX-PARTE BIRD, JANUARY 27TH, 1899.—The absurdity of the provisions of § 2 (1) of the Vaccination Act, 1898, which require that the parents or person responsible for having a child vaccinated must "satisfy" the magistrate before whom he is brought, that he "conscientiously believes that vaccination would be prejudicial to the health of the child," in order to escape liability to a penalty under § 29 or § 30 of the Vaccination Act, 1867, was fully demonstrated in the above case, which formed the ground of the first appeal under the section.

One Walter Bird had endeavored to "satisfy" the stipendiary magistrate of Sheffield as to his child, as required by § 2 (1) of the Act, but failed to do so. Being convinced that the stipendiary ought to have been "satisfied," he applied for and obtained a rule from the court of Queen's Bench (the Lord Chief Justice and Mr. Justice Wills), calling on the stipendiary to show cause why a *mandamus* should not issue directing him to hear and determine the case, as he had declined to grant exemption to the child on the ground that he did not believe that Bird conscientiously believed that vaccination would be injurious to the child.

In granting the rule the Lord Chief Justice said, *inter alia*:

"The section clearly said that the magistrate was to be satisfied, not in his opinion that vaccination would be prejudicial to the health of the child, but satisfied that the applicant conscientiously believed that vaccination would be prejudicial to the child."

When the case came on for hearing before the Divisional Court (Lawrence and Channell, J. J.), after the affidavits of the parents had been read and explained by counsel, who stated that the parents had been prosecuted and had suffered great inconvenience, Channell, J., said: "The magistrate said in his affidavit, 'A certificate was not given because I was not satisfied that he believed that vaccination would be prejudicial to the health of the child.' They could not grant a *mandamus* to compel him to be satisfied. . . . He has to satisfy the magistrate of his belief, and he has not done so. Even if the magistrate is wrong, we cannot make him be satisfied."

The rule was discharged (Himes' "Handy Guide to the Public Health Acts," London, 1901).

Dr. Creighton's views upon vaccination are sufficiently set forth in his article in the twenty-fourth volume of the "Encyclopædia Britannica," and in his book entitled "Cowpox and Vaccinal Syphilis." In the former he takes the ground that there is neither identity nor even affinity between vaccinia and variola. He also asserts his belief that the diminished activity of variola is due to epidemiological laws, and not to vaccination. In his exceedingly superficial statement of the practical working of vaccination laws, like Dr. Wallace, he omits reference to the convincing experience of Prussia since the enactment of more efficient laws in 1874, although a dozen years or more had elapsed from that date to the publication of his article in the "British Encyclopædia."

The various publications issued by the opponents of vaccination are characterized mainly by the absence of facts and the presentation of an abundance of theory. For example, a recent work by Mr. William Tebb, intended to prove the "synchronicity between the spread of leprosy and vaccination," introduces many arguments in support of an alleged connection between the one and the other. But leprosy produced its most disastrous effects in the twelfth, thirteenth, and fourteenth centuries, when vaccination was unknown. There were then nineteen thousand lazarettos in Europe. Now that the human race is much more widely distributed over the globe, leprosy is far more rare, and exists to its greatest extent in countries where vaccination is but little practised. In the United States, where probably more than three-fourths of the population is vaccinated, leprosy is confined chiefly to a very small number, among whom the disease was introduced directly from other and infected countries.

Leprosy has for many years been prevalent in Bombay, but since the introduction of vaccination there, by the British Government, the ratio of lepers has gradually diminished.

Much importance has been attached by the opponents of vaccination to certain statistics which were published in 1872–73 by Dr. Keller, the chief physician of the Austrian State Railway, who was himself an opponent of vaccination. These statistics were quoted largely by Lorinser of Vienna, Vogt of Berne, and by Reichsperger, all of whom were antivaccinationists. Körösi recently investigated the sources of these statistics, and ascertained that Keller was dead, and that the original documents could not be found. He then corresponded with all of the physicians who had contributed material to these statistics, who were still living and could be found, and learned that not only had Keller suppressed important data, but had actually altered the returns to suit his own views. One of the physicians who contributed to the returns confessed that "the data were prepared in conformity to the taste of their chief, whom he knew to be opposed to vaccination."

The committee of the Ninth International Medical Congress who examined the proofs of these statements reported that they were "forced to declare that the statistics of Dr. Keller were found to be false; that they are an unpardonable effort to mislead public and scientific opinion, and that henceforth no weight should be attached to them, having been proved by us to be entirely incorrect."

VAGINA, ANATOMY OF. See *Sexual Organs, Female.*

VAGINA, CONGENITAL MALFORMATIONS OF THE.—DEVELOPMENT OF THE VAGINA.—A knowledge of the mode in which the vagina is developed is essential to a proper understanding of its congenital malformations.

The lower portions of the two Müllerian ducts coalesce to form the vagina, and by the ninth week of embryonal life the intervening septum disappears, and this union is complete, although the appearance of the cervix and the differentiation of the genital passage into uterus and vagina cannot be said to take place before the fifteenth or sixteenth week. In the nineteenth week of fœtal existence a slight projection of mucous membrane makes its appearance on the posterior wall of the entrance to the genitalia, just above the point of union of the vagina with the urogenital sinus, and a little later a smaller projection at a slightly higher level may be seen on the anterior wall. These elevations subsequently unite laterally, and thus form the hymen, which, by the twentieth week, is fully developed.

VARIETIES OF CONGENITAL MALFORMATIONS.—The vagina may be entirely absent; it may be more or less completely closed by a transverse, or divided by a longitudinal, septum; though not seriously misshapen it may still be too short or too narrow; or it may communicate with cavities from which it should properly be separated. There are yet other errors in development, which are, however, of less import.

A. *Absence of the Vagina.*—When there is total failure in development of the lower portions of the ducts of Müller the vagina is entirely absent, and only a thin septum intervenes between the bladder and the rectum, in which some little connective tissue, but no muscular elements, are discoverable. A fibrous strand or cord may, however, indicate the situation which should be occupied by the vaginal tube. When the Müllerian ducts are developed, except at their very lowest extremities, or are not prolonged downward far enough to open into the aditus urogenitalis, then only the most inferior portion of the vagina is wanting.

Absence of the vagina is usually associated with some other marked maldevelopment, such as absence or a rudimentary condition of the uterus. The condition of the uterus will determine the existence or non-existence of retained fluids.

In absence of the vagina the urethra is found to be abnormally relaxed.

If there is hæmatometra, an operation designed to create a passage where the vagina should be located is imperative; and even when only a very rudimentary uterus can be discovered, and there is no retention, the general health of the individual is often markedly improved after operative interference is instituted, and the uterus has been known to take on active growth.

When there is sufficient space between the bladder and rectum, a vagina can be made by stretching and tearing the intervening tissues with the finger, aided by the use of blunt-pointed scissors, if great resistance is encountered.

A sound in the urethra, and the finger of the operator or of an assistant in the rectum, are useful guides. The operation should be completed at one sitting, and the passage should be made larger than it is thought desirable to have it subsequently remain. Undue contraction is prevented by the use of a vaginal plug of glass, and the cicatricial tissue which forms over it is said to resemble very closely normal mucous membrane.

When the uterus is well developed, and there is retention, but no vaginal passage can be formed, Battey's operation may be indicated.

B. *Atresia of the Simple Vagina.*—In this condition the occlusion of the vagina is absolute. The obstruction may be seated at the hymen—atresia hymenalis, or at some point within the vagina proper—atresia vaginalis.

Atresia Hymenalis.—Atresia hymenalis is the most common variety of vaginal atresia. The duplicature of mucous membrane constituting the hymen here forms an obstruction, which, although thinner and more elastic than the atresias situated above in the vagina, yet may be considerably thickened and of almost cartilaginous toughness. As menstrual blood accumulates, the hymen bulges downward, and the vagina dilates above, until it forms a sac filling the pelvic cavity. The uterus at first is undisturbed, and rests upon the summit of the distended sac. Ultimately the cervix, and even the uterus, if no outlet is found below, become dilated. The tubes likewise suffer, but the blood discovered in them is by some not regarded as an overflow from the uterine cavity, since the uterine ends of the tubes are often closed, and the blood is located in small diverticula or sacs near the fimbriated extremities, and is said to originate in hemorrhages from the mucous membrane of the oviducts themselves. The blood may, however, subsequently escape into the peritoneal cavity from the fimbriated ends of the Fallopian tubes.

Atresia Vaginalis.—In atresia vaginalis the obstruction (or obstructions, for there may be several, located one above the other, and separated by layers of different kinds of retained fluid) is generally found in the lower third of the vagina. The thickness of the atresia varies in different cases, and whatever may have been its original dimensions, pressure from the fluid accumulation above produces sometimes a remarkable degree of thinning. Thus the obliteration may be 1.2 inch thick, or of membrane-like delicacy. In atresia vaginalis, however, we do not find the elasticity and distensibility met with in atresia hymenalis. The occluding membrane, made up largely of connective tissue, is of a firmer texture and greater thickness, and yields less readily beneath the superincumbent weight. As a result of this, the lower part of the vagina and the vulvar orifice are seldom dilated, and the former is not uncommonly narrow and cone-shaped, although attempts at coition may materially modify its shape, while the occluding diaphragm viewed from below may appear quite flat.

It is very important, in view of proposed operative interference, to ascertain the seat and thickness of the occluding membrane, and this is best done by the various combined methods of examination, a catheter or sound placed in the bladder being employed to assist the finger in the rectum or vagina.

Above the obstruction, as in atresia hymenalis, mucus or blood accumulates. The seat of the atresia, and the activity and frequency of the menstrual function, determine largely the quantity of the accumulated blood; but, as has been pointed out, nature, discovering an obstacle to escape, retards in some way the amount of blood effused, so that it is never as great as one would expect to find it, considering the number of periods that have occurred, and is always less in congenital atresia than in the acquired condition. It is probable, also, either that the uterus is in an immature and inactive condition, or else that the fluid elements of the accumulated blood have been largely absorbed. The peculiar characteristics of the retained liquid would seem to support this last assumption, for it is found to be dark reddish-brown in color, and of a thick, tenacious consistence, the mucus mingled with it preventing coagulation.

Microscopically it is found to contain shrivelled blood corpuscles, and extravasated blood pigment, with flat epithelial cells, mucous corpuscles, and granular débris.

As in atresia hymenalis, the genital tube above the point of obstruction dilates as the retained fluid accumulates. At first the vagina, then the cervical canal, and finally the uterine cavity become filled and expand often to a remarkable degree; the distended vagina will, however, always constitute the major part of the tumor. If the liquid is mucus, the conditions known respectively as hydrocolpos and hydrometra develop; if blood, then the terms hæmatocolpos and hæmatometra are employed. Fortunately, the walls of the dilated portion of the vagina, although overstretched, do not become thinned. On the contrary, they hypertrophy, especially their musculature, and the condition known as "excentric hypertrophy" is thus developed.

The vaginal walls internally may be thrown into folds, although the sac be greatly distended. Occasionally, in new-born children, the folds of mucous membrane on opposite walls of the vagina become united, forming a thin, transparent diaphragm, which soon ruptures spontaneously, and is seen no more.

The origin of the obstruction in atresia hymenalis has been variously explained. It is said that the fusion of the lower ends of two solid Müllerian ducts will produce this abnormality, or that there may be an overgrowth of the fold of mucous membrane which constitutes the hymen and a union of its free edges toward the centre of the ring. Fœtal inflammation may likewise produce an agglutination of these same free edges after the hymen has been completely formed. Numerous hypotheses have likewise been advanced to explain the origin of atresia vaginalis. Either the lumen of the vagina at some point has never been established, as when the Müllerian ducts as solid cords have united, but have failed to become hollowed or tunnelled at the point in question, or else, after a normal formation of the vagina by proper coalescence and perforation of these ducts, its walls, for a variable distance, become united one with the other, as the result of an inflammation during intra-uterine life. And further, the idea has been suggested that, in cases in which there is but one septum, the canal above the septum may belong to one Müllerian duct and that below to the other. In explanation of the fact that atresias are most often seated in the lower third of the vagina, it should be borne in mind that the walls of the vaginal tube are very closely approximated just above the seat of the hymen, and agglutination is thereby rendered easy.

Atresias of the vagina are important only as interfering with menstruation and coition. Hence, although exceptionally before puberty these occlusions may give rise to inconvenience or suffering (as in certain cases of profuse secretion of mucus and the formation of a hydrocolpos, a condition rarely of significance in adults), yet in the majority of cases it is not until the establishment of the menstrual function, and, more rarely, when graver rudimentary conditions exist and the catamenia do not appear, not until after marriage, that symptoms manifest themselves and a physician is consulted. Certain well-known general conditions may likewise postpone the ushering in of the first menstrual period, and then if an accumulation occur it will be of mucus and not of blood.

In atresia of the hymen or of the vagina proper, when puberty arrives the usual disturbances which precede and accompany the catamenia are noticed, but there is no discharge. At the time of the next period these disturbances are somewhat accentuated, and, as the fluid accumulates, gradually change to suffering, which is experienced now during the intermenstrual period as well. The tumor produces pain and a feeling of weight in the pelvis, and by pressure or traction upon the bladder and rectum interferes with micturition and defecation. There is sometimes, too, no little constitutional disturbance. The amount of fluid and the consequent size of the tumor determine in large part the intensity of suffering, which is also influenced by the general condition of the patient.

Usually, after menstrual molimina have been noticed for three successive months, a tumor begins to be apparent, although it may not be noticed until a much later period, and this swelling gradually enlarges until it bulges at the vaginal inlet and causes a perceptible increase in the size of the abdomen. Certain conditions previously described may, however, retard its development, and the sac may never attain very great proportions.

If menstruation has never appeared and the accumulation of mucus has not been excessive, it may be that futile or unsatisfactory attempts at intercourse first reveal the existence of an atresia. Yet if the atresia be elastic or high-seated, repeated efforts at cohabitation ultimately form a fairly roomy canal, or, if the diaphragm be low or unyielding, intercourse may be carried on through the urethra or anus. It is extraordinary how greatly the urethra may become dilated under these circumstances, and it is still more singular that incontinence of urine so seldom results Occasionally sterility first induces a patient to seek medical advice.

Spontaneous rupture of the occluding membrane and evacuation of the retained fluid are rare in both forms of vaginal atresia; they occur in only one per cent. of cases of atresia vaginalis. And, indeed, although a source of temporary relief, this natural effort at cure is of somewhat questionable value. Pyocolpos and pyometra almost invariably result, and the danger to the patient is, if anything, aggravated. Yet if spontaneous perforation does not occur, and no surgical procedure looking to the emptying of the sac is instituted, the outlook is extremely unfavorable. Rupture of some portion of the distended genital tube, or of a blood sac in the oviduct, is almost sure to occur, or else without rupture a grave peritonitis may develop.

The symptoms observed at puberty, and repeated periodically afterward. which have already been detailed, are quite characteristic, and, with the accompanying physical signs of a gradually increasing retention tumor, leave but little doubt as to the diagnosis. It is true that amenorrhœa and abdominal enlargement may, and sometimes do, give rise to the impression that pregnancy exists, but this is rapidly dispelled by a local examination and a careful inquiry into the history of the case. In view of the serious nature of the malformation in question the physician is justified in insisting at least upon an examination of the rectum and abdomen, if not of the genitals, in all doubtful cases. And this examination should be undertaken early and be performed carefully; for although the recognition of a vaginal atresia is a matter of no great difficulty, yet it is not always easy to determine the exact seat, and more especially the thickness, of the obstructing membrane, which are matters of great importance when surgical interference is attempted.

The various combined manual and digital methods of exploration are the means generally employed, and a sound or catheter of some resistant material, placed in the bladder, often assists in arriving at a definite opinion. In children the persistence of dysuria may, after simple remedies fail, suggest the necessity for an examination; and in adults dyspareunia and sterility, in a case in which menstruation has never occurred, likewise require investigation. To differentiate between atresia hymenalis and atresia vaginalis is not always so easy as one would suppose. In atresia hymenalis, if there be retention, the sac distends the perineum and protrudes from the vulvar orifice. The obstruction in atresia vaginalis is thicker and less elastic, and there is not so much likelihood of distention of the lower vagina and separation of the vulvar fissure; but if it be seated, as is usual, in the lower third of the vagina, the sac may bulge through the genital outlet, the hymen being seen adherent to it like a fringe. However, in atresia vaginalis the lower part of the vagina is often narrow and cone-shaped, and the diaphragm itself may appear flat. Atresias of the vagina which are located at a higher level are more difficult to delimit accurately, but are less likely to give rise to confusion with imperforate hymen.

It is not always easy in a given case to decide whether an atresia is congential or acquired. Even in children injury and subsequent inflammation of the vagina may produce occlusion, although stenosis, rare as a congenital condition, is more likely to result.

The existence of a rudimentary state of other portions of the genital apparatus, and the absence of tissue irregularities, cicatricial bands, and the remains of destructive inflammation, point to the congenital nature of the affection. Atresia of the hymen is very rare as an acquired condition.

The prognosis, in cases of vaginal atresia with retention, is almost without exception unfavorable, and this is especially the case when the fluid consists of menstrual blood. Where nothing is done, a fatal termination is invariably to be expected, through rupture of some part of the sac, or as a result of septic infection or peritonitis, independently of rupture. If perforation of the occluding membrane and evacuation of the cavity do occur, pyocolpos and pyometra follow with rare exceptions, and the danger to the patient, though less imminent, is hardly less certain. Even in spite of the most active treatment, the existence of a large sac secreting pus, which often is in free communication with the peritoneal cavity, is a constant source of apprehension, and a termination by no means favorable is to be anticipated.

In every case of atresia with retention it may be safely said that surgical intervention is urgently required. But even this is not free from danger or difficulty. For immediate rupture of a blood sac in the Fallopian tube may introduce a complication of the greatest gravity, or septic peritonitis may subsequently develop. In atresia hymenalis an operation is likely to be followed by a better result than in atresia vaginalis.

While the greater number of the congenital malformations of the female genitalia appeal only to the student of development and of pathological anatomy, vaginal atresias possess great clinical interest and are of the utmost practical importance. It is true that in a certain proportion of cases of vaginal atresia relief is sought before puberty is reached, and in other instances not until sexual intercourse proves to be difficult or impossible, and conception fails to occur; yet in the majority of cases of atresia, where suffering follows the establishment of the menstrual function and is dependent upon retention of the menstrual fluid, surgical intervention is urgently demanded. Almost without exception the condition of the patient is not recognized until this time. or else the obstruction could be divided before stasis had begun or before it had become considerable. The most satisfactory results are to be looked for when an operation is undertaken while there is yet no hæmatometra.

Although the methods of operating vary according to the nature of the obstruction and the taste of the operator, yet the indications are always the same. In every case an opening must be made through the occluding tissue (at a time midway between the two menstrual periods), sufficiently large to permit the free egress of the retained fluid, and this opening must be maintained in order that the sac may be thoroughly emptied and kept empty. In atresia without retention the same general plan of procedure is necessary, so that the vaginal tube may be kept sufficiently patulous to offer no obstacle to intercourse, conception, and delivery. Hymeneal atresias may be incised or punctured, and the opening thus made can be immediately or subsequently enlarged with the finger.

Atresias of the vagina which are simply due to an adhesion of its walls are sometimes easily broken down with the finger alone or with some blunt instrument. But if the atresia is due to a pronounced rudimentary condition of the genital canal, bloodless dilatation is hardly possible. In such cases the obstructing tissue must be carefully and slowly divided with a knife, or, preferably, with blunt-pointed scissors and the finger, a silver catheter guarding the urethra and bladder, and an assistant's finger the rectum, until the retention tumor is reached. Breisky, of Prague, who minutely describes the method of operating in high vaginal atresias, accompanied perhaps with atresia of the cervix, advises that as soon as the sac is encountered it should be punctured opposite the site of the cervix, or, if this cannot be found, at the lowest part of the vault of the tumor, with a long-handled lancet-shaped knife, the blade of which is surrounded and protected by a cannula. As soon as the blade has been projected from the cannula into the tumor, and the opening has been enlarged laterally, the knife is withdrawn and the cannula is pushed for some distance into the sac. The blades of a dilator, especially designed for this purpose, are next introduced alongside of the cannula, and the opening into the tumor can be enlarged in any direction, to any extent, or with any degree of rapidity that is deemed desirable. After this dilatation a German silver tube is introduced to serve for drainage, and likewise for the introduction of antiseptic fluids, and the dilator is removed. Whatever form of drainage-tube is employed, it should always be of some resistant material, and should be provided with large fenestrations. As the walls of the retention tumor subsequently contract, a tube smaller than the one first used should be substituted.

Although this mode of operating is based upon sound principles, and is intended to prevent any injury being done to the surrounding hollow organs and peritoneum, to enable the surgeon to control the rapidity of the escape of the retained fluid, and to maintain after the operation a free communication with the sac, yet it is quite probable that the same results could be achieved without the aid of the special instruments described, and with a greater degree of simplicity in manipulation.

The prognosis in cases of neglected vaginal atresia is unfavorable, nor is a more hopeful issue always to be anticipated after operation. Like many other gynecological procedures the danger here is out of proportion to the magnitude of the operation itself: for even puncture of a thin hymeneal septum may be followed by a fatal result.

The untoward accidents which may accompany or follow measures instituted for the relief of atresia vaginalis are: (1) injury of neighboring organs or of the peritoneum; (2) rupture of tubal blood sacs; and (3) septic infection.

The first of these dangers is not to be anticipated in operating upon the imperforate hymen or upon vaginal atresias of moderate extent, but where there is a considerable defect of the vaginal tube, and the atresia is broad and deeply seated, it requires the greatest care, especially when sharp-pointed instruments are used, to avoid wounding the urethra, bladder, rectum, or peritoneum.

Rupture of the tubes may follow operative interference in even the simplest forms of vaginal occlusion. The Fallopian tubes, distended with blood, or containing diverticula, or sacs filled with blood, are very prone, when the menstrual function has been established for some time, and there has been considerable retention, to form adhesions with surrounding tissues or organs. When the retained fluid is evacuated, and the distended genital canal collapses and contracts, great traction is exerted from below upon the fixed, thinned, and friable tubal wall, and rupture is very apt to occur. Increased pressure of the abdominal walls, blood forced by uterine contractions into the tube, and even contractions propagated from the uterine to the tubal wall, are said to increase the probability of this untoward accident. Rupture of the tube is a most unfortunate complication, to prevent which efforts have been made to alter slowly the size and position of the overfull uterus and vagina by withdrawing the fluid gradually through a small trocar puncture, or by several successive tappings. It is certainly wise to proceed slowly, and to withdraw the greater part, if not all, of the retained fluid through a small opening, which is to be enlarged after evacuation is completed. In this way changes in pressure occur slowly, and the genital canal has adequate time to adapt itself to its new position and surroundings. But the entire operation should be concluded at one sitting, or otherwise, while avoiding rupture of the tube, we court danger through septic infection, and subsequent disintegration of the tubal walls may occur as a result of this process. Breisky suggests that in some cases it might be well to perform abdominal section and remove the hæmatosalpinx, or incise and drain it, if such is known to exist, before the operation upon the atresia is attempted.

Septic infection, the third of the complications already mentioned, may be caused by absorption from the divided surfaces of the atresia, and the actual cautery and galvanic current have been used instead of the usual cutting and puncturing instruments in order to obviate this danger. But such an origin is somewhat questionable in view of the greater liability of the contents of an incompletely emptied sac to undergo decomposition, and the much greater importance which this factor assumes. It is septic decomposition and absorption which increase so signally the risk of repeated punctures and gradual evacuation. Emmet long ago showed the fallacy of this procedure, and the principles which he then urged upon the profession have now been accorded universal acceptance and approval. We should evacuate the cavity slowly if tubal rupture is anticipated, but, nevertheless, always at one sitting. Subsequent risk of decomposition within the sac is diminished by providing for adequate drainage. The sac immediately after operation may be thoroughly irrigated with an appropriate solution thrown into it under low pressure, and not so hot at first as to stimulate uterine contractions; but if the entrance of air is prevented, or only sterilized air is admitted, the danger to the patient is materially lessened. When the operation is performed with the spray and other antiseptic precautions, and the outer end of the drainage-tube is wrapped in some absorbent material impregnated with an efficient germicide, the outlook is rendered exceptionally favorable. Under certain circumstances it might be judicious to postpone washing out the canal until after evidences of decomposition have become apparent, in the meanwhile care being exercised to secure adequate drainage. Irrigation is always indicated when pyocolpos and pyometra are recognized.

When the immediate danger to the patient is over, the physician is confronted with the problem of how best to keep patulous the opening that has been made. The tendency of artificial passages through extensive atresias to close is remarkable; various plans have been suggested to obviate this difficulty. The use of the glass tube, which can be introduced into the vagina by the patient, and can be worn for as long a time as is desirable, is especially commended by Emmet. Breisky, on the contrary, prefers dilatation with the fingers or speculum, to be begun eight days after the operation, and to be repeated at suitable intervals. If the divided edges can be covered with a flap of skin or mucous membrane, as has been done in exceptional instances, an excellent result is assured. Cohabitation, if the patient be married, materially assists subsequent efforts to keep the canal open. Puncture of hæmatocolpos through the rectum or bladder should be mentioned only to be condemned.

C. *Congenital Stenosis of the Simple Vagina.*—While atresia of the vagina means complete, stenosis implies only partial, occlusion of that canal, so that menstrual blood can find an exit, and conception can take place, things impossible in the former and more rare condition.

As in atresia, the hymen or the vaginal canal above it may be affected, though congenital stenosis of the hymen is uncommon. There may be a septum perforated with openings so small as only to become apparent when the menstrual blood trickles through them, or bands of tissue extending from one portion of the vagina to another, or again, spiral or ring-shaped folds projecting from the vaginal surface. Pronounced stenoses are not commonly encountered where the remaining portions of the genital apparatus are normally developed.

The same causes which produce atresia of the vagina, though operating less actively, occasion stenosis of this canal, namely, fœtal inflammatory processes occurring late in embryonal development, and overgrowth of the hymeneal folds.

In this condition there may perhaps be temporary amenorrhœa when the stenosis is very pronounced, followed by dysmenorrhœa from forcible contractions of the vagina and uterus; but since there is always some opening for the escape of menstrual blood there is no development of a retention tumor nor of the painful and alarming disturbances incident thereto. Cohabitation may be interfered with, but there is no insuperable obstacle to conception, and while labor is occasionally made tedious and difficult, the characteristic tissue changes of pregnancy often render the structures soft and dilatable. Still, in certain cases, without surgical intervention delivery cannot be accomplished, and even rupture of the vagina during labor has been known to occur.

The diagnosis is easy, as a rule, although it may sometimes be difficult to find an opening, and the condition is hence mistaken for an atresia. It is, however, not impossible to confound acquired with congenital stenosis, and a spasm of the muscles of the pelvic floor may lead one into error.

For obvious reasons the prognosis in stenosis presents none of the grave aspects that characterize atresia of the vagina.

When to lessen the difficulties attending coition, and to increase the probabilities of conception, it is desirable to enlarge the strictured vaginal canal, this may be accomplished by the use of tents, sounds, dilators, and the like, but the results are never so satisfactory as when the edges of the occluding bands or folds are incised, and dilatation by speculum or antiseptic tamponing is afterward systematically employed. Cohabitation alone often ultimately achieves the desired end, and during labor the advancing head accomplishes an extraordinary degree of dilatation. Yet it is never safe at this crisis to rely entirely upon nature's efforts to overcome the obstruction, for the most untoward accidents have been known to occur. It is best during delivery to divide at once any obstructing band which seems likely to delay materially the progress of the child, though incision should always be made as superficially as possible.

D. *Divided or Duplex Vagina.*—In this condition the vagina is divided into two lateral halves, rarely of equal dimensions, by a more or less perfect septum, consisting of two folds of mucous membrane, separated by a little muscular and connective tissue. This partition may be complete, or may be perforated by a number of openings, or its presence may alone be indicated by a band or by bands of tissue connecting the upper, middle, or lower portions of the anterior and posterior vaginal walls. With double vagina the uterus is usually also double, but may be single, and there may be a portion in each half of the vagina, or the uterus may have two openings in one side and none in the other. When the uterus is single and the vagina double, only that half of the latter is suitable for coition which ends in a cul-de-sac above: and in one-horned uterus, with atrophied second horn, the side of the vagina which corresponds to the atrophied half of the uterus is generally found in a very rudimentary condition.

There may be atresia of both halves of a duplex vagina, although one side—in a vast majority of cases the right—is alone occluded as a rule. As a result of this, bilateral or unilateral hæmatocolpos may develop. Spontaneous perforation of the obstructing membrane and evacuation of the contained fluid, and rupture of tubal blood sacs, occur more often here than in the case of atresia of the simple vagina.

Duplexity of the vagina results from a persistence of the septum between the Müllerian ducts, which should have completely disappeared by the end of the twelfth week of embryonal life. Coalescence of the two ducts of Müller begins not far from their points of outlet, between the lower and middle thirds of the future genital tract, and extends upward and downward, but more slowly in the former than in the latter direction. A single vagina with a double uterus is hence a more common condition than a double vagina with a single womb.

The septum of a duplex vagina may interfere with coitus, and during labor the descending fœtal extremity may not follow either canal, displacing the partition laterally, but may push the septum or band before it, delivery being thus impeded.

When there is atresia of both halves of a duplex vagina the symptoms will be almost identical with those accompanying occlusion of the simple canal. When, however, only one half is obstructed, moliminal disturbances will occur with retention in the obstructed half (hæmatocolpos and hæmatometra lateralis), but a menstrual discharge will regularly escape from the patent portion of the tube, and in the intermenstrual periods a catarrhal outflow will occur.

The diagnosis is facilitated by remembering that in this condition there are present all the symptoms accompanying atresia of the simple vagina with the exception of amenorrhœa; the menstrual flow regularly recurs and the retention tumor that is developed has a distinctly lateral situation. This latter fact may lead the examiner to confuse hæmatometra and hæmatocolpos lateralis with peri-uterine hæmatocele, with cystic enlargements of the ovary and Fallopian tube, or with soft uterine myomata. But if the atresia is seated near the vaginal outlet, no such error is likely to arise, and familiarity with the history of the case will usually solve any apparent difficulties.

The same dangers attend atresias of the double vagina that are present in obstruction of the simple canal. Rupture of the Fallopian tubes may occur, or, after spontaneous perforation of the occluding diaphragm, pyocolpos and pyometra may develop with subsequent involvement of the tubes and pelvic peritoneum, or the patient's general health may suffer seriously from the long-continued suppuration and purulent discharge.

The septum can be divided with scissors without much risk of hemorrhage even during labor, when it offers, or seems likely to offer, any serious obstacle to delivery, or in the non-pregnant female when intercourse is difficult or conception impossible.

E. *Faulty Communications with Other Cavities.*—If it be remembered that in the embryo the urogenital tube and the intestinal tube terminate in a common conduit—the cloaca, a depression on the external surface of the ovum,—the genesis of the abnormalities in question is easily explicable. In the normal course of development a septum (completed in the tenth week of intra-uterine existence) divides the urogenital sinus in front from the rectum behind. If this septum does not appear the cloaca persists, there is no anus, and apparently the rectum empties into the vagina a short distance above the hymen. To this condition the strange name atresia ani vaginalis has been accorded; while if the communication is below the hymen, it is called atresia ani hymenalis or vestibularis. The simple term persistent cloaca would more accurately describe both abnormalities. The opening of the intestinal canal into the cloaca may be small, and, if not actually possessing a sphincter, may yet be able to resist the involuntary passage of fæces and flatus, which are voided periodically and at will. If the communication be large, however, the patient suffers from those symptoms which characterize the more extensive forms of perineal laceration.

Numerous other abnormal communications have been observed, as, for example, an opening from the vagina into the normally formed rectum, from the vagina into the urethra or bladder, or between a ureter and the vagina. Again, the ileum, colon, and vagina have been found opening upon the surface of an extroverted bladder.

The sinus urogenitalis may persist as a long and narrow passage, so that the urethra opens, apparently, not into the vestibule, but into the vagina.

The causes of these faulty communications are largely arrests in development occasioned by fœtal inflammatory processes; but in the production of persistent cloaca (atresia ani vaginalis or vestibularis) hereditary influence seems to have some force, since this condition has been known to have been present in several members of the same family.

For the relief of this last condition the perineum should be divided from before backward, the end of the intestine is to be sutured in the middle of the incision thus made, and the remainder of the wound closed by stitches. The abnormal opening into the vagina will often close spontaneously.

F. *Blind Canals or Inversions of Vaginal Mucous Membrane.*—Occasionally lacunæ of the vagina attain unusual dimensions and are recognized as blind tubes, sometimes large and long enough to admit the little finger, lined with smooth mucous membrane and lying parallel to the long axis of the vagina, or they are deflected into the perivaginal connective tissue. The point of exit of these tubes is usually near the vaginal outlet at the sides of the columna ruga posterior.

G. *Infantile Vagina.*—Sometimes the vagina, though perfectly developed, from an arrest of growth in childhood, fails to attain adequate dimensions, and retains its infantile character throughout later life, being too short, too narrow, or both. Uterus fœtalis and uterus infantilis are not infrequently associated with this condition.

VAGINA, DISEASES OF.—I. CYSTS.—Cysts of the vagina are not met with very frequently. Usually they are located in the lower third of the vagina and occur with equal frequency upon either the anterior or the posterior wall. When deep-seated they are small and do not encroach much upon the lumen of the vagina, but as they increase in size the vaginal mucous membrane becomes distended, loses its characteristic wrinkles and assumes the appearance of an ovarian tumor, especially when it protrudes at the vulva. As a rule they grow slowly and rarely attain a great size. These cysts may be of glandular origin or may have their origin in the remains of the Wolffian bodies. In those cases in which several cysts are found connected in a row at the side of the vagina they have doubtless originated in local dilatations either of one of Gärtner's ducts or of an undeveloped duct of Müller. The contents of the cysts are usually a clear yellowish transparent fluid, but they may be discolored by disorganized blood which has escaped into them. They rarely give any symptoms beyond that of mechanical obstruction. It is well to remember, in making a diagnosis, that these cysts have been mistaken for cystocele, rectocele, urethrocele, vaginal hernia, and cysts of the vulvovaginal gland. In all cases of vaginal cyst it is best to remove them except in old women in whom the tumor is small. They may be punctured and drained, or injected with some irritating fluid to set up an obliterating inflammation, or they may be dissected out. The last sometimes proves a most tedious and difficult procedure. Schroeder's operation consists in removing by scissors all of the cyst wall that rises above the level of the vagina and stitching the mucous membrane of the vagina about the circumference of the excavation to the cyst wall. The surface occupied by the remainder of the cyst soon assumes the character of the vaginal mucous membrane, the cavity becomes flattened out, and no trace of the tumor remains. In this connection it may be well to mention the fact that large blebs are sometimes found in the vagina, and have been named by some authorities air cysts of the vagina. They are usually found in the upper portion of the canal. They collapse on puncture or they rupture and disappear. They are more apt to be present during gestation than at any other period.

II. NEW GROWTHS.—Carcinoma has been known to develop primarily in the vagina, but as a rule the only malignant growths observed in the vagina are those which have developed primarily in the uterus. For information in regard to them the reader is referred to the article entitled *Uterus, Diseases of: Malignant New Growths.*

III. VESICO-VAGINAL CYSTOCELE.—Cystocele is a descent or prolapse of the base of the bladder into the vagina, and declares itself by the presence of a protruding mass at the introitus vaginæ. It varies in size from a small ovoid to a large mass protruding entirely out of the vulva (Fig. 4941). Under the latter circumstances it is usually accompanied by procidentia of the uterus and prolapse of the rectum. A cystocele partakes of the character of a true hernia, and in its ordinary form must be regarded as a hernia of the bladder which protrudes into the vaginal canal and presents itself at the vulva. The symptoms which are steadily progressive are dysuria, retention, and incontinence due to overdistention. Later, there may follow cystitis, ureteritis, pyelitis, rarely a vesical calculus. The etiology of the condition varies in different periods of life. In virgins and nulliparæ it is due to a supravaginal elongation of the cervix, occasioned primarily by hypertrophy of the uterine tissue. This permits the descent of the upper supports of the vagina, producing a sagging of its anterior wall and the base of the bladder. This initial elongation pushes down the vaginal supports; but later the rôles are reversed and the vaginal prolapse drags down and increases the elongation of the cervix. In multiparæ the condition is usually associated with laceration of the cervix and perineum, with retrodisplacement and descent of the uterus. In the process of parturition the anterior vaginal wall, as well as the other parts, has suffered serious injury, reducing its resisting power and permitting the development of the hernial pouch into which the bladder descends. The diagnosis of the condition is not difficult. A protruding mass presents itself at the vulva; it is soft and flabby when the bladder is empty, tense and elastic when the bladder is full. A sound passed through the urethra readily turns down into the protruding tumor, and by means of this the boundaries of the bladder may be readily determined.

The condition of urethrocele must be distinguished from that of hypertrophy of the tissues which lie below the urethra. This latter condition is by no means uncommon (see Fig. 4942).

Treatment.—In aged women in whom an operative procedure is not advisable on account of the dangers of anæsthesia, shock, and depression, a pessary can usually be fitted to retain the mass in the vagina and thus afford relief. The Gehrung hard-rubber pessary has been found most serviceable for this purpose. A soft-rubber ball that can be inflated after insertion is effective, but requires constant attention and frequent renewals. Such devices are merely temporary expedients. For permanent relief some operative procedure must be resorted to. Sims and Emmet were very ingenious in devising different methods of plastic work upon the vaginal wall, and they carried these methods to a high degree of perfection.

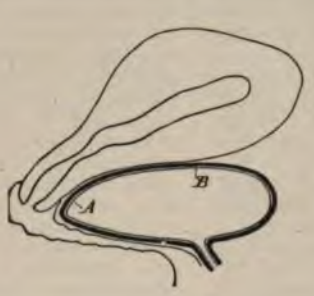

FIG. 4944.

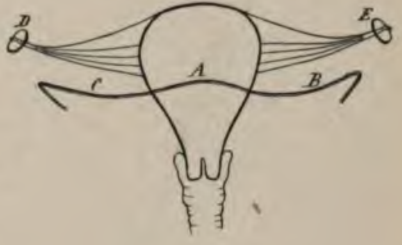

FIG. 4945.

FIGS. 4943, 4944, AND 4945.—Diagram showing some of the Details of the Author's Operation for the Relief of a Vesico-Vaginal Cystocele, and the Principle upon which it is Based. Fig. 4943 shows the position of the bladder and its relations to the uterus before the operation. After the bladder has been freed from its sheath, it is rotated on its transverse diameter until the point *A* is carried up to *B*, and the point *B* to *C*. The effect of this is shown in Fig. 4944. The bladder is then stitched in its new position, in which its base (from *A* to the urethra) forms a straight line. In Fig. 4945 the line *A B C* corresponds with that of the tear through the peritoneum across the face of the uterus and broad ligaments, *C* and *B* being the points at which the corners of the bladder are attached on either side; *D* and *E* represent the internal abdominal rings through which the round ligaments pass.

The fundamental idea in these methods was to denude areas of various sizes and shapes in the mucous membrane of the vagina, and then to cover them over by introducing sutures into the surrounding edges of the mucous membrane and drawing upon them until all the slack over the hernial mass had been taken in. These operations took the name of *colporrhaphy*. The stitches were usually passed in a transverse direction. Stoltz simplified this by merely denuding an oval or round area of mucous membrane, the size varying with the size of the cystocele, and then drawing the edges together with a puckering string, which had been passed around the circumference of the denuded area, about one-third of an inch from the edge. This string was worked in and out of the mucous membrane, like the gathering string of a tobacco pouch. All of these operations, however, failed to give permanent relief. Sooner or later the steady pressure caused the contracted tissue to stretch and eventually to give way, and thus the original condition was reproduced. The true cause of the difficulty was not overcome by these methods.

If it be granted that a cystocele is a hernia, it would seem quite as rational a procedure, and would give promise of quite as satisfactory results, to denude the skin over an inguinal hernia and bring the edges together with stitches, as to expect to cure a cystocele by simply denuding the vaginal mucous membrane and covering in the raw surface. The fascia is the sustaining tissue in all herniæ, and the only permanent relief consists in cutting out the overdistended and atrophied area of fascia and bringing into apposition the edges of the strong, well-nourished areas that have either resisted, or have not been subjected to, the destructive pressure. In the relief of cystocele, however, the bladder does not adapt itself to the new condition so readily as the intestines do after an operation for inguinal hernia. The base of the bladder, by reason of the diminution in the extent of the vaginal wall, is thrown into wrinkles and folds, producing pockets in which the urine may accumulate, be retained, undergo decomposition, and inaugurate the unfortunate sequelæ of cystitis, calculus, ureteritis, pyelitis, etc. Some way must be provided, therefore, for smoothing out the redundant tissue of the bladder wall produced by the operation upon the fascia. This is all accomplished in the author's procedure, as follows:

The Author's Operation for Cystocele.—This device has for its object the attainment of two distinct results: First, to free the wall of the bladder from all connection with the vagina, as the contents of an inguinal hernia are freed from the sac, so that all of the overstretched vaginal sheath or fascia, and vaginal mucous membrane as well, may be cut away and the well-nourished areas secured for support of the bladder; and, second, to smooth out the redundant base of the bladder produced by thus diminishing the size of its capsule. The technique of the operation is as follows: A transverse incision is made through the vaginal wall just in front of the cervix, as for vaginal hysterectomy. Through this the bladder is dissected from the uterus and the peritoneal cavity entered, the peritoneum being torn well out to either side. A longitudinal incision is then made in the anterior vaginal wall from the middle point of the transverse incision to the neck of the bladder. Through this the bladder wall is freely dissected from the vaginal wall on either side until its base is set entirely free. The bladder is now rotated upon its transverse axis, the base being carried up against the face of the uterus and stitched there with chromicized catgut. In doing this the surgeon should select, in the base of the bladder, a point so situated that by stitching this particular part of the bladder to the uterus he will cause all the slack between the latter organ and the symphysis pubis to disappear. He should next select, on the sides of the bladder, two other points equally distant from the median line and on the same level with the points first selected, and by means of sutures he should firmly attach these two parts of the bladder-wall to the torn edges of the peritoneum on the face of the broad ligaments. In doing this, however, he should be careful to insert the sutures into each broad ligament at points far enough removed from the median line to cause them, when tied, to take in all the slack in the base of the bladder from side to side. The effect of this mode of employing sutures is to stretch the bladder taut and smooth in every direction. The fascia and mucous membrane along the longitudinal line of the vaginal incision are now trimmed off sufficiently to make them fit snugly the base of the bladder, and they are then to be stitched together with interrupted sutures of chromicized gut. The dressing consists of a light packing of gauze in the vagina. In cases in which lacerations of the cervix and perineum complicate the cystocele, these injuries should be repaired at the same sitting. If displacement of the uterus also exists, this may be relieved by shortening the round ligaments through the anterior vaginal incision previous to stitching up the bladder.

IV. DISEASES OF THE VULVA.—The vulva, the pudenda, or the external genitals of the female, comprise all the structures immediately external to the hymen and surrounding the entrance to the vagina. Anatomically these parts are very distinct. Posterior to the hymen are the fossa navicularis, the posterior commissure or fourchette, and the perineum. Anteriorly are the urethral orifice, the vestibule, the clitoris, and the mons veneris, and at the sides the labia minora (sometimes called the nymphæ because they preside over the water brooks), and the labia majora. It is important to recognize the position of certain ducts opening in the mucous membrane of these parts. The most important of these are: the Bartholinian ducts, which supply an exit for the secretions of the glands of the same name, and whose orifices lie at either side of the hymen and exterior to it; and the mucous crypts known as Skene's glands, which may be found inside the meatus urinarius. These ducts, as well as the meatus, are the frequent foci of inflammation in the mucous membrane of the vulva. The hymen marks the boundary between the external and internal organs of generation, and may be classified as belonging either to the vulva or to the vagina. When intact, or in its caruncular form after rupture, it participates in all inflammatory processes of the vagina or vulva.

The function of the vulva is to close the entrance to the vagina and to protect it against the entrance of air, dust, and bacteria. This is accomplished not only by the contact of the labia due to their anatomical position, but by the adhesive secretions which cover their internal surfaces and agglutinate them together. The importance of this function has become clearer during recent years, as we have realized that air and dust are the carriers of bacteria, and that bacteria are the source of inflammation.

The *hygiene of the vulva* is a subject that has been sadly disregarded, and yet is of supreme importance in preserving the health of the genital organs of girls and of women. In the proper observance of the laws of hygiene applicable to these parts lies the prophylaxis of many of the inflammations of the genital tract. Only the commonest attention to cleanliness is necessary to prevent the accumulation of secretions in the creases and folds of the pudenda, and yet it is a very common experience in examining women, even of the better class, and those who would be insulted if they were told that they were not cleanly, to find accumulations of smegma, in the sulci between the labia minora and majora and about the clitoris, discolored with dirt and of most unpleasant odor. Muco-purulent discharges also frequently escape between the labia and smear their external surfaces. Such secretions afford a lodging-place for the clouds of dust that roll up from the street under the women's skirts, and become culture media for all sorts of micro-organisms, which travel from these foci along the genital tract to the vagina, cervix uteri, fundus, and Fallopian tubes. The proximity of the anus is another source of bacterial infection, and therefore in women especially it demands hygienic care. These parts certainly demand as frequent bathing as the face, and should be thoroughly cleansed with soap and water at least once every day. Open drawers, so commonly worn by women, expose these parts to contact of street dust. They should never be worn The tight drawers afford the only efficient protection against street dust and sudden changes of temperature, in both old and young. Women should also be taught to change the napkin frequently during the monthly molimen, whether it becomes saturated or not. Menstrual discharges take on fermentation very promptly, and when kept for several hours in contact with the heated parts about the vulva, they not only make the individual offensive, but become active sources of infection to the genital tract. If the menstrual flux is free or excessive, the necessity for frequent changes of napkin can be obviated by taking a tepid aseptic vaginal douche for cleansing purposes once or twice each day. By having the temperature of the fluid used in the douche at 110°–115° F., the amount of the flow can be materially lessened or entirely interrupted. When the douche is used simply for cleansing purposes, the temperature of the water should not be above 100° F.

Through tradition as well as in accordance with the Hebrew law it has long been accepted as axiomatic that a woman should not bathe during the monthly molimen. A moment's reflection should satisfy any reasonable person that such teaching is unwise. If there is ever a time in a woman's life when she needs a tub bath it is during the days of menstruation. During this period not only are the glands of the genital tract stimulated to an unwonted degree, but the cutaneous glands of the groins and axillæ, and indeed of the entire surface of the body, take on unusual activity. These sudoriferous and sebaceous excretions, if not removed by the daily bath, undergo fermentative changes, become rancid and foul-smelling, rendering many an otherwise attractive creature anything but an agreeable companion. Women are aware of this, and, to overcome it and make their presence less offensive, they saturate their handkerchiefs and clothing with perfumery of all kinds. In the mean time the pores of the skin become occluded with accumulations of excretions, the glands cease to do their physiological work, and the woman suffers from headache and indigestion.

Malformation of the Vulva.—The key to all malformations is usually to be found in the embryology of the affected part. The malformation is the result either of a lack of development, an excessive development, or a misdirected development. In the vulva the first and simplest form, although not the most common, is illustrated by what is known as the infantile vulva, *i.e.*, the character of the vulva during infancy persists into adult life. The labia majora are less developed than the other parts, the vulvar cleft being more exposed to view. The mons veneris is lacking in prominence, and there is absence of hair. The persistence of this form of the vulva is usually indicative of imperfect development of the internal generative organs as well. The type of excessive development is seen in cases of double vulva. Three such cases have been observed and recorded. In these there were two vulvæ situated side by side in the interfemoral space. The type is exhibited in what is known as pseudohermaphroditism, in which there is such an excess of development of some parts and lack of development of others, or such a confusion of development of the apparent organs of both sexes that it becomes difficult to decide to which sex the individual belongs. Such cases are rare, and are interesting as curiosities or freaks of nature rather than as cases for medical or surgical treatment.

A condition of practical importance is that of *vulvar atresia.* This is produced by more or less permanent adhesions between the labia of opposite sides, thus apparently obliterating the vulvar cleft. There is usually a small opening anteriorly, through which the urine finds exit with greater or less difficulty, but the menstrual discharge is frequently retained in these cases. But even if the discharge be not retained, trouble is apt to arise when attempts at sexual intercourse are made. The labial adhesions may give way under this pressure, or it may be necessary to dissect them apart. Sometimes the labia may be torn apart, but if this occurs in the nuptial bed serious hemorrhage may result. Adhesions may not be confined simply to the labia; they may also involve the clitoris and the prepuce, or adhesions between these parts may exist independently. This condition is analogous anatomically to the adherent prepuce in the male, and may be attended with similar nervous symptoms, even persisting to adult life. The treatment consists in freeing the tissues from these adhesions. This may be accomplished in some cases by simple manipulation with the fingers. In other cases, however, the adhesions have become so thoroughly organized as to require careful dissection under general anæsthesia.

Vulvo-vaginal Anus.—This malformation, known under various names as anus vulvalis, vulvar anus, atresia ani vaginalis, or atresia ani vestibularis, is the result of arrested development at the cloacal stage. There is no anal opening in the normal position, the contents of the rectum finding exit through an opening near the site of the hymen, either external or internal to it. There may be two openings near to each other, or one may be at the normal site of the anus and the other at the hymen. In some of these cases the patient may have satisfactory control of the movements of the bowels. Under such circumstances the discovery of the condition may be entirely accidental, and no surgical interference is required. But when fæcal incontinence exists, operative measures become necessary. The effort of the surgeon should be to make an artificial anus at the normal seat of that orifice. Control may be secured by splitting the fibres of the levator ani muscle and dragging the rectum through to secure sphincteric control, or the rectum may be twisted upon itself 180° for the purpose of securing a valve-like action, or both devices may be employed. To relieve this condition effectually requires all the ingenuity of the most experienced plastic surgeon. Some authorities advise delaying all interference till the age of puberty. But there are many reasons for the opinion that the earlier the abnormality is relieved the better. In the young and formative years nature will do more toward developing sphincteric control than in later years. Moreover, by early repair the child will be saved years of discomfort and embarrassment that would necessarily retard its mental, moral, and physical development.

Analogous to the condition just described are the malformations known as *hypospadias* and *epispadias*. In the former the posterior wall of the urethra is lacking, and in the latter the anterior wall. Epispadias may be accompanied by extroversion of the bladder or by extension of the sinus to the clitoris, dividing it into two parts. The one symptom of these conditions is incontinence of urine. Control may be secured by plastic operations, and in cases in which sufficient length of urethra can be secured for the purpose, the urethra may be dissected out and twisted on its longitudinal axis one-fourth or one-half the circumference of a circle and stitched in that position.

Injuries of the Vulva.—These may be due to external violence, to coitus, or to parturition, and are serious on account of the profuse hemorrhage that is apt to attend them. The patient may fall astride a stepladder or the back of a chair, or as a child she may fall on a picket fence, or in sliding down an incline may transfix these parts on any pointed object. There is on record the case of a child who, on sliding down from a haymow, came astride the sharp stake of a hayrack. The stake entered at the vulva, passed up through the abdomen, and made its exit below the ninth rib of the left side, entirely transfixing the body. It is noteworthy that the child recovered and lived for three years, dying finally of scarlet fever.

Bicyclists may be thrown from their saddles upon the frames or handle-bars of their wheels and receive serious injuries of the vulva. Coitus rarely produces injuries except in cases of rape in children and women of advanced years. In such cases damage is done to the hymen, the fourchette, and the posterior wall of the vagina. In parturition the vulva may suffer from contusions or lacerations by the head of the child or from the unskilful use of the forceps. In cases of external violence and in puerperal cases it is well to remember that there may be deep hemorrhage into the connective tissue, resulting in hæmatocele. The tumor thus formed may be small and inconspicuous, or it may assume large proportions, dissecting into the connective tissue of the pudenda, and even spreading up into the abdominal wall. The tension upon the external tissue may be so great as to cause rupture of the walls of the tumor and allow the clots to escape. If an artery is involved in the injury, the condition may be converted into one of actual hemorrhage. In a small hæmatocele the clot under gentle pressure usually becomes absorbed, but in cases of severe contusion or of excessive hemorrhage gangrene may supervene. The symptoms of pudendal hæmatoma or hæmatocele are rapid swelling of the labia and pain. Discoloration of the skin follows, the color changing from red to blue and green, and, as absorption progresses, to bronze. The tumor at first is tense, but gradually it becomes boggy and soft. If the hemorrhage is copious, there may be symptoms of shock. The treatment consists in stopping the hemorrhage, if still in its active stage, by applications of ice, or by pressure effected by means of pads and bandages. If this is not effectual and the tumor continues to develop rapidly, it may be necessary to cut down upon the bleeding vessels and secure them by ligature. If in due time absorption does not set in, and the tumor shows signs of breaking down and suppurating, with more or less elevation of temperature, the tumor must be treated as an abscess, *i.e.*, by free incision and drainage.

Vulvitis.—If we accept the modern scientific dictum that all inflammation is the manifestation, or the result, of an invasion by micro-organisms, inflammations of the vulva may be classified according to the genus of the infecting organism. But, as all the infecting germs have not yet been discovered, and as the part played by each organism in a mixed infection has not been positively determined, the clinical picture, the signs, and symptoms must still be depended upon in many instances as a reliable guide to diagnosis and treatment. Irritating discharges from the vagina, which spring from gonorrhœal or from septic inflammation of the vagina or the uterus or from cancerous ulceration of the cervix, may cause inflammation of the vulva. The infection may come from without or from the morbid germs carried in the discharges. In such cases applications of silver nitrate in solution (1 in 20), should be made to the external parts after they have been thoroughly cleansed, and then some protecting ointment, as oxide of zinc, should be applied. At the same time vigorous treatment must be directed to the cause of the disease.

Aphthæ or thrush of the vulva is an infection similar to that which invades infants' and children's mouths. It is apt to attack nursing women. The infecting agent is the vegetative organism oïdium albicans. The disease is characterized by a white exudate elevated on an inflammatory base. It occurs in discrete patches. The treatment consists in bathing the parts thoroughly with a solution of bichloride of mercury (1 in 2,000),—the procedure to be repeated daily.

Chancre and chancroid of the vulva have the same significance and characteristics as the same lesions in other parts, and the treatment is the same.

Diphtheria of the vulva is found almost exclusively in puerperal women, although it may attack children. It is usually ushered in by a severe chill, followed by a sharp rise of temperature to 104° or 105° F., and a rapid and feeble pulse. Inspection reveals the presence of the yellowish-gray membrane containing the Klebs-Loeffler bacillus. Thorough antiseptic washes should be employed and prompt constitutional treatment instituted. Full doses of antitoxin hypodermatically are the sheet anchor.

Erysipelas of the vulva is due to the invasion of the streptococcus erysipelatis, and is recognized as a desperate condition. It may follow operations upon the external genitals, may appear without warning as a complication of diabetes mellitus, especially in aged women, or may be the first stage in the march of invasion of a puerperal sepsis. In the last instance the serious symptoms manifest themselves in the uterus and adjoining structures. The rich supply of lymph spaces and channels in and about the pudendal structures afford a good field for the spread of this particular infection, and the treatment should be prompt and vigorous, both sustaining and local. Iron internally and lead and opium wash externally still hold as the specifics. The bowels should be kept freely open with salines.

Skin Diseases of the Vulva.—Skin diseases have been treated very fully in the articles devoted to them, but there are certain localized conditions of the skin of the external genitals which come more directly under the care of the gynecologist, and which may therefore properly be considered here. Among these may be mentioned such common affections as intertrigo, erythema, and eczema, all of which are largely the result of filth. Thorough and persistent attention to cleanliness, and, in aggravated cases, the employment of soothing lotions or dusting powders, constitute all the treatment that is called for.

Folliculitis is a pustular eruption due to the invasion of the hair follicles by the staphylococcus pyogenes albus, aureus, or citreus. The entire skin surface of the vulva may be completely covered with conical-shaped pustules, each having a hair springing from its summit. The disease is apt to occur in anæmic, debilitated women, but is due directly to lack of cleanliness. Sometimes the skin is red and inflamed, and burning and itching may be present. In other cases there will be no unusual sensation whatsoever, the pustules being discovered by accident, as it were, after they have invaded a large area of tissue. Constitutionally the treatment should be sustaining, and locally the application of strong antiseptics is indicated. Moist dressings of bichloride of mercury, 1 in 2,000, or carbolized or sulphurated ointments, may be applied to the affected skin, for the purpose of promptly destroying the infecting agent. Epilation is usually unnecessary.

Herpes genitalis has already been discussed in sufficient detail in a previous volume (Vol. IV., page 685).

The parasitic affections of the vulva, *i.e.*, the common ones, are eczema marginatum, or ringworm, and the irritation caused by the pediculus pubis. The former appears in reddish, moist, pigmented areas, of circular or curved form, and with raised borders. Over the surface of these areas are scattered small vesicles or pustules with yellowish crusts. These may be confined to the labia or they may spread back to the anus or forward over the mons veneris and abdomen, and out on to the thighs. The sovereign remedy is sulphur, either in the form of sulphurous acid on compresses, or as one of the sulphur ointments. The pediculus or louse that infests the hairy parts of the pubes is a crab-like insect, and can be found holding fast to a hair, and inserting its proboscis into the sebaceous follicle, from which it derives its sustenance. It produces an intense itching. When the presence of the parasite, however, is once discovered, relief is promptly secured by one or two applications of mercurial ointment (blue ointment), which destroys both the insect and the nits.

Pruritus Vulvæ.—Many affections of the vulva are attended with the most intense burning and itching. In neurotic patients it becomes absolutely intolerable, and in some instances causes loss of sleep, physical exhaustion, and nervous depression leading to melancholia and other forms of insanity. The distress may be aggravated by the effort to procure relief by scratching or rubbing the parts. In this way sexual excitement and orgasm are produced and a habit of masturbation is established.

Pruritus is only a symptom, but like dysmenorrhœa it is so common and persistent, and withal so obscure in its etiology, that it demands a special chapter for itself in all gynecologic treatises, even the most recent and scientific. It will be treated here under the following headings: Puerperal pruritus, diabetic pruritus, parasitic pruritus, and neurotic pruritus—also termed kraurosis vulvæ.

Puerperal Pruritus.—Pruritus is not an unusual accompaniment of pregnancy, and may arise at any time during the period of gestation. At this time the secretions from the glands about the vulva and vagina are markedly increased, and, unless the patient is scrupulously clean, they are apt to become culture media for irritating microorganisms.

In this variety of pruritus, as in all cases of this affection, the parts should be carefully inspected to exclude parasites, the urine should be examined to exclude or confirm the presence of diabetes mellitus, and the amount of the local secretions should be determined.

If parasites or diabetes be present, the appropriate treatment should be applied; otherwise hygienic measures should be prescribed, including sitz-baths and vaginal douches of bichloride of mercury or carbolic-acid solutions. Local applications of black wash (oxide of mercury), carbolic-acid solution (1 in 40), or Unguentum zinci oxidi are also efficient.

Pruritus is one of the early symptoms of diabetes mellitus, and in all cases of itching and burning of the vulva the urine should be examined for the presence of sugar. The exhibition of appropriate treatment for this disease will permanently relieve the local symptoms. Local applications, similar to those recommended above, may be necessary for immediate relief.

The two parasites that most commonly infest these regions are the pediculus pubis and the trichophyton tonsurans or ringworm. The former seeks its habitat among the hairs of the pubes, gaining its sustenance from the sebaceous glands about the hair follicles. It hangs with its head seemingly buried in the skin, and is difficult to remove. This insect is commonly known as the crab louse. It deposits its eggs or nits on the hair shafts. Two or three applications of Unguentum hydrargyri (blue ointment) will destroy both the insect and the nits. Kerosene oil also acts efficiently.

Kraurosis vulvæ is characterized by a withered, parchment-like appearance of the surfaces of the labia majora and the external surfaces of the nymphæ. It may also extend to the mons veneris and the tissues about the clitoris. The folds are gradually obliterated, and there is a general contraction of the introitus vaginæ. Intercourse is extremely painful, and an intolerable burning and itching persist during the early stages. These latter symptoms may become intermittent as the disease progresses. In the early stages there may be thickened, hypertrophied areas of skin which are sensitive to the touch; they are interspersed throughout the areas of sclerosed atrophic tissue. Gradually the whole surface becomes atrophic and takes on the parchment-like appearance. The disease, which comes late in life, usually after the menopause, is a progressive one, and is relieved only by the removal, by dissection, of all the vulva. It is not necessary to postpone the operation until the disease has become self-limited. The amount of tissue removed is of no great importance except that it should include all that may possibly be invaded. The operation consists in making an incision, at the junction of the skin and mucous membrane, from the clitoris around the entire circumference of the introitus. A second incision, concentric with the first, is made through the skin around the entire vulva at the outer margin of the invaded tissue. The tissue included between these two incisions is next dissected out. The edges are then coaptated by interrupted sutures of chromicized catgut or silkworm gut. Bleeding parts may be secured by ligature, but the general oozing is controlled by the sutures. In cases in which the disease invades the mons it is necessary to include the clitoris in the exsected tissue. A strong ligature of catgut, transfixing the clitoris at its base, will control hemorrhage from the vessels of that organ. In applying the stitches the parts should be adjusted, as the necessities of the case require, to give nice apposition.

Hypertrophy of the Vulva.—Hypertrophy of the clitoris is not uncommon. It may be congenital or acquired. It usually accompanies those malformations which go to make the pseudohermaphrodite. Fehling has reported the case of a girl, twenty-one years of age, with a clitoris five inches long, an inch and one-half thick, terminating in a glans one inch long. Hypertrophy of the labia minora, especially elongation, is not infrequently met in gynecologic practice. Certain pathologic processes may produce this; it may also be congenital or it may be the result of manipulation. As is well known, the Hottentot apron is simply the enormously elongated nymphæ produced by manipulation practised upon the female children from infancy. Elephantiasis vulvæ is a pale or grayish-white tumor arising from any or all of the pudendal structures. It may attain a large size, reaching to the knee. It is composed of fibrous and subcutaneous connective tissue and enlarged and numerous lymph vessels. The surface may be smooth or warty, and when the lymphatic tissue predominates the tumor may present the appearance of a bunch of grapes. Various venereal affections may accompany this condition. The treatment is surgical and consists of radical removal of all the hypertrophied tissue.

Condylomata, or venereal warts of the vulva, present the appearance of warty growths springing from the mucous membrane or from the skin of the vulva. They are auto-inoculable, and may spread on to the mons and down over the perineum and anus, and even on to the thighs. They may be due to simple filth infection of the papillæ of the skin or they may spring from the inflammatory base of a gonorrhœic or syphilitic infection. In rare instances these excrescences become confluent and form large cauliflower-like masses resembling carcinoma. The clinical symptoms and the microscopic examination will give a well-marked differential diagnosis. The treatment consists in their removal either by caustics, by the galvano- or thermo-cautery, or by the scissors. They are apt to bleed profusely when curetted or cut away, and it becomes necessary to touch the base with caustics, with perchloride of iron, or with a strong solution of salicylic acid (ʒ i. ad ℥ i.). In some instances it may be necessary to put in catgut sutures to control the hemorrhage.

There are tumors of the vulva which cannot properly be classified as neoplasms, but which nevertheless demand attention here for the purpose of presenting the factors involved in a differential diagnosis. These are intestinal hernia, omental hernia, hernia of the ovary, and cyst of the vulvo-vaginal gland. Intestinal (inguinal) hernia may appear suddenly during a supreme effort at lifting, or as a result of a sudden and unexpected strain, or it may come on gradually. It is usually pyriform with the larger base below, and on percussion it gives the tympanitic note. It may or may not be reducible. Hernia of the omentum gives the same clinical features with the exception of the tympanitic note. Hernia of the ovary is apt to be congenital, but not always. The tumor is small, sensitive, generally irreducible, and it increases in size and becomes painful at the menstrual period. Ovarian hernia occurs also in women whose abdominal walls have been relaxed by frequent and repeated gestation. In these cases the Fallopian tube may be present with the ovary, a coil of intestines and the omentum. The presence of the ovary is manifested by the characteristic dull, sickening pain, aggravated at menstruation to a degree of acute suffering, and by nausea and exquisite tenderness on pressure. In these latter cases the hernia may be reducible, but in congenital cases the ovary is usually fixed.

The treatment of ovarian hernia is surgical, but in all instances, in which this is possible, the ovary should be returned to the pelvic cavity and the hernial opening permanently closed. In exceptional instances, however, extirpation of the ovary is the only resource available, but this must not be undertaken without a recognition of the possibility that it may be the only ovary that the patient possesses, and that the operation is not by any means devoid of risk.

Cyst of the vulvo-vaginal gland is an affection of so great frequency and importance as to demand a separate and independent article (see article on *Bartholin's Gland*, Vol. I., p. 734).

Varicose tumors of the vulva occur frequently during pregnancy. In some cases they cause great pain; in others they burst and occasion serious hemorrhage. Gentle massage and pressure are sometimes efficient in emptying the veins, but the condition may become so extreme, even during pregnancy, as to demand operative procedure. A ligature *en masse* or a mattress ligature may be applied, and the tumor cut away; or the skin may be incised at the base and a catgut ligature applied, after which the skin may be sutured over the stump. Complete asepsis must be observed.

Cancer of the Vulva.—Primary malignant disease of the vulva is comparatively rare. Histologically, it may be epithelioma or sarcoma. Topographically, it may originate in the clitoris, the peri-urethral tissue, the labia, or the perineum. It occurs late in life, with the greatest frequency between forty and sixty years of age. The neoplasms are characterized by a rapid and extensive new formation of tissue and a tendency to early ulceration. The lymph glands, especially those in the inguinal region, are usually involved. The secretion consists of a serous or bloody fluid with a fetid odor. When the peri-urethral tissue is involved the urethra, by vaginal touch, is felt as a round, hard cylinder. The tendency of the disease is to spread internally, the vagina, the rectum, and the bladder being successively involved. The earliest symptom may be a pruritus, but, as the disease advances, the pain becomes increasingly severe. The progress of the disease, if it has not already advanced too far, may be arrested by complete extirpation either with the thermo-cautery or with the knife and scissors. The *x*-ray gives promise of a permanent cure in many of these cases. In those in which ablation is not practicable or the *x*-ray fails to cure, palliative measures consist in thorough and frequent cleansing by douches and antiseptic washes and in the employment of iodoform gauze dressing. The best deodorizers and disinfectants are bichloride solutions, ichthyol, carbolic acid, and formaldehyde. Anodynes are required, both locally and hypodermically, and as frequently and in as full doses as may be necessary to relieve the suffering.

V. VAGINITIS.—*Definition.*—Vaginitis is an inflammation of the mucous membrane which lines the vaginal canal. It appears in all grades of severity, from a simple blush of color, with slight heat and dryness, to the most virulent inflammatory action with its attendant constitutional symptoms.

No period of life is exempt from it. It is met with in young girls, in women during the child-bearing period, and in women who have passed the climacteric.

It is most important to distinguish the two varieties—simple or non-specific, and specific or gonorrhœal. They differ primarily in their cause or etiology, and in their remote effects; the one when uncomplicated being attended with only a certain amount of personal discomfort and a limited impairment of general health, while the other may involve, in its later manifestations, serious inflammatory action within the peritoneal cavity—an inflammation which may result in chronic invalidism or even in death.

For convenience of description the subject will be considered under two heads: Simple or non-specific, and specific or gonorrhœal. Simple vaginitis demands consideration under three heads, as it appears: I. In girls prior to puberty; II. In unmarried women; III. In married women.

VAGINITIS IN CHILDREN.—Vaginitis in young girls between the ages of three and seven, and even later, is a very common affection. It usually shows itself in the form of a chronic catarrh. But it may vary in severity from this mild subacute inflammation to one attended with copious discharge and pain, with swelling and excoriation of the labia. The vulva and vagina, as far as can be seen, are sensitive and red, and even the buttocks and inner surface of the thighs may be inflamed and irritated. As a complication in children, it must not be forgotten that gonorrhœal peritonitis is not uncommon, the infection reaching the abdominal cavity through the Fallopian tubes. Forty cases of this character have been collected from the literature. A mistaken diagnosis is apt to be made, owing to the fact that the appendix is naturally involved in the general inflammation. The condition should be suspected in every case of general peritonitis occurring in young girls between the ages of four and seven, and examination of the vaginal secretions should be made in every case. The prognosis is favorable if the abdomen is promptly opened and the intestines are washed with decinormal saline solution and argyrol (two to five per cent.).

Causes.—It most frequently occurs in weak or strumous subjects, and results from lack of cleanliness. It may arise from "taking cold." In the light of our present knowledge, however, we must understand by this simply a lowering of vitality which affords opportunity for some infectious germs already present to secure a foothold. Seat-worms are a frequent cause, owing to the intense itching they excite, which induces the patient to rub and scratch the parts, usually with dirty hands and finger nails. Or these parasites may find their way into the vagina and inflame the parts by their presence. Self-abuse must also be reckoned among the causes of this disorder and should be ever present in the mind of the physician when he is consulted for this trouble, especially if the case is an aggravated one or persistently does not yield to treatment.

Gonorrhœal poison is also the occasional cause. Dr. J. Lewis Smith records the case of a young man who was under treatment for gonorrhœa, when his two nieces, four and six years of age, respectively, both became infected with specific vaginitis, probably from the towels.

Purulent ophthalmia, which is usually considered the accidental accompaniment of specific vaginitis, may itself be the origin of the vaginal affection. They are reciprocally dependent.

The exanthemata are frequently accompanied and followed by a vaginal catarrh, due either to the direct action of the disease upon the membrane, as occurs in otorrhœa, or to the reduced condition of the vital powers.

Treatment.—The parts should be bathed frequently in warm water and all excoriated surfaces smeared with a protective ointment. Astringent injections thoroughly administered with a glass or hard-rubber syringe are usually necessary, and in some instances must be continued for days and weeks. Tannin or alum solution (five per cent.), sulphate of zinc (two per cent.), nitrate of silver (one per cent.), are all efficient injections and should be administered twice each day. I have found a combination of iron and potash in the usual proportions for a gargle very satisfactory: Tinct. ferri chlorid., ʒ ij.; potass. chlorat., ʒ i.; glycerinæ, ℥ ss.; aq. ad ℥ iij.

When ascarides are present a dose of castor oil should be given, to be followed for several days by daily injections of salt water, lime water, or infusion of quassia, in both rectum and vagina. In the mean time the general hygiene and nourishment of the child, together with appropriate tonics, must not be neglected. Caution must also be given regarding the danger of purulent conjunctivitis and ophthalmia from the infectious discharge. When masturbation is present, of course the child must be put under proper surveillance and restraint.

VAGINITIS IN UNMARRIED WOMEN.—Simple vaginitis is rarely a primary affection, being secondary to some inflammatory condition in neighboring organs of the pelvis. As a rule, it begins and continues in a subacute form, but this may at any time take on the character of a violent acute inflammation. On the other hand, the acute form may be excited primarily by some special cause and may gradually pass into the chronic. It is important to determine early in the treatment of the case whether the inflammation be primarily in the vaginal mucous membrane or whether it be induced there by the irritating qualities of a discharge coming from some source beyond the vagina; viz., the cervix, the uterus, the Fallopian tubes, or even a pelvic abscess. Thomas mentions the fact that he has seen two cases of profuse and obstinate vaginal discharge, regarded as the result of vaginitis, which were in reality produced by pelvic abscesses which emptied their contents into the upper part of the vaginal canal. He says: "An element in such cases calculated to mislead the superficial examiner is the fact that vaginitis does really exist to a limited extent as the result of the purulent flow from the abscess."

Etiology.—When the disease is primary, in unmarried women, the most frequent cause is "taking cold." It may arise from undue retention of the menstrual discharge behind a too constricting hymen, where, through contact with the air, it undergoes decomposition and so becomes a source of irritation. Self-abuse is an occasional cause.

Anæmic young women, with a nervous erotic temperament, will often have a constant leucorrhœa with an irritated condition of the vulva and vaginal walls. In these patients the affection is due simply to the vitiated condition of their general health. In our large cities the shop-girls or clerks are the class of patients in which this condition is most often found. The custom of compelling these girls to stand constantly, long hours in succession, in the cramped and narrow spaces behind the counter in crowded stores in which the air is vitiated, produces most disastrous results. Finally, tight lacing, by crowding the viscera down toward the pelvis and by keeping them in a constant state of passive congestion, greatly favors the perpetuation of the disease which we are now considering.

Diabetes is an occasional cause of vulvitis and vaginitis. Accompanying this disease is usually an intolerable itching of the vulva and mons veneris. Through scratching for its relief and the repeated bathing of the labia with urine there is set up an inflammation of the vulva that extends sometimes well into the vagina. It is very intractable, on account of the ever-present irritant.

VAGINITIS IN MARRIED WOMEN.—In married women, especially those who have borne children, simple vaginitis is not uncommon. In addition to the causes common to all women, as chilling of the body, want of cleanliness, pediculi, ascarides, diabetes, etc., they are much more frequently subject to uterine affections than are the unmarried. Among such affections may be mentioned lacerations of the cervix and the diseased conditions resulting therefrom, the disorders dependent upon rough or excessive intercourse, upon the use of pessaries, which abrade the mucous membrane or simply act as irritants, and upon the accidental contact of irritating substances used for application to the uterus, *e.g.*, chromic acid. Boroglyceride, which is universally employed for saturating vaginal tampons, may, if used in too great strength, not only set up a general vaginitis but cause deep abrasions. The author in consultation recently has had occasion to point out to a colleague the fact that his boroglyceride tampons (fifty per cent. boroglyceride) were the cause of deep and extensive abrasions in the posterior vaginal fornix.

The most frequent cause of a vaginitis is an irritating discharge from the cervix or uterus. In these cases the irritation usually commences at the vulva, where the secretions come in contact with the air, and undergo decomposition, which renders them still more irritating. From this point the inflammation gradually travels back throughout the entire extent of the vagina.

Symptoms and Treatment.—The subjective manifestations vary with the intensity of the inflammation. In very mild cases the patient is conscious simply of a leucorrhœa with slight itching or burning.

A careful examination both by touch and by sight with a Sims speculum is most important. The vagina should be carefully swabbed out and dried with absorbent cotton. By this means the amount and extent of the inflammation can be learned, its primary or secondary nature ascertained, and the cause usually determined. Treatment can then be directed with intelligence and some degree of scientific accuracy. As the affection in this mild form is usually secondary, it demands only palliative treatment, the main efforts being directed to the original cause. Cleanliness and the soothing and astringent effect of heat, both of which are obtained by the hot-water douche, are usually sufficient to relieve the symptoms. Recovery is hastened by brushing the inflamed tract thoroughly with a solution of nitrate of silver, twenty or thirty grains to the ounce. A vaginitis, it must be remembered, is frequently aggravated and, indeed, sometimes induced, by the poor quality of the glycerin used on vaginal tampons. This is frequently a source of great annoyance, as it is not generally understood.

In an acute attack the clinical features differ very little, and in some cases not at all, from the specific form of the disease. The description of both is therefore embraced in the one account given under the head of Specific Vaginitis. The treatment is also the same for both affections.

SPECIFIC VAGINITIS.—Synonyms: Gonorrhœa in the female, Gonorrhöe, Vaginite, Blennorrhagie, Blennorrhœa, Elytritis.

Definition.—Gonorrhœa in the female is an inflammation of the genital and urinary passages, characterized by a purulent discharge which has been produced by contact with an infecting substance, as the result usually of sexual intercourse. It may run a very acute course and then become chronic. It may be subacute in its inception, and may slumber in this relatively inactive state for years or until aroused to an acute manifestation by some disturbing element. In an acute case, when first seen, the inflammation is usually coextensive with the entire visible mucous membrane of the genital tract, but it may be limited in extent and confined to the vulva, the urethra, the vagina, or the cervix uteri.

Hardy, Rémy, and, more recently, Bumm, have pointed out the fact that the membrane lining the canal of the cervix uteri may be the original seat of the disease, the virus being absorbed by the cervix directly from the penis during the copulative act. Indeed, the last author maintains that the cervix is, as a rule, the primary seat of all gonorrhœal inflammation. He says: "Gonorrhœa never occurs primarily in the vagina, but usually spreads thence from the cervix, or, more rarely, from the urethra. The stratified pavement epithelium forms so good a protecting tissue that the gonococci cannot effect an entrance unless changes which render the more delicate layers accessible have occurred. Surfaces covered with cylindrical epithelium, viz., the interior of the cervix, are not so resisting."

The frequency with which the cervix is involved and the persistence of the affection in this locality mark it as a most favorable ground for the inception of the disease. The anatomical structure of the mucous membrane, as pointed out by Bumm, makes his *a priori* argument seem reasonable. This view is now accepted by the best observers.

The tendency of the disease, whatever locality it may invade first, is to extend throughout the entire tract of mucous membrane, from the vulva through the vagina, passing through the uterus, into and through the Fallopian tubes to the ovary, and invading the ducts of all the glands opening on all these surfaces.

Sources of Contagion.—There is no doubt regarding the identity of the disease in the two sexes. The gonorrhœal discharge from an individual of one sex, when applied to the genital mucous membrane of the opposite sex, produces a similar discharge, with the same intense and protracted symptoms. But cases occur in men after intercourse with women who, upon subsequent examination, present no sign of the disease. Furthermore, Ricord (and all his host of admirers and followers have insisted on the truth of his statement) declared that a man could acquire gonorrhœa by intercourse with a woman who did not have the disease. At the present time no such belief can be maintained. It seems far more reasonable, in the light of our present knowledge, to believe that, in these obscure cases, the woman, although apparently free from the disease, is in reality afflicted with a latent gonorrhœa.

"True gonorrhœa requires no idiosyncrasy, no ale or champagne, no excess, no weakened condition of the urethra for its development, but simply intercourse with a female [or male] having a gonorrhœal discharge. No abrasion of the membrane is necessary. Simply contact of the virus with the membrane is sufficient to establish the disease" (Van Buren and Keyes).

Latent Gonorrhœa.—The serious nature of gonorrhœa in women and the importance of early recognizing its presence, except for the purpose of avoiding contagion, are matters which have been sadly neglected. The idea of gonorrhœa has been so intimately associated with urethral trouble that unless that particular part of the body was affected no anxiety was experienced. As the acute symptoms rarely continue longer than ten days or two weeks, and then subside without leaving a urethral stricture in their train, this affection in women has been thought a comparatively simple and harmless affair. But since Dr. Noeggerath, in his now classic paper, pointed out the latent propensities of this vicious disease, attention has been more carefully centred upon it, and it is now receiving some of the consideration which its importance demands. The fact is recognized that, after a partial advance toward recovery, the disease may linger for years, and, by gradually extending itself, be the cause of cervical catarrh, endometritis, salpingitis, ovaritis, sterility, and the oft-repeated attacks of peri-uterine inflammation with which its victims are afflicted. But these unfortunate sequelæ not only follow an acute attack in which due warning of their impending arrival has been given, but they may be the first indication of trouble, so insidious is the disease in its latent form.

Dr. Noeggerath's views regarding the frequency of gonorrhœa in women were so extreme, and he insisted so strenuously on sterility as its inevitable consequence, that his paper met with almost universal dissent. This was in 1872. But the pendulum has now recovered its equilibrium, and the careful observer is daily recognizing in his practice cases which illustrate the correctness of the picture which Noeggerath so faithfully drew.

The tenets of Noeggerath's creed are that gonorrhœa, though apparently cured, may exist, in a latent form, in both the male and the female, throughout an entire lifetime; that this latent form may be transmitted to the female, to continue there in a quiescent state for an indefinite period, or, travelling along throughout the mucous tract, excite serious uterine, peri-uterine, or peritoneal inflammation, or at any moment burst forth into acute gonorrhœa. He undertakes to show that the wife of every husband who at any time of his life before marriage has contracted a gonorrhœa is, with very few exceptions, afflicted with a latent gonorrhœa, which sooner or later brings its existence into view through some form of disease of the uterus or its appendages.

While we may not give assent to the universality which Dr. Noeggerath claimed for this form of the affection, it embraces such a large class of cases that it is most important to recognize it, and I cannot do better than place before the reader Dr. Noeggerath's graphic description of a typical case.

"Mr. M——, a merchant of New York, formerly a commecrial traveller, like almost every one of his tribe, acquires a gonorrhœa. The treatment recommended by a renowned specialist is carefully followed, and the affection cured in two months. Two years later this gentleman marries a healthy, robust young girl. Three months later the woman begins to complain of backache and general malaise; it becomes difficult for her to attend to the common household affairs; the usual promenade, instead of being a pleasure, becomes fatiguing. Menstruation, which appeared hitherto without any premonitory symptoms, is now connected with backache, more profuse than usual, and followed by a white discharge. By and by the desire to urinate becomes more frequent, and is occasionally accompanied by burning at the meatus. The white discharge gradually extends from one period to the next. About eight weeks later a pain is felt in the left side of the abdomen, which suddenly increases, upon an unusually severe exertion, to such an extent that the patient has to take to her bed. At the same time the dysuria is increased, the discharge becomes profuse and of a greenish-yellow color, like matter. The physician attending her recognizes an acute attack of perimetritis.

"A year after this she consults me for sterility. I find her suffering from general weakness, backache, pain in the left side, increased before the now scanty menstruation, and a muco-purulent discharge.

"On examination the uterus is found in right lateroversion and anteflected; the left vaginal roof, or parts above, hardened and contracted; the uterus, soft, succulent, very tender on being gently pushed into its normal position, great tenderness of posterior cul-de-sac, cervix of a high color, surrounded by a thin rim of eroded tissue, discharging a tenacious yellow mucus; both outlets of Cowper's gland eroded to some distance and painful to the touch.

"In the history of this patient we find no trace of the existence of acute gonorrhœa either before or after marriage but a condition very like it, if not truly gonorrhœa, is being developed during the acute attack of perimetritis. The patient has never been infected, in the accepted meaning of the word, but she gradually develops a condition which we usually observe as the result of an attack of acute gonorrhœa."

These cases of latent gonorrhœa are distinguished from simple leucorrhœa in the following manner: If the upper part of the vagina be filled with a copious, glairy, greenish-yellow glue which adheres to the cervix tenaciously when the attempt is made to remove it, gonorrhœa is present. And even when the discharge is scanty, pellucid, white, or of a pale-straw color, it is gonorrhœa, if the five following conditions also exist: (1) If there is also a red, eroded, narrow rim about the os; (2) if there are signs of present or past peri-uterine inflammation; (3) if there is catarrh of the vulvo-vaginal or peri-urethral glands attended with condylomata in the fourchette or around the urethral orifice; (4) if the discharge is very difficult to relieve; (5) if it has developed, soon after marriage, in an otherwise healthy woman, without other morbific cause.

These clinical features are quite sufficient for a diagnosis; but if, in addition to them, the gonococcus be present, the cause of the trouble is at once made clear.

Thus, latent gonorrhœa accounts not only for a large percentage of the manifold troubles embraced under the terms peri-uterine and pelvic inflammation, but there is no doubt that some of the cases of puerperal fever supposed to be due to septic poison are really caused by a latent gonorrhœa; especially those cases in which the inflammation is circumscribed and the general septic condition is absent.

Symptoms.—The patient's attention is early attracted, usually from three to five days after the impure intercourse, by a sense of heat and burning in the vagina. This is followed by aching and weight in the perineum, a throbbing pain through the pelvis, a profuse purulent and offensive discharge, frequent desire to micturate, and swelling of the labia. A severe attack will be ushered in by a chill and sharp rise of temperature—103° to 104° F.,—anorexia, nausea, and general nervous excitation. The mucous surfaces about the vulva become excoriated, and the inflamed parts so sensitive that motion is very painful. If the nymphæ are large they may swell to such an extent as to protrude beyond the labia and become constricted, a condition analogous to paraphimosis.

Accompanying the discharge an almost intolerable itching about the vulva sets in. This is usually worse just when the patient gets warm in bed and wishes to settle down for the night, and it leads her to scratch and tear her person for relief.

As a rule the poison finds its way into one or both of the ducts of the vulvo-vaginal glands, which open just in front of the lateral carunculæ myrtiformes. Thence it may invade the gland and set up an abscess. This is extremely painful when once the capsule is put upon the stretch, and continues so until relief is afforded by the bursting of the abscess or by artificial evacuation.

All cases are not so severe. Instances occur in which the redness, swelling, and sensibility are but slight, and the discharge is scant.

Physical Signs.—When the parts are exposed to view, the labia are seen to be swollen and tense, the mucous surfaces smooth and red, or abraded and livid in color; at the same time they are sore and sensitive to the touch. As the labia are separated purulent matter of a creamy or greenish color, sometimes streaked with blood, is seen exuding from the vagina. In the cases which come under observation at the public clinic this discharge may bathe all the external parts, excoriate the perineum back to and around the anus, irritate the integument on the interior aspect of the thighs, and become mingled with the hair of the mons veneris, where it dries in yellowish crusts. The clothes are also soiled and stained with this yellowish discharge. To the touch, when digital examination is possible, the vaginal canal is found to be hot, the papillæ and rugæ rough and prominent. The introduction of the speculum is always painful, sometimes intolerable, and should be managed with great care. When exposed to view through a speculum (and Sims' speculum should always be used in these cases) the vaginal membrane presents a swollen, roughened appearance, the color varying in different cases, and in successive stages of the disease, from a bright red to a deep livid or leathery color, with patches here and there in which the mucous membrane is denuded of its epithelium. These superficial abrasions are found throughout the entire canal, including the vaginal surface of the cervix. About the external os is a ring of inflamed and granulating tissue, and hanging in the os is a mass of muco-pus. If a pessary has been worn, the imprint of it, when removed, still remains in the mucous membrane, and may be marked by abrasion.

The urethra may or may not be involved, the scalding which attends micturition being frequently due to contact of the urine with the excoriated vulva. When, however, the lips of the meatus are swollen and irritated, and pressure by the finger along the canal of the urethra from behind forward causes pus to appear in the meatus after the parts have been carefully cleansed, there can no longer be any doubt about the disease having involved the urethra. Formerly the involvement of the urethra was regarded as a diagnostic sign, but this is not now considered reliable.

Diagnosis.—The differentiation of the gonorrhœal form of inflammation from simple acute vaginitis is extremely difficult, and in some cases impossible, at least by a study of its clinical features alone. If a history of recent suspicious sexual contact or intercourse can be obtained, in conjunction with the well-known clinical manifestations, the question, for all immediate practical purposes, is settled. But final judgment rests absolutely upon the discovery of the gonococcus in the discharges. Microscopic examination must, therefore, never be omitted. In making a diagnosis, and to the same degree in applying treatment, the fact must not be lost sight of that gonorrhœa in woman does not always mean a vaginitis. The two sites of infection that are far more frequent than the vagina are the urethra and the cervix uteri. It is in the secretions from these two sources that the gonococcus must be sought. The secretions of the urethra may be milked out by drawing the finger, with graduated pressure, along the urethra from the neck of the bladder to the meatus. Discharges from the cervix may be obtained by a pipette or on a cotton swab rotated within the cervical canal.

Prognosis.—Can an acute case of gonorrhœa be absolutely cured? There is abundant evidence to prove that cases are so cured, and the physician is justified in assuring a patient that, with proper treatment, the probabilities are that such will be the result in her individual case. But the virus has the property of penetrating so deeply into tissues, and the abundant crypts and follicles and ducts and glands afford so secure a lodging-place for the infectious organism that the question of its total eradication is beyond all ken. The more recent the attack and the more limited the area of infection the more favorable the prognosis.

Treatment.—The importance of stamping out the disease promptly cannot be over-estimated. Whatever line of treatment is pursued must be followed up with the greatest thoroughness, persistence, and attention to detail.

If it be granted that the gonococcus is the causative agent, the use of the most efficient germicide is the indication *par excellence.*

Oppenheimer has made successive experiments to determine which parasiticide is most efficient against the gonococcus. His method of experimentation was to cultivate the gonococcus in sterilized blood serum, the micrococci developing on bits of thread suspended or laid in it. Different substances were then applied to the solution and their effects noted. Alum, bismuth, and acetate of lead were absolutely inert, as were also balsam of copaiba and extract of cubebs. Solutions of bichloride of mercury, 1 in 20,000; carbolic acid, 1 in 20; permanganate of potassium, 1 in 25; weak solutions of nitrate of silver, and a strong solution of either iodine, bromine, or chlorine destroyed the gonococci promptly. Regarding copaiba and cubebs, it is important to state that, by an ingenious experiment, he seems to prove that these substances undergo a chemical change in the system, the products of which change are destructive to the gonococcus. This accounts for the efficiency of these drugs in internal medication.

Conclusions reached by such purely experimental methods must be tested by clinical experience. Nitrate of silver not only acts efficiently in destroying the gonococcus in culture fluids, but is found most satisfactory also in stopping the discharge, relieving the congestion, and restoring a healthy tone to the tissues. Efficient as nitrate of silver has proved as a germicide, it has, when applied to living tissues, the unfortunate property of coagulating the albumin and forming a coating over the epithelial cells. This retards its penetration into the deeper structures and confines its influence to the superficial tissues. Quite recently the pharmacologists have evolved various proteid silver salts. These salts, which contain varying amounts of silver, are known under the following names: argonin, protargol (8 per cent.); albargin (15 per cent.); nargol, argentanin, argyrol (30 per cent.), and many others. Of these, argyrol contains the greatest proportion of silver and is coming into general use. It is highly soluble in cold or warm water and, when applied to inflamed tissues, either in weak or in strong solution, causes no pain or irritation. It does not coagulate albumin or precipitate the chlorides, and therefore is free from any caustic action. Its innocuousness is certified to by ophthalmologists, who assert that it can be dropped with impunity into the eye in strengths of from five to twenty per cent., and that it produces most beneficial results. Moreover, these proteid salts have great penetrating action on vital tissues. A strand of catgut immersed over night in a one-per-cent. solution of argyrol was found to be impregnated through and through with the silver. Fresh stains on linen may be readily removed by hot water, and dry stains may be eradicated by a saturated solution of potassium iodide, followed by hot water.

In all acute cases of gonorrhœal vaginitis it is advisable, if there be no decided contraindications (such as weakness), to administer a purgative dose of calomel, gr. viij.-x., with an equal quantity of bicarbonate of soda, to be followed from time to time by saline cathartics. If the external parts are much inflamed a hot sitz-bath will afford great relief and will produce a tranquillizing effect upon the system.

If the case is seen within forty-eight hours after an exposure, effort should be made to abort the disease. Whenever possible, the patient should be confined to her bed and one of the silver salts—argyrol, for example—should be used freely and persistently. As soon as the parts will tolerate a speculum (and in mild cases this can be done immediately), the vagina should be thoroughly exposed by means of Sims' speculum, all discharge carefully wiped away, and the mucous membrane dried with absorbent cotton. Any excoriated points are to be touched with the stick of nitrate of silver and the entire membrane thoroughly swabbed with a twenty-per-cent. solution of argyrol. It is also well to swab the cervical canal with the same solution. Should the urethra be involved, an applicator moistened with the same solution should be passed into it, or half a drachm of the solution, of the same strength, may be slowly injected into the urethra and held there for from five to ten minutes. These applications may be repeated every second day by the physician, the patient on alternate days taking vaginal douches of argyrol, 1 in 200. At the expiration of from five to seven days the argyrol may be discontinued, and vaginal douches of sulphate of zinc, four to six grains to the ounce, three times a day, may be substituted. At the same time capsules of santal oil and balsam of copaiba, āā. gr. v., should be administered by mouth. At the end of ten days the secretions should be carefully examined. If no diplococci are present, the patient may discontinue treatment and be pronounced cured.

If leucorrhœa occurs later, or if bladder symptoms arise and gonococci appear, the disease must be considered chronic and a regular siege begun. If the cervical glands are involved, the entire cervix may be reamed out or amputation performed. Before resorting to so radical a measure, it may be wise thoroughly to dilate the cervix with the steel dilator from time to time, and then to apply argyrol. The dilatation expresses the secretions from the ducts, crypts, and glands, and permits of a more efficient diffusion and penetration of the medicament. If the infection travels into the body of the uterus it must be followed by thorough swabbing of the endometrium with argyrol. The wisdom of employing curettage under these circumstances is questionable. The ducts and glands of the endometrium are more shallow and simple than those of the cervix and hence more amenable to the effect of the application, while curettage may open lymph spaces to the infection and thus permit it to advance beyond the reach of the germicide. If the infection reaches the uterine appendages, it may be limited in its extension and severity by making an opening at once into the cul-de-sac of Douglas and inserting an iodoform drain. Unless general peritonitis threaten, no radical operation should be instituted till the pus has become circumscribed and the acute symptoms have subsided. The pus becomes sterile in the course of a few months, and then ablation can be performed with comparative immunity; or, in the course of a few years, conservative work may be done successfully upon the appendages.

Argyrol is also the best remedy to apply to the bladder when a cystitis develops as a complication. It may be used daily in the strength of from five to twenty per cent. The urine should first be drawn and then the bladder slowly distended with the injection, to the fullest degree of toleration (fifteen to twenty ounces). A long-standing urethritis may result in a urethro-vesical fissure, causing frequent and painful micturition and tenesmus. Dilate the sphincter vesicæ with the steel dilator, apply argyrol, and afterward administer urotropin, gr. x., night and morning. In persistent cases it may be necessary to resort to an artificial vesico-vaginal fistula, for the purpose of affording rest to the parts and thus permitting them to heal.

The patient and attendants must be cautioned about the contagious nature of the discharge, especially the danger to the eyes. All cloths and napkins used about the patient should be burned or at once soaked in strong bichloride solution. In the mean time the patient must be kept in bed, if possible; the diet should be light, simple, and nourishing; she should drink plenty of milk and avoid all spirituous or malted liquors.

When an anodyne is necessary, chloral may be tried, or, better still, opium may be administered in the form of a Dover's powder or in that of a suppository containing either opium or morphine.

The pruritus is at times the most difficult symptom to relieve. The most efficient application is carbolic acid, which can be used in the strength of a five-per-cent. solution, although it is well to commence with a weaker solution and increase the strength if necessary. The parts thus affected may be brushed with a solution of cocaine or of the nitrate of silver; both are efficient.

Should one of the vulvo-vaginal glands become involved it will be necessary to open it as far within the vaginal outlet as possible. This condition may be mistaken for a prolapsed ovary or an inguinal hernia. The former is excluded by the previous history and the latter by its percussion note and, possibly, by reduction. The opening of the abscess will afford temporary relief; but when once this gland has been invaded, it becomes a source of frequent annoyance, and a permanent relief is obtained only by its complete eradication.

Buboes are not apt to occur. When they are present, an effort should be made by purgatives and counter-irritants to dispel them. A grateful application consists of an ointment composed of equal parts of Ungt. hydrarg., Ungt. belladonnæ, ichthyol, and lanolin. Apply with pressure. If suppuration is inevitable dissection alone affords the desired relief.

Granular vaginitis and adhesive vaginitis are described by some authors as distinct forms of inflammation. They also occur as phases of simple or gonorrhœal vaginitis, and hardly demand special consideration. The former, however, sometimes declares itself as a distinct form of vaginitis in connection with pregnancy.

VI. VESICO-VAGINAL FISTULÆ.—A fistula is an abnormal communication through the tissues between two organs or passages, or between an organ or passage and the exterior of the body. The course of the communication may be either direct or tortuous. A vesico-vaginal fistula is such a communication between the bladder and vagina; by means of it the urine constantly or spasmodically makes its escape.

These urinary fistulæ are classified according to their location as follows: I. Vesico-vaginal fistula (proper). This is situated in the vesico-vaginal wall and involves only that tissue. II. Vesico-utero-vaginal fistula. This comprises cases in which the tear reaches up to, or dissects off the vesico-vaginal tissue from, the uterus, and necessitates, when an attempt is made by surgical means to repair the defect, the passage of the suture through uterine tissue. III. Vesico-uterine fistula. In these cases the vaginal wall is intact, the bladder communicating with the uterus and the urine thus finding its way through the os into the vagina. IV. Urethro-vaginal fistula. This term is applied to cases in which an opening exists in the base of the urethra, through which urine escapes into the vagina. But this can occur only during the act of micturition. V. Uretero-vaginal fistula. This is the rarest form of fistula. It is the result of an extensive tear or loss of tissue involving the ureter. Dr. Emmet claims that this lesion is more commonly the result of a pelvic abscess. During the inflammatory process the ureter becomes occluded by pressure, perforation ensues, and the urine finds its way into the vagina. A uretero-vaginal fistula may be congenital, and cases are on record in which one ureter opened into the vagina and the other took the normal course and discharged the urine from one kidney into the bladder. Under these circumstances a diagnosis becomes obscure and difficult. During infancy and childhood simple incontinence suggests itself as an efficient explanation of the apparent phenomena, and repeated physical castigation is apt to be the lot of the unfortunate sufferer. It is only when the child has come to mature years that a sufficiently thorough investigation is instituted and the exact condition discovered. Congenital ureteral fistulæ usually open at a point below the neck of the bladder. Uretero-vaginal fistulæ occur not uncommonly from accidental wounds of the ureter in hysterectomy for cancer or for fibroid tumor of the uterus.

The most common location of a vesico-vaginal fistula is in the median line and directly behind the symphysis pubis. The usual form of a section of the fistula is oval, linear, angular, or round. The most common is the oval, due, as Dr. Agnew explains, to the superior contractile power of the longitudinal over the circular muscular tissue of the vagina. These fistulæ vary in size from an opening so small that it is found with great difficulty and admits only the smallest probe, to those that involve the whole of the anterior vaginal wall, together with the entire base of the bladder and the urethra. One illustration of the latter has come under my own observation and care. In this case there was no trace of urethral tissue whatever. The entire base of the bladder was wanting, and, stretching across the common cavity, behind the symphysis, and springing from and continuous with the tissue of the recto-vaginal septum, was a strong cicatricial band which reached from side to side of the pelvis, leaving only sufficient room for two fingers to pass with difficulty between it and the symphysis. Through this small opening the inflamed and sensitive fundus of the bladder frequently prolapsed. Such cicatricial bands, of greater or less density and resistance, and reaching across the vagina in the most diversified directions, are a common complication in cases of fistula.

Etiology.—The most common cause of urinary fistula is injury due to parturition. If the delivery be premature and rapid, especially when attended with undue rigidity of the soft parts, laceration of the cervix uteri is apt to occur. Especially is this the case in primiparæ of advanced age, and in cases in which morbid changes have occurred in this tissue. When sufficiently extensive this laceration results in a permanent fistula. The vesico-utero-vaginal and the vesico-uterine are the varieties most often produced in this way. The tear, beginning in a rigid os, extends out upon the vagina or up the cervix to the vesico-cervical junction. In the process of repair this may all heal with the exception of an opening at the junction of the vagina with the cervix. Or all the tissues below may heal, leaving an opening at the upper angle of the tear—a vesico-uterine fistula.

It is universally accepted now, however, that the majority of fistulæ are caused by the sloughing away of tissue due to severe and prolonged pressure of the presenting part of the child during parturition. So long as the pressure is intermittent, and not too long sustained at any one time, no harm is done; but when impaction occurs and the pressure becomes continuous, circulation is obstructed and the vitality of the soft tissue thus compressed is destroyed. Necrosis occurs, the slough separates, and the urine makes its escape. According to Agnew, over ninety per cent. of vesico-vaginal fistulæ are thus produced, while in Emmet's experience ninety-five per cent. of his cases were the result of prolonged and difficult labor.

When the fistula is produced by laceration the urine makes its escape at once and the condition is immediately suspected. But in cases of protracted labor time is required for the slough to separate and the urine may not escape for several days. The average time is ten days, but it may occur in four or five, and again it may be delayed for a month. One case under my care gave a history of retention of urine, following confinement, that persisted up to the ninth day, when suddenly her bladder burst and a flood of urine was discharged through the vagina. It was evident in this case, however, from the presence of cicatricial bands, that there had been some sloughing as a result of the pressure, and that the separation of the necrotic tissue had led to what she described as the "bursting of her bladder."

Ill-adjusted, displaced, and neglected pessaries have been known to ulcerate through the vaginal wall and produce fistula; vesical calculi likewise may ulcerate through into the vagina, leaving a fistulous opening. Urinary fistulæ are sometimes produced by gunshot wounds, by rough manipulation of a sound or catheter in the bladder, by accidental puncture during operations on surrounding tissue, as in the operation for atresia vaginæ or in amputation of the cervix uteri in malignant disease, etc. Contrary to former teaching, malignant dis-

of the uterus in itself almost never produces a vesi-
istula. The essential tissue of the bladder is so highly
nized, so well nourished, that it is enabled to resist
encroachments of such morbid action. As has been
, however, fistulæ are not infrequently produced in
course of operations for the relief of such troubles.
casionally cases of congenital fistula present them-
es, but they are rare. The same methods of relief
ly to them as to other cases; but at an early age the
s are usually too small to permit of successful opera-

equency of Fistula.—No statistics can be given show-
the frequency of this accident. I have no hesitancy,
ever, in saying that it is a rare condition, and, if
experience of New York gynæcologists is an index
e experience of practitioners throughout the country
the world, it is becoming more and more infrequent.
Woman's Hospital, in New York City, was estab-
d primarily for the express purpose of relieving
læ, and its early history bears record of few cases of
ferent nature. During the first five or six years of
xistence it was customary to have two or three ope-
ns each week for the relief of fistulæ. At the present
scarcely that number can be seen there in a year.
is change is due to two causes: First, the operation
become so popularized that when such an accident
occur, the local physician repairs the injury; sec-
the prompt application of forceps in cases of diffi-
labor prevents the damage to the tissues which
wise would be likely to occur. Whatever abuses
injuries may attend the too frequent and too early
of forceps in parturition, all authorities are now
d that their timely use is most efficient in prevent-
istulæ. "Authors are disposed to attribute the acci-
of vesico-vaginal fistula in many cases to the awk-
use of obstetric forceps; but from a careful analysis
se cases, and my own experience, I am well satisfied
for one case thus produced their judicious applica-
has prevented it fifty times" (Sims). "I do not
ate to state that I have never met with a case of
o-vaginal fistula which, without doubt, could be
n to have resulted from instrumental delivery"
net).
nptoms.—In cases in which the bladder is punctured
incised wound, the fact is at once made known by
mediate and involuntary escape of urine through
uncture. The same phenomenon indicates the pres-
of a fistula caused by laceration, due to too rapid de-
, or by ulceration due to the pressure of a pessary,
lus, or any foreign body in the vagina. This escape
ine may be continuous from the date of its first ap-
nce, or may be interrupted. But as the vast ma-
of fistulæ are due to prolonged and difficult labor,
sual symptoms are those that follow such an expe-
. The presence of bruised and sloughing tissues
shes a warning of the more serious condition to fol-
But the actual extent of the injury cannot be known
the slough separates and the urine escapes by the
ous opening thus established. This may occur on
ond day, and may be delayed until the third week.
this time on, the urine may flow constantly, or may
tained for several hours, according to the position
patient and the nature and seat of the fistula. If
sion is high up in the septum, the bladder will have
ive power until it becomes filled up to that point;
hen the patient is in an erect posture there will be
voluntary escape of urine if the bladder is evacuated
ently enough to prevent the overflow. Sometimes
l of the vagina, the pressure of the uterus, or the
ximation of the edges of the fistula, especially in
like openings, may afford retention for hours. In
o-vaginal fistula, when only one ureter is involved,
may exist the unusual condition of an almost con-
dribbling of urine from the vagina with occasional
al micturition. Unless the woman devotes almost
ntire time and efforts to personal cleanliness, the
ns and cutaneous surfaces over which the urine
soon become inflamed and excoriated. The vulva,
the thighs, and the nates, being kept constantly wet with this irritating excretion, become red, swollen, and abraded. Frequently they are the seat of vesicles and pustules, and even occasionally of deep ulcerations and abscesses. Such abrasions within the vagina soon become coated with a calcareous or phosphatic deposit that causes the greatest suffering. When there has been an extensive loss of the tissue of the vaginal wall the base of the bladder may become inverted through the opening. Under these circumstances it is just as likely, as in the condition just described, to undergo abrasion, and to become coated with a deposit, both of which alterations render it exquisitely sensitive. Otherwise the size of the fistula makes little difference with the discomfort of the patient. A woman may be as constantly wet when the opening is not larger than a pin's head as when it is large enough to admit one or two fingers, the small opening, as Dr. Emmet explains, acting like the spigot in a barrel. A disagreeable urinous odor is constantly emitted from her person, a circumstance which excludes her from society and forbids her participation in the ordinary pleasures and duties of life. Dieffenbach gives a sad picture of many of these unfortunate women of his time, shunned by their friends, disgusted with themselves, and dragging out a most pitiable and miserable existence.

Diagnosis.—When the symptoms above described exist, the probabilities are that a urinary fistula will be discovered. Sometimes, however, a chronic cystitis will result in paralysis of the bladder and constant dribbling of urine from the urethra, producing all the disagreeable symptoms of a fistula. If the fistula is larger, a digital examination will readily detect the lesion without the use of speculum and probe, but pinhole openings are sometimes most difficult to discover. In long-standing cases of extensive lesions, with abrasions and cicatricial bands, the true relations of the parts are discovered only by careful and painstaking investigation. When the opening is very minute, the whole field of the vagina must be gone over carefully with tenaculum and probe. The folds of the vagina are smoothed out and the probe is gently insinuated into every suspicious lead or fissure. Should this fail to reveal the fistula, resort can be had to injecting milk, or water stained with indigo or cochineal, into the bladder. A simple method consists in administering by stomach methylene blue, gr. iss., night and morning. This will give the urine an indigo-blue color and will promptly reveal the point of escape through the vaginal wall. In carrying out this method it is necessary that the bladder be allowed to become slightly distended with the chosen fluid, while the septum is carefully watched for its appearance upon the vaginal wall. Bozeman has devised an ingenious test for cases in which the previous methods are contraindicated by reason of the irritability of the bladder. The test is based upon the fact that urine instantly passes through linen, while secretions of the vagina do not. The suspected location of the fistula is carefully dried with absorbent cotton, a piece of thin linen is spread smoothly upon it, and carefully watched for the point of moisture to appear.

Prognosis.—In artificial fistula, made for the relief of calculus, or an obstinate cystitis, it is a well-known fact that it is with difficulty that the fistula can be kept open long enough to effect a cure. Not until Dr. Emmet devised his method of "working the buttonhole," was this difficulty obviated. In these cases the fistula is a simple slit or fissure, the edges of which fall naturally together when the speculum is removed. We may, therefore, infer that where the lesion consists of a laceration in the vesico-vaginal septum, due to rapid labor or accidental puncture, unless it be so situated that the natural strain of the parts tends to keep the lips of the wound apart, under proper attention to cleanliness and frequent emptying of the bladder, spontaneous recovery may be hoped for. Even when a slough has occurred, spontaneous recovery has taken place in a limited number of cases. In the majority of instances, however, the lesion becomes permanent and requires surgical interference for its relief.

"Prior to the application of the metallic suture by J.

Marion Sims, and a proper mode of exploration furnished by his speculum, any attempt for the relief of the injuries under consideration was uncertain in result, and the operation regarded as an opprobrium by the profession." To appreciate fully the significance of these words of Dr. Emmet, and the credit due to Sims, it may be interesting and profitable in this connection to look into the history of the treatment of the lesion under consideration.

History of the Different Operations for Vesico-Vaginal Fistula.—With Henri de Roonhuysen—a Dutch obstetrician of Amsterdam (1663)—rests the honor of being the first to devise, employ, and describe an operation for the relief of vesico-vaginal fistula. The description which he gives is so unique and interesting, and so rarely to be found, that I give it in full. This is from a French translation of the original by Herrgott, of Strasburg. The operation is done in the following manner: The patient is placed upon her back on a table, in a good light; the upper part of the body is covered, the lower part fixed with bands as in the operation for cystotomy. This done, the vagina is dilated by a speculum as large as the circumstances will permit. The vaginal mucous membrane along the border of the tear, where it is in contact with the vesical membrane, must be denuded, but the bladder itself must be touched as little as possible, for by the kindly act of nature the vagina is united by inflammation to the borders of the tear in the bladder in such a way that, when only as little a portion as necessary has been denuded, it is wont to heal perfectly. This freshening (of the edges) can be done by means of a little sharp pinch of the scissors or bistoury, or any other instrument the surgeon is in the habit of using. I find that it is accomplished quite well by a slight, sharp pinch of the scissors, but they ought to be as sharp as possible in order that they may not produce contusion, but freshen a little the edges of the tear to make them red or bleeding, so that they may unite immediately and contract adhesions to each other. The retention need not always be accomplished with gold or silver pins, as is done in harelip, but with pins made from the strong quills of the swan, sharpened and pointed. These are preferable, not only by reason of their flexibility, but on account of the fact that they do not cause contusion of the surrounding parts if one takes the precaution to guard them with waxed silk. For when the pins are applied they adapt themselves by virtue of their elasticity. The parts must then be anointed with a cicatricial salve (of which he gives the formula), and upon the wound should be placed two or three flat pledgets saturated with oil or warm balsam, and the vagina filled with pieces of sponge saturated with oil, for the purpose of making a little pressure upon the wound and of sustaining the dressing. All this should be steadied with some compresses and supported by a T-bandage, which should remain in place three or four days. The bandage and compresses are removed when the patient wants to urinate, but she ought to do it with caution. The patient should remain constantly in bed, lying upon her back, the hips slightly elevated, until healing is accomplished.

Roonhuysen does not describe cases operated upon by himself, nor does he state how many times he practised the operation; but a Swiss surgeon, J. Fatio (1752), records two successes by Roonhuysen's method. Naegele claimed that this procedure of Roonhuysen was simply impossible, basing his objections upon the quill pin, but he nowhere claims to have tried it. Kilian made similar objection to the operation. But Herrgott has experimented with quill sutures in tissue similar to that of the vagina, and finds them entirely practicable. Moreover, the minute and careful description of all the details of the procedure bears evidence in itself of being a genuine account of what had actually been done.

In this simple description of Roonhuysen's we find all the principles and methods of treatment necessary for dealing successfully with fistulæ. He used the speculum thoroughly to expose the parts, vivified the edges of the fistula with knife or scissors, avoided the bladder membrane in denuding, and fastened the edges with a suture. What have we added to this more than to modify the suture and adjust a self-retaining catheter?

The method, however, was not established, either by him or by any of his immediate followers, as a recognized procedure in surgical practice, and was forgotten. Aside from the use of the catheter by Vorlten (1720) and the introduction of silk interrupted sutures, no progress in dealing with fistula was made during the eighteenth century. Cauterization of the edges with the hot iron and with nitrate of silver was used, but with only limited success. In the beginning of the last century Naegele (1809) renewed interest in this lesion and its repair. He devised and employed four methods of operation, but failed to obtain any success. Professor Ehrman (1826) operated in two cases by simple suture after freshening the edges, and obtained complete success in one of them after repeated cauterizations.

Gosset, of London (1834), reported a successful case operated upon by him, in which he used uninterrupted sutures of silver gilt, or gilded silver wire, fastened by twisting. Jobert de Lamballe, the same year, in France, introduced the method of transplanting tissue from the labia, the buttocks, or the thigh, and fastening it to the denuded edges of the fistula. This did not prove satisfactory in its results, and he adopted the interrupted suture with the additional procedure of incising the tissues at certain points in the vagina—cystoplastie par glissement—to relieve tension upon the sutures and allow the edges to rest in contact.

Then Dieffenbach (1845) gave his experience to the profession. He says: "I have operated upon one woman eighteen times without success. I have closed the entire cavities of these unfortunate women gathered from all countries. I have lived in the midst of them, and I have realized only a small number of successes." He claimed to have cured by the suture only one fistula of any considerable size, but a great number of small ones by the actual cautery.

Wurtzen, of Bonn, who after Dieffenbach was for a long time the only one who operated upon fistulæ, failed to cure in one case after thirty-three operations. According to the statistics of Simon, Wurtzen, up to 1842, cured only 4 women out of 18. From 1842 to 1852 he cured 7 out of 17, or 11 successes in 35 cases.

Gustave Simon (1854), published a critical review of the operation of Jobert in which he presented his own method of operating, and reported six cases in which he had obtained perfect success in four, and partial success in the other two.

In our own country, Hayward, of Boston, was the first to report a cure, May 10th, 1839, achieved by him in a case of fistula of fifteen years' standing, which had resisted treatment by cauterization and the use of the catheter. He operated with the patient in the lithotomy position, the vagina being opened by means of retractors, and the anterior vaginal wall being pressed down by a bougie in the bladder. The edges were denuded, the surfaces coaptated by interrupted silk sutures, a catheter was fastened into the bladder, and the patient put to bed upon her right side. Upon the sixth day firm adhesion had taken place and the stitches were removed. He says: "I had never seen the operation done till I did it myself, nor could I find any description of the mode which others had adopted that was sufficiently clear and explicit to be of much service." In 1851 he reported a series of 20 operations on 9 different patients, with 3 perfect successes, 4 great relief, 2 no benefit. Of these, 5 had 1 operation, 2 had 2, 1 had 5, and 1 had 6.

In 1847 Pancoast, of Philadelphia, reported two cures by a method called his "plastic suture." The peculiar feature of this consisted in splitting one edge of the fistula and paring the other to a wedge shape. The latter was then slipped into the former and held by sutures. The same year, 1847, Mettauer, of Virginia, reported a successful case of fistula treated by him with leaden sutures after freshening the edges. He also used the catheter. So simple seemed the process of cure, and so pronounced his success, that he did not hesitate to declare that all fistulæ are susceptible of relief.

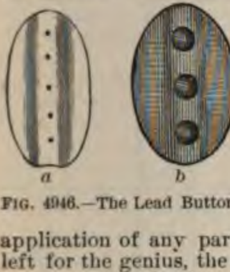

FIG. 4946.—The Lead Button.

From this brief historical sketch it becomes apparent how perfectly at sea the profession was, even as late as the middle of the last century, regarding any well-established procedure, and how little faith it had in the successful application of any of the devices used. Here and there, occasionally, an operator met with success, and the achievement was heralded as a great triumph. But no two adopted exactly the same method, and the success was ascribed more to good luck than to the proper application of any particular surgical method. It was left for the genius, the careful observation, the untiring energy and enthusiasm of one of our own countrymen, J. Marion Sims, to grasp all the essential principles, to work out to complete success, and give to the profession, what is recognized the world over as a thoroughly reliable method of dealing with urinary fistulæ in women. The more credit is due him as he worked independently of others, and without any adequate knowledge of what had been accomplished by them. Yet, as Dr. Emmet says, "were we assured that Dr. Sims was as familiar as we are at the present time with what had been accomplished before his day, it should not lessen the credit due to him. What had been done fell on barren soil, bore no fruit, was not appreciated, and was destined to be forgotten. From Dr. Sims' hands the operation was accepted by the profession; it was immediately put into successful practice, and to the present day it has not been materially modified for the better, either in its principles or in its mode of execution." His first article was published in the *American Journal of the Medical Sciences*, 1852. The essential features of the procedure, as there set forth by him, were, first, suitable means by which the vagina could be thoroughly explored and the fistula brought into view—viz., the knee-chest posture and the duck-bill speculum; second, a suture which could be left in place long enough to secure healing without exciting inflammation or ulceration — viz., silver wire secured by perforated shot; third, a method of draining the bladder during convalescence—Sims' self-retaining catheter. During the next five years he modified somewhat the details of these proceedings, and set them forth in an address before the New York Academy of Medicine, in 1857, on "Silver Sutures in Surgery." In the operation as then described, one which he regarded as perfect in all its details, he substituted the simple interrupted silver suture, secured by twisting, for the clamp suture, and, instead of the knee-chest position, employed what is known universally as the Sims posture.

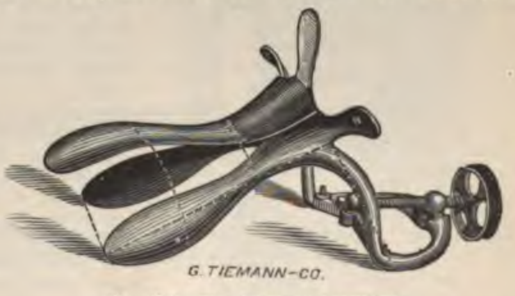
While Sims was thus perfecting the details of his operation, Gustave Simon, of Darmstadt, Germany, was also employing his mechanical skill and ingenuity in endeavors to relieve the same distressing affliction. The results of his labors, and the details of his operation, were given to the profession in 1862, although he had previously published an article on the subject in 1854. He placed the patient in an exaggerated lithotomy position; exposed the fistula by a duck-bill speculum of his own device; and, by means of lateral retractors, vivified the edges with a knife, regardless of encroachments upon the bladder membrane, and used silk sutures in uniting the edges. When much strain was expected, he employed a row of deep sutures far from the edge to hold the parts, and a row of superficial sutures to obtain nice approximation of the edges. He allowed his patients to sit up and pass urine naturally, when possible. Simon also devised and practised what he called kolpokleisis, in cases in which the fistula itself could not be closed. This consisted in completely occluding the vagina by denuding a surface on the anterior wall of the vagina below the fistula, and a similar one on the posterior wall, and uniting them by suture. This made a common receptacle for the urine and menstrual blood, all of which was passed through the urethra.

Intimately associated with the operation for repair of fistulæ, both in this country and abroad, is the name of Bozeman. He is a strong advocate of long and complete preparatory treatment and of the use of the button suture. The latter consists of a strip of sheet lead nicely cut and moulded to fit the tissues in each individual case. This is perforated, along the median line, with a row of holes (Fig. 4946, *a*) through which the silver sutures are drawn and made fast by perforated shot (Fig. 4946, *b*). This, it is claimed, acts like a splint, and so favors healing by preventing motion. It has the disadvantage, however, of concealing the wounds, preventing the nice adjustment of the edges, and of tightening or loosening each individual stitch, opportunities for doing all of which things are afforded by twisting the wire. He employs a peculiar speculum invented by himself (Fig. 4947), and a contrivance for sustaining the patient in the knee-chest posture when under ether.

His method yields most favorable results in his own hands, but is too complicated for the general practitioner.

Dr. Bozeman is a vigorous opponent of the operation of kolpokleisis as practised by Simon. He claims that in many cases in which this was resorted to by Simon, a sufficiently long and persistent course of preparatory treatment would have enabled the patients to be relieved, with entire restoration of bladder and marital functions. Kolpokleisis, even in cases that resist all other efforts at relief, is only a delusion. It may keep the patient dry, and thus afford relief for a short time; but unfortunate consequences always attend the retention of urine in a pouch thus formed when complete drainage is not secured. The urine decomposes, calculi form, and a cystitis may be established that, sooner or later, leads to disease of the kidneys, uræmia, and death. Dr. Emmet insists that kolpokleisis should never be resorted to under any circumstances.

The man who, while claiming no originality in the matter, has done the most to popularize the operation for fistula in this country, is Dr. T. Addis Emmet.



G. TIEMANN-CO.

FIG. 4947.—The Bozeman Speculum.

Treatment.—Methods of Cure. Spontaneous Cure. Small fistulæ will frequently close without any interference, through the processes of granulation and healing. The smaller the fistula the greater the probability of such an occurrence. This process of nature can be encouraged and hastened by proper attention to cleanliness. The constant drainage of the bladder, too, by a self-retaining catheter, assists greatly this spontaneous cure. Any procedure that maintains a constant healthy, granulating process along the edge of the fistula tends to the accomplishment of a cure. Corradi cites a case of his, recorded by Jenks, which for a year had resisted all methods of treatment, even Sims' operation. He thereupon had a gold button with double facets made to fit the fistula. The button was inserted so that one facet was in the bladder, the other in the vagina. Micturition was immediately established, and not a single drop of urine passed any longer by way of the vagina. For five years the woman wore this button without experiencing any inconvenience. Then by accident the button dropped out, and the urine continued to pass entirely by the urethra. A few days afterward Corradi examined the patient, but found no fistula. In this case the stimulus of the button had encouraged granulation till it had reached up over the head of the facet that was in the bladder, while the button was sloughing out below.

Caustics.—For many years caustics were the chief reliance in the cure of fistulæ. As late as 1839, Dupuytren declared that sutures were of no avail against the injurious influence of the urine on the wound, and nothing but the actual cautery was sufficient to excite the necessary degree of granulating activity in the edges of the fistula. All the caustic acids, caustic potash, nitrate of silver, and the actual cautery were employed. In cases of extremely small fistulæ the actual cautery will frequently effect a cure. Among the caustics of a chemical nature nitrate of silver is the best. It is used not only as an independent means of causing a fistula to heal, but also for the purpose of completing the cure after suture, when an opening has been left in the angle, or when points along the line of union have failed to unite. In such cases the silver should be applied frequently and its use should be continued until strong, healthy granulations have been produced. After that, cauterize less frequently; allow the granulations to accomplish what they can before burning them again.

DETAILS OF THE OPERATIONS.

Preparatory Measures.—It is important that the general health of the patient should be in as good condition as may be. But one need not wait too long for this. The local condition of the parts is still more important. Before operating, the edges of the fistula and surrounding parts must be put into as healthy a condition as possible. Sitz-baths, hot-water douches, and the most scrupulous methods of personal cleanliness should be employed. All incrustations of urinary salts, whenever found, are to be gently removed by streams of warm water or by a cotton swab, or they may be picked off with the dressing forceps. The excoriated surface beneath is then brushed over with a solution of nitrate of silver. This preliminary treatment must be repeated two or three times a week, and in the mean time the parts should be kept thoroughly protected from the urine by an ointment. The most efficient ointment for this purpose is that given by Bartholow, under the head of Boracic Ointment. "Take of boracic acid, finely levigated, 1 part; white wax, 1 part; paraffin, 2 parts; almond oil, 2 parts. Melt the wax and paraffin by heating with the oil, and stir the mixture briskly, along with the boracic acid powder, in a warm mortar, until the mixture thickens." When it is required for use, a certain amount of it should be rubbed up with a little vaseline or glycerin. It should be used quite stiff, so that it may form a coating over the inflamed and delicate surfaces. With careful attention to cleanliness and the constant use of this ointment, I have kept patients with artificial fistulæ entirely free from abrasions, excoriations, or irritation.

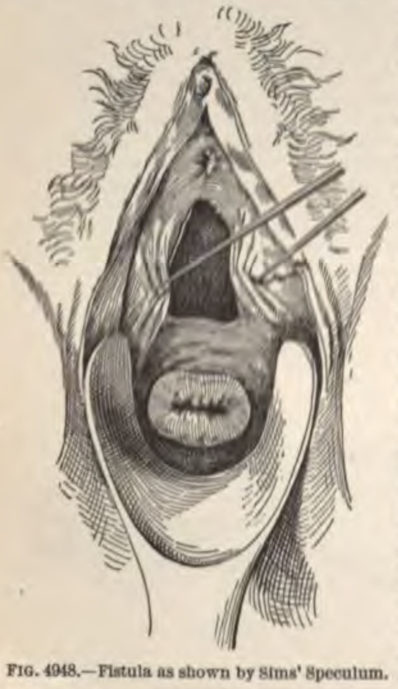


FIG. 4948.—Fistula as shown by Sims' Speculum.

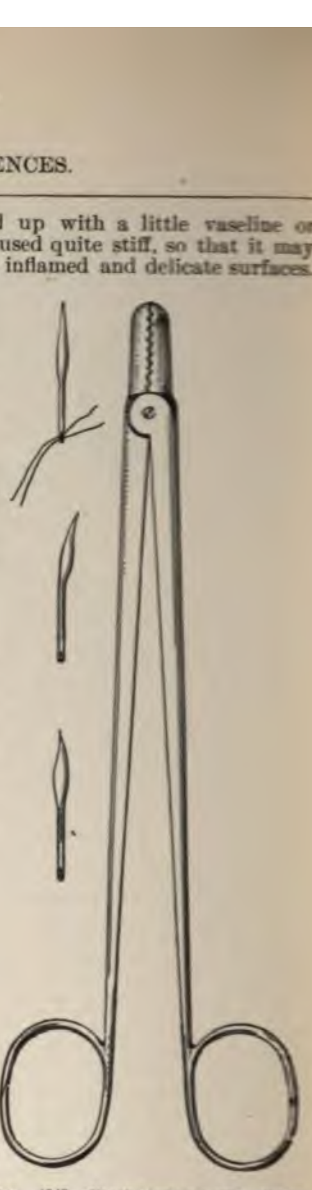

FIG. 4949.—Needle-holder and Different Patterns of Needles.

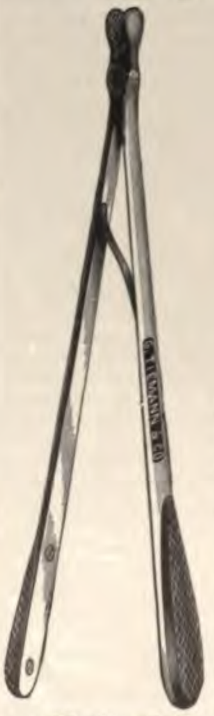

FIG. 4950.—Emmet's Needle-holder.

All cicatricial bands that stretch across the vagina, obstructing the view and narrowing the canal, or distorting the relations of the parts, must be thoroughly obliterated. This is accomplished by nicking or cutting them here and there along their course and causing their absorption by pressure. When these constricting bands exist across the posterior wall, reaching up on to the sides of the vagina, they can be put upon the stretch by placing one or two fingers in the rectum and the thumb in the vagina. Then, with a pair of blunt scissors in the right hand, each band is snipped or cut superficially at several places, and the pressure of the thumb increased to tear the tissue still deeper. By adopting this plan one may avoid the hemorrhage that would be produced by the deep incisions of a knife. When the bands cannot be reached in this way, a speculum must be inserted and pressure made here and there with a depressor to bring the bands into view. When once they have been revealed, they may be snipped by the scissors in the manner already described. To keep these bands on the stretch and stimulate absorption by pressure, a "Sims glass plug," or a "Bozeman dilator," should be inserted immediately after they have been snipped, and these contrivances should be held in place by a layer of cotton and a T-bandage. This plug or the dilator can be procured of any size, and must be adapted to each individual case. It should be large enough to distend well the parts. Its presence occasions some distress, which may be relieved by anodynes. During the healing process the patient is kept in bed, and the plug kept as constantly in place as the circumstances will permit. It should be removed at stated intervals to permit the use of carbolized douches, and it should be well smeared with carbolized vaseline before being reintroduced. At the expiration of ten days or two weeks, if the parts are not sufficiently pliable and the vagina is not roomy enough to permit the easy performance of the operation, the process just described is to be repeated.

If cicatricial bands do not exist, but the canal is narrowed through loss of tissue, and if the edges of the fistula are so drawn apart that they cannot be brought into apposition, longitudinal incisions, three or four in number, parallel to the long diameter of the fistula, should be made through the mucous membrane of the vagina with a knife, and the dilator or plug then inserted as described above. Sometimes this becomes a very painful and tedious process. A much more satisfactory method consists in splitting the edge of the fistula throughout its entire extent and dissecting the bladder wall free from underlying tissue widely in every direction until the edges of the fistula in the bladder wall can be readily approximated. Then the vagina should be incised longitudinally on each side, to remove undue tension, and afterward the edges of the fistulous opening should be stitched together—the edges of the bladder wall first and those of the vaginal mucous membrane afterward. The wounds left by the lateral incisions may be allowed to heal by granulation.

FIG. 4951.—Sims' Fork.

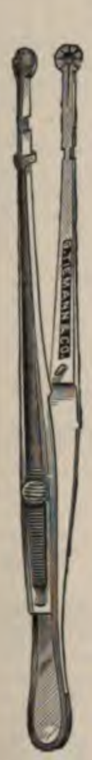

FIG. 4952.—Twisting-tongs.

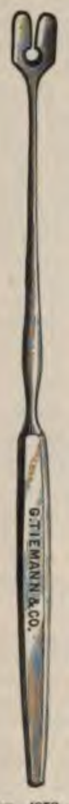

FIG. 4953.—Shield.

Sims' Operation.—The patient, properly dressed and protected by covering, is placed in Sims' posture. It is well to have two nurses and two assistants. One nurse holds the speculum and elevates the buttock; the other attends to the sponges. One assistant administers ether; one assists in the operation and does the sponging. The instruments required are: Sims' speculum, long-handled left and right curved scissors (Emmet's cervix scissors are usually sufficient), a long-handled knife with narrow blade, two or three tenacula, needles and needle-holder, counter-pressure hook and fork, twisted silk for carrying No. 27 or 28 silver wire, twisting tongs, wire shield, sponge-holders, and sponges (see accompanying cuts).

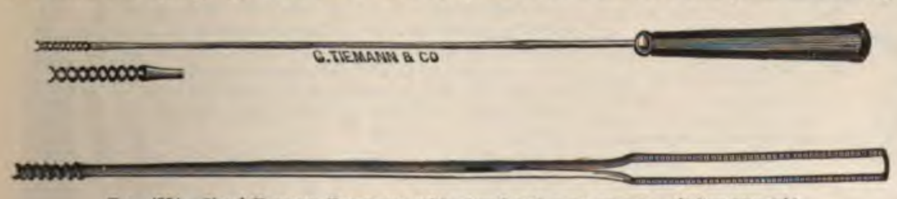

FIG. 4954.—Sims' Tampon Extractor, with closed and open screws. (After Mundé.)

The steps in the operation can be comprised under three heads: First, denuding or vivifying the edges of the fistula; second, introducing the sutures; third, adjusting the edges and fastening the sutures.

Denuding.—The line of union should be, as nearly as possible, in the long axis of the vagina; but more important still is it that the margins be drawn together in the line of least traction or resistance. The margin of the fistula is caught with a tenaculum at any selected point, and a strip of tissue is removed with the scissors or knife.

It is a good plan to make this strip of tissue encircle the entire fistula without cutting or breaking it. Then you are sure of obtaining a perfectly clean surface. When the vesical mucous membrane is included in this denudation there is apt to be troublesome hemorrhage. Sims therefore advised that this be carefully avoided; the incision taking the direction of the dotted lines, as in Fig. 4957, *a* being the vesical mucous membrane and *b* the vaginal. If the removal of one strip gives a surface wide enough to afford firm union, the wound is ready for the sutures. Ordinarily, however, it is necessary to take off a second or third strip outside this, on the mucous membrane of the vagina, in order to get as broad a surface of union as may be. At each end of the fistula the denudation must be made to terminate in an acute angle by extending the denudation out to a point on the vaginal membrane. This prevents all puckering of tissues when the sutures are tightened; it also diminishes the likelihood that any little orifices will be left at either end of the line of union. Should any troublesome hemorrhage occur, it can usually be controlled by adrenalin or by hot sponges, torsion, pressure, or ligature. To exert pressure, Dr. Emmet recommends pushing the centre of a handkerchief of gauze or cloth through the fistula, then packing cotton into the sac thus formed in the bladder till the mass is too large to be drawn through the opening. After this

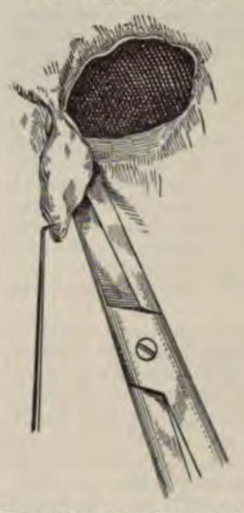

FIG. 4955.—Denuding with Scissors.

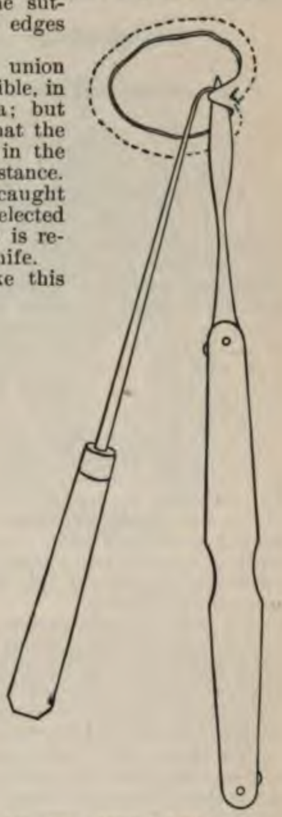

FIG. 4956.—Denuding with Knife.

has been done, it will be found that, by pulling on the corners of the handkerchief, any degree of pressure can be made. Another of Dr. Emmet's devices is to pass a suture from the vagina through the septum into the bladder, at some distance from the margin of the fistula, and out into the vagina again, thus surrounding the offending vessel, and ligating it temporarily in the tissues. Care must be taken in doing this to avoid ligating a ureter. If the mouth of the bleeding vessel can be caught, there is no positive objection to ligating with fine silk or with catgut; but the leaving of any foreign body between the lips of the wound is to be avoided if possible.

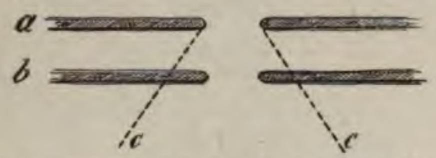

FIG. 4957.—Showing Direction of Incision (viz., that of dotted lines ending at c).

Introducing the Sutures.—The needle may be either straight or slightly curved, and from one-half to one inch in length. It is armed with a double carrying thread of fine silk about six inches long, into which the silver wire of the same length is hooked and made fast. The wire should be sharply bent over the thread in order that, when it reaches the tissues, it may be forced through them (by the aid of the forceps) with the minimum amount of difficulty.

It is well to begin suturing at the proximal angle of the fistula. Here the tissue is caught up with a tenaculum and the needle inserted at about one-fourth of an inch from the margin of the denudation, and directed through the tissues so that it will come out just at the edge of the mucous membrane of the bladder.

Puncturing the vesical membrane causes hemorrhage at the time, and may result in a permanent leak hole. As soon as the point at which the needle is to emerge is determined, counter pressure is made just beyond with the blunt or counter-pressure hook. This facilitates the passage of the needle and prevents straining of the tissues. The needle is thus pushed through as far as the grip of the needle-holder will allow. Then it is caught at the point and drawn through while the counter pressure is still applied. The needle is then inserted at the point corresponding to its exit on the edge of the mucous membrane of the bladder, on the opposite side of the fistula, and directed through the tissues till it makes its appearance through the vaginal mucous membrane one-fourth of an inch from the margin of the fistula. The counter pressure is applied as before. The needle, with carrying thread and silver wire, is now drawn through till the ends of the wire can be grasped on both sides. If the tissues are delicate and there is danger of tearing them, it is well to support the thread, as it is drawn through, with a Sims fork. But the wire must not be drawn into the tissues till the needle has been passed through both sides, and then it is to be slid through both sides at the same time; otherwise it is likely to get badly kinked. The ends of the wire are twisted together one or two turns and held out of the way by the assistant. In this way the stitches are passed one after the other from one-fourth to three-eighths of an inch apart, and as evenly in all respects as it is possible to get them.

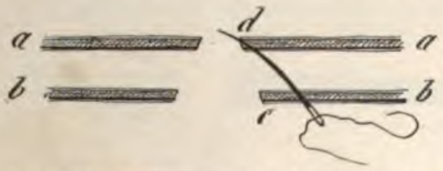

FIG. 4958.—Showing Direction in which Needle is to be Passed. a d, Bladder membrane; c b, vagina.

Securing the Stitches.—Commencing now at the remoter angle of the fistula, the surgeon should grasp firmly both ends of the first wire, two or three inches from the tissues, with the twisting-tongs, and he should make the tension sufficient to draw the suture taut. With slight pressure of the tenaculum the wire of either side is now bent, near the tissues, at a sharp angle, till it meets the wire of the opposite side directly over the line of union that is to be formed. The shield is then slid down the wire and firmly pressed against the tissue, while sufficient strain is put upon the wire, by pulling, to bring the edges of the wound into firm apposition. While this tension is still maintained, the wire is bent over the shield and twisted down to the tissue. (Fig. 4959.) The shield is now removed in order that the operator may see whether this suture holds the edges in close and exact apposition. If it does not so hold them, the shield is reapplied and one or two more twists are given to the wire. Or, if the twisting has been carried too far and strangulation or cutting of the tissues threatens, the tension can be relaxed by giving the wire one or two turns in the opposite direction. And in this lies the advantage of securing silver wire by twisting rather than by clamp, button, or shot.

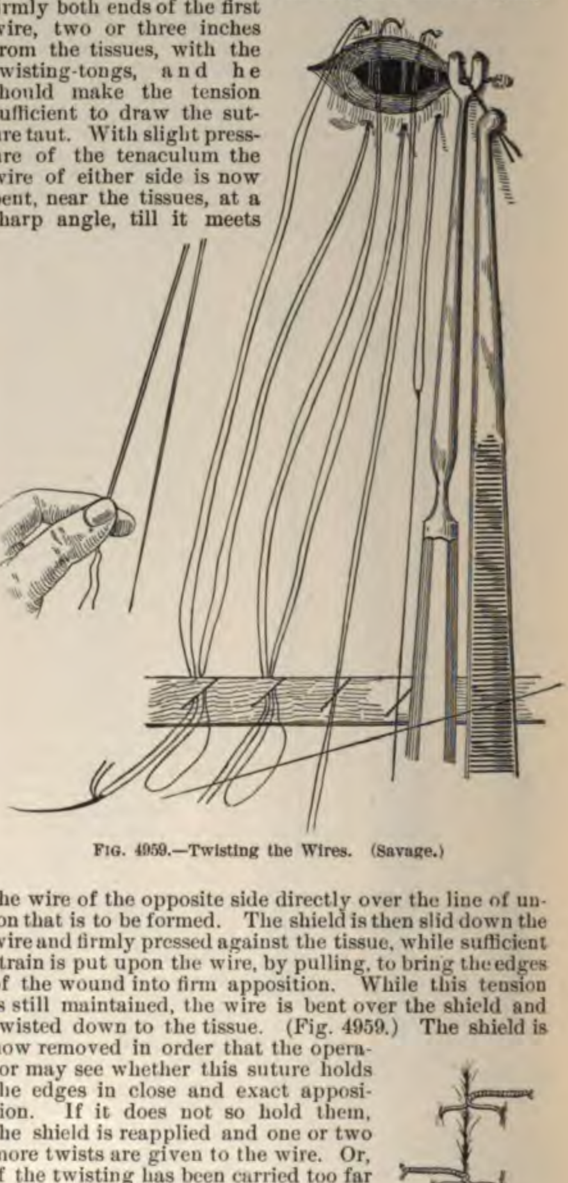

FIG. 4959.—Twisting the Wires. (Savage.)

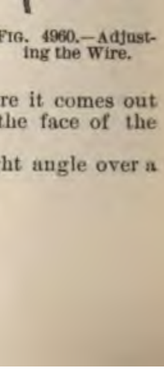

FIG. 4960.—Adjusting the Wire.

The sutures are now shouldered by catching the loop of the stitch with a tenaculum at the point of exit from the tissue, and pulling at a right angle to the line of the fistula, first on one side and then on the other, so that the wire shall be bent at a right angle where it comes out of the tissue, and shall lie flat across the face of the wound.

The twisted end is next bent at a right angle over a tenaculum, flat upon the vaginal membrane, and cut off so that it shall have a length of about half an inch. It is customary to turn the twisted ends alternately to one side and to the other.

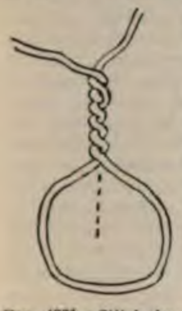

FIG. 4961.—Stitch before Shouldering. (Mundé.)

When the sutures have all been disposed of successively in this manner, the wound should be thoroughly inspected, all everted points should be carefully tucked in with a tenaculum, and all inverted points of mucous membrane should be turned out. This completes the operation. But before the patient is removed from the table the bladder should be carefully inspected by passing a catheter. If any blood clots are discovered they must be dissolved by normal saline solution and washed out; if there is any active hemorrhage it must be controlled by applications of either hot water or ice-water or by injections of adrenalin.

The self-retaining catheter is now placed in position, and the patient put to bed with a narrow dish between her thighs to catch the urine. The catheter should be removed and thoroughly cleansed every night and morning, and a vaginal douche administered at least once a day. The bowels may be kept constipated till after the fifth day, or an evacuation may be obtained daily by Hunyadi water or by some other laxative. It was Dr. Sims' custom to keep the bowels quiet. The patient is kept upon her back, and pain is relieved by opium or by morphine. The sutures may be removed upon the eighth, tenth, or twelfth day, according to the relative vitality of the patient and the healing qualities of the tissues.

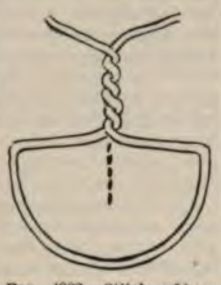

FIG. 4962.—Stitch after being Shouldered. (Mundé.)

Care must be exercised not to pull the wound apart in removing the sutures. Catch the twisted end with the twisting-tongs, and straighten it up gently to a right angle with the surface. While this is being done, the loop of the suture will rotate in the tissues and bring a bright point of it into view, when it can be easily snipped with wire scissors. The view is facilitated by making slight pressure on the tissues with the points of the scissors at the point of exit of the suture. In drawing the suture out, the surgeon should direct his force in such a way that the tissues shall not be constantly pressed toward the line of union, nor dragged away from it.

Some cases require several operations before a cure can be effected, but slight points of nonunion, either at the angles or along the line, may be made to heal by touching them frequently with the stick of nitrate of silver and by keeping the catheter in the bladder.

Simon's Operation.—It will not be necessary to describe so minutely Simon's operation, but simply to speak of the main points in which it differs from the Sims operation, and to illustrate them by the accompanying cuts. Simon worked along the same lines of procedure that Roonhuysen described, and not only attained great success in his operations, but caused it to be adopted among his German confrères as the standard operation. The characteristic features of Simon's operation are these: First, he employs an exaggerated lithotomy position, patient on back, hips elevated. Second, instead of avoiding the vesical mucous membrane, he intentionally incises it if the edges contain much cicatricial tissue. Third, he repudiates the superiority of silver wire and uses silk. Fourth, he employs no stationary catheter, and allows the patient to void her urine if possible. Fifth, the bowels are kept in a relaxed state to avoid straining, the diet is not restricted and the patient is not necessarily confined to bed.

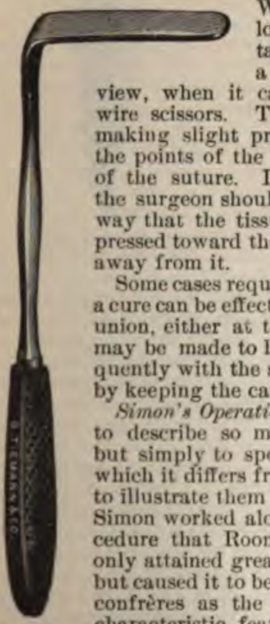

FIG. 4963.—Simon's Retractor.

Position of the Patient.—The breech-back (Steiss-Rückenlage) position is attained by elevating the hips and flexing the legs over the belly, so that the breech becomes the most projecting part. If the fistula is situated high up in the vagina, the hips must be well elevated, and the thighs flexed as much as possible. The lower the fistula is situated in the vagina, the less the degree of elevation and flexure necessary. Whenever it is possible to expose the fistula well by traction upon the cervix, either by forceps or by threads passed through, the speculum is dispensed with, and only side retractors are used, with a staff introduced into the urethra to steady the parts. When this is not practicable Simon uses specula devised by himself. These consist of an anterior and a posterior speculum, and two side retractors (Fig. 4963).

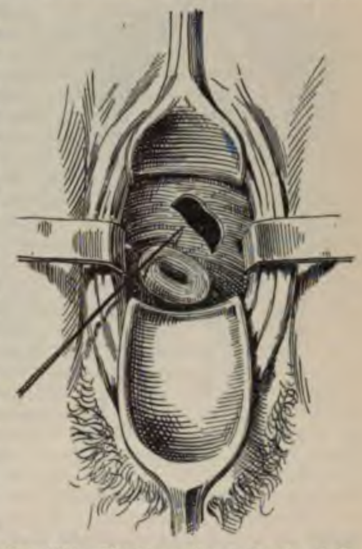

FIG. 4964.—Fistula as shown by the Goffe or by Simon's Speculum.

Vivifying the Edges.—The Simon method carries the incision deep enough to extirpate all cicatricial tissue, making a funnel-shaped excavation, and includes all the tissues down through the vesical mucous membrane. Simon prefers the knife.

Sutures.—When the fistula is small a single line of silk sutures is used. In the larger fistulæ every second or third stitch is made a sustaining suture, and is passed at a considerable distance from the edge, thus including enough tissue to support the line of union and take the strain off the more superficial (uniting) sutures. This Simon called his double line of sutures. It is of very little importance whether the sutures go through the vesical membrane or not, but care must be taken to prevent the membrane being inverted and caught between the edges of the wound.

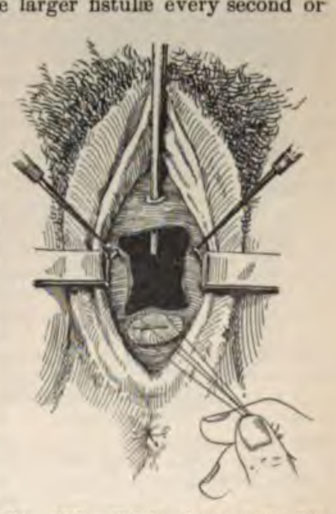

FIG. 4965.—Fistula shown with Retractors and Staff. (Simon.)

After-treatment.—The patient takes any position in bed that she desires. She passes urine normally whenever she feels the desire, either lying upon a bedpan, sitting up, or getting on the hands and knees. If urination is impossible without too much straining, the catheter is passed at proper intervals. A daily vaginal douche is given, and the bowels are kept open. Vesical tenesmus is relieved by sedatives. Silk sutures cannot be left as long in place as silver wire; they should be removed at some time between the sixth and the eighth days.

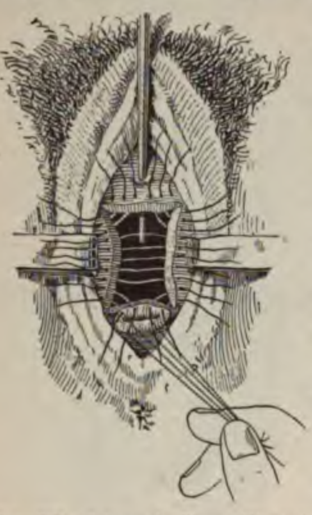

FIG. 4966.—Sutures in Place. (Simon.)

General Remarks.—The principles and methods established by these two great teachers, Sims and Simon, can be followed successfully in all cases. Succeeding operators have modified many details, or have combined into a successful procedure some of the features of each. Each operator follows his own fancy in regard to the needle or the needle-holder which he shall use, and the material of which his ligatures shall be made. Chinese silk, silver wire, iron wire, silkworm gut, and chromicized catgut are used indifferently; but in large fistulæ, and those so situated that they cannot be reached easily for fastening the ligatures, silver wire is preferable.

There is no department of plastic surgery which gives so great scope for the ingenuity of the operator as that of vesico-vaginal fistulæ. Each case is a problem *per se* and demands its own special and individual treatment. No case should be undertaken without careful study of all the factors that are involved in its successful treatment. The modern methods of vaginal section have led to greater freedom in incising the vagina for the purpose of reaching for operative purposes the tissues beyond, and they have demonstrated the feasibility of dissecting freely the vaginal sheath from the bladder, thus giving direct access to the bladder wall. Acting upon this principle, the author has devised the following method of dealing with vesico-vaginal fistulæ, whether large or small, and wherever situated:

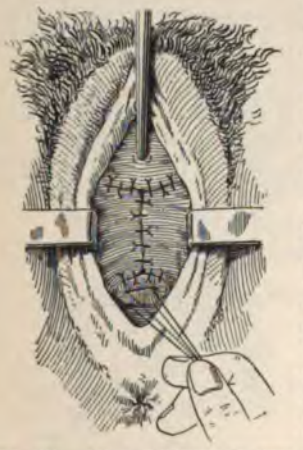

FIG. 4967.—Lines of Sutures to close the Fistula shown in Figs. 4965 and 4966. (Simon.)

The Author's Operation. — Vesico-vaginal fistula is best treated by separating distinctly the vaginal wall (and that includes the vaginal sheath, or fascia, as well as the mucous membrane) from the wall of the bladder, so that the two distinct openings can be closed separately, each in its own way. The operation consists of three distinct steps: First, incising the vagina down to the wall of the bladder by a longitudinal incision reaching, in the median line, from the cervix to the neck of the bladder. A transverse incision, reaching well across the vagina, is next made in front of the cervix; then afterward the bladder is to be separated from the vagina well out beyond the location of the fistula on whichever side of the median incision the fistula may be located, or if the fistula is in the median line the separation should extend on both sides sufficiently far to set the bladder wall free for some distance beyond the borders of the fistula. In extensive fistulæ it may be necessary to dissect the entire bladder quite free from all its attachments, not only for the purpose of bringing the fistula within the reach of surgical procedure, but also to remove all strain upon the tissues. The third step consists in denuding the edges of the opening in the bladder and closing it with one or two tiers of chromicized catgut sutures, care being taken not to pierce the vesical mucous membrane. After this has been accomplished the orifice in the vagina may be denuded and closed, and the vaginal incisions sutured. If the fistula involves the ureter, it can be easily and efficiently dealt with after the separation of the vesico-vaginal septum.

In cases that involve loss of tissue at the lower portion of the vagina, extending to one or both rami of the pubis, there may not be enough tissue between the fistula and the bone for the passage of the sutures. In such cases the tissue can be dissected up from the bone to a sufficient extent to give holding ground for the sutures, or a flap may be dissected off the vagina above and brought around to cover the opening. Jobert was a most skilful operator in the use of flaps, which he procured from other portions of the vagina, from the labia, or even from the buttocks and thighs.

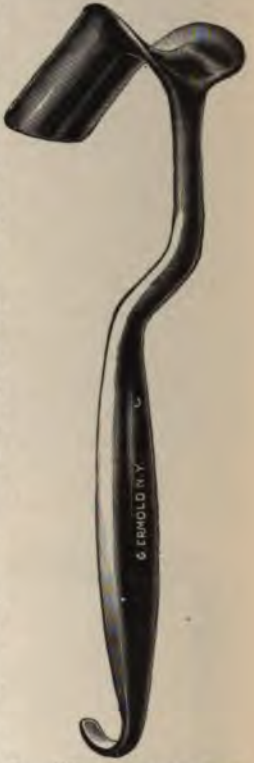

FIG. 4968.—The Goffe Speculum, made in two sizes.

In vesico-utero-vaginal fistulæ, where such a course is practicable, only the anterior lip of the cervix uteri should be utilized in closing the opening; but in some cases it is found necessary to stitch the posterior lip to the anterior border of the fistula, thus turning the os uteri into the bladder. Menstruation then occurs through the bladder and conception, as a rule, becomes impossible.

In vesico-uterine fistulæ, Dr. Emmet boldly slits up the cervix till he reaches the fistulous opening, thus, as he claims, reproducing the original lesion The fistulous tract is then denuded and the entire wound closed by sutures, as in trachelorrhaphy. Uretero-vaginal fistulæ are perhaps the most difficult to deal with. Landau recommends excising an oval piece from the vesical and vaginal wall, thus producing a vesico-vaginal fistula into the upper angle of which the ureter opens. Then the fistula is to be closed by sutures which, at the upper angle, shall include only the vaginal mucous membrane. If the urine is successful in forcing its way into the bladder in spite of the partial constriction of the ureter which may occur from the stitches, it will continue to do so. There is no danger of occlusion by the presence of granulations, for the flow through the ureter is constant. Another device for securing a patulous condition of the ureter is to introduce an elastic catheter from the vagina into the ureter, and then to pass the lower end out through the bladder and urethra. The uncovered portion of the catheter, as now seen through the vagina, is to be covered with the vaginal mucous membrane and the lower ureteral wall.

If a vaginal operation has failed or it seems useless to undertake such an operation, then resort must be had to ureteral cystotomy through an abdominal incision. (See also the article on *Ureters.* (*Surgical.*)

Occasionally a patient presents herself in whom there has been such extensive loss of tissue that all hope of closing the fistula must be abandoned. The question of closing the vagina (kolpocleisis) then arises. This is to be adopted with great hesitation. Indeed, in this country, the experience of the best operators is opposed to it. Continence of urine may be obtained, but, as has been previously stated, it is only at the risk of constant vesical tenesmus, calculus, and chronic cystitis, with all its train of direful consequences. When the base of the bladder, filled with intestines, becomes inverted and protrudes at the vulva, Emmet recommends that enough of the sides of the vagina be united, as in kolpocleisis, to give needed support, but that an opening be left at the most dependent point to allow of free drainage. By proper attention to cleanliness and the use of rubber urinals for females, which can now be procured at the instrument-makers, the patient can be made very comfortable.

VII. TAMPONING THE VAGINA.—Custom has established the use of two words to signify the placing of cotton, wool, or other similar substance in the vagina—viz., tamponing and tamponade. Tamponing signifies the complete packing of the vagina for the purpose of stopping or preventing uterine hemorrhage; tamponade is used when a limited amount of cotton or other similar substance is employed for purposes of medication.

The Tampon.—The use of the tampon originated in the idea of placing something in the vagina to facilitate the formation of a clot. It was first practised by loosely stuffing in a handkerchief, napkin, roller bandage, or a few wads of cotton. Such tampons are more or less effective in stanching temporarily the external flow of blood. But in a short time the tampon becomes saturated and hemorrhage again becomes apparent.

To Dr. Emmet we owe the thorough and efficient method of tamponing the vagina as it is now used, or should be used. His method is based on the idea of pressure. And while the stoppage of all hemorrhage depends upon the formation of a clot, the pressure thus produced carries the uterus high up in the pelvis, compresses all the pelvic vessels, thereby diminishing the blood supply, and transfers the formation of the clot from the vagina up into the uterus.

To tampon the vagina properly a Sims speculum is indispensable. As Mundé ("Minor Surgical Gynecology") very forcibly remarks: "Every practitioner who takes, and is liable to meet with, cases of uterine hemorrhage (and what practitioner is not?) from miscarriage, polypi, polypoid endometritis, fibroid uterus, or cancer, should not only possess a Sims' speculum, but should know how to use it and how to tampon the vagina so securely that not a drop can escape so long as the tampon is retained."

When the hemorrhage is free it may be necessary to tampon the cervical canal as far as the tampon can be forced into it. This will prevent the escape of blood from the uterus, and the blood, in turn, by accumulating and forming a clot within its cavity, stimulates the uterus to contract and so control the hemorrhage. There is no danger of the uterus enlarging to accommodate the clot as it increases in size, except directly after delivery, and when this is to be feared other methods of inducing contraction of the uterus must also be resorted to—*e.g.*, ergot, applications of cold, pressure through the abdominal wall, constitutional stimulants, etc.

If there is reason to believe that the hemorrhage is produced by something within the uterus,—as, for example, a retained placenta, or a polypus, which can be removed at the time,—this indication, as a matter of course, is to be acted upon first. But frequently these cases of hemorrhage occur in the night, or some other reason for delay in operating exists, or the patient may be so reduced that the first indication may be to prevent further loss of blood. Under these conditions resort must be had to the tampon.

The best material for the tampon is plain sterilized cotton, non-absorbent, squeezed out of carbolized water, and flattened out into discs one-half the diameter of the palm of the hand and about one-half inch thick. Non-absorbent is better than absorbent cotton, as it retains its elasticity and so, by its expansile power, increases the pressure. It is well to have, in addition, five or six tampons that have been squeezed out of alum water, of the strength of an ounce to the pint. These are the first to be used about the cervix and fornix vaginæ.

The bladder must be emptied either naturally or by catheter, and, if the case is not too urgent to permit time for it, the rectum should be unloaded by enema. The patient is placed in the Sims position, the Sims speculum is introduced, and the cervix is brought well into view. All coagula and fluid blood are wiped away with absorbent cotton held in dressing forceps, and the vagina is hastily swabbed out with bichloride solution, 1 in 5,000. If the os is patulous and the hemorrhage free, it may be well to pass the applicator, wrapped with absorbent cotton and dipped in iodine, as far up as to the fundus. If a decided impression on the uterus seems necessary, the cotton can be slipped off and left in the uterus as the applicator is withdrawn; but care should be taken to leave the end of it protruding from the os. The uterus will be stimulated by this means to contract, and probably to force out the cotton. In some cases one or two small plugs can be packed into the cervix. This will assist materially in stanching the flow of blood.

One of the disc-shaped tampon balls is now placed over the os, another posteriorly to the cervix, one on either side, and one in front. These are not rolled up into balls, but are spread out and moulded to the vaginal fornix by pressing them all about with the dressing forceps in the right hand, and a stiff probang stick, or another pair of closed dressing forceps, in the left. This completes one circle or layer of the tampons. Another layer is to be placed upon this in the same way, the discs being crowded well in against the cervix until the fornix is filled out flush with the external os. Disc after disc is thus placed around the cervix in a circle and well packed down. Each disc inserted is held in place by the rammer in the left hand until the next one can be inserted; in this manner the pressure is at no time relaxed. As the walls of the vagina stretch, and the diameter of the canal increases, a circle of discs is placed around the central one; then another concentric circle is placed outside of that, and so on until the vaginal wall is reached, the pressure being always made at first toward the centre. But as the lower section of the vagina is reached all the pressure is made toward the hollow of the sacrum, the final discs in each layer being tucked in against the anterior vaginal wall. The whole process is similar to that employed by a dentist in filling a dental cavity with gold leaf. No great force is used at any time in the proceeding; but, by firmly packing down each disc of the elastic cotton, the vagina can be gradually distended, if necessary, until the tampon nearly fills the entire calibre of the pelvis.

At first, the point of the speculum should be directed well toward the back, and then, as the work of packing advances, the end of the instrument should be allowed to slip along the floor of the pelvis. Sometimes the space thus left by the speculum can be filled in with two or three extra discs. Upon finally removing the speculum great care must be exercised not to dislodge the tampon.

When the vagina is thus packed there is no possibility of any further hemorrhage. The amount of cotton used and the thoroughness with which it is packed must vary with individual cases. A slight degree of pressure is sufficient in some cases, and the extreme degree of thoroughness alone suffices in others. It is necessary in all cases to confine the patient to bed, and when the tampon is large an anodyne is required. The pressure is especially painful about the neck of the bladder, and, if this persists in spite of the anodyne, some of the discs in this region can be removed at the end of an hour or two without impairing the integrity of the tampon. When such removal becomes necessary there is usually retention of urine and the patient has to be relieved with the catheter.

The tampon should not be allowed to remain longer than twenty-four hours. At the end of this time it has usually become soaked along one side, at least, with the bloody secretions. It is then more or less offensive and must be removed. It may be that it has done its work and is no longer necessary; in any event, it has ceased to be of use and should be replaced by a fresh one.

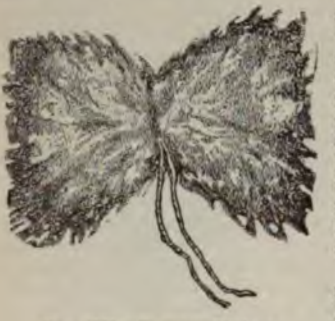

FIG. 4969.—Tampon Pledget.

It is most advisable, as recommended by Mundé, that the surgeon should keep on hand, in a well-stoppered bottle, a supply of absorbent cotton which has been soaked in some styptic solution—*e.g.*, subsulphate of iron (one part to three of water) or alum (one part to twelve)—and allowed to dry. This can be applied directly to bleeding surfaces, as in cancer, before one proceeds to the application of the tampon.

If Sims' speculum is essential to the placing of the tampon, Sims' screw tampon extractor is quite as important for its removal. By means of this instrument the first few pieces of cotton are removed without the use of the speculum. The external parts are separated by the left hand, and the screw, guided along the finger, is screwed into the discs, and they are removed one by one till the pressure is somewhat removed from the perineum. Then the speculum is introduced a short distance, and, as fast as the cotton is removed, it is slid farther and farther in until, with the final emptying of the vagina, it will have reached the farther end of the canal. In removing the tampon pledgets great care must be exercised not to overlook one, especially about the cervix or interior of the uterus. When so overlooked they are apt to be the cause of septic infection, occasioning a chill, rigors, and a rise of temperature.

Tamponade.—The tamponade is not so formidable an affair. It is in constant every-day use for the treatment of all kinds of uterine difficulties. It is employed for various purposes, the most important of which have been enumerated by Mundé under eight different heads, as follows: (1) As a carrier for the application of medicinal agents to the cervix and vagina; (2) as a means of retaining certain substances introduced into the uterus in their proper position—such as pledgets of cotton, tupelo tents, stem pessaries; (3) as a means of retaining the uterus or a prolapsed ovary in position; (4) as a mechanical support and stimulus to the pelvic vessels and as an alterative to the pelvic tissues by means of pressure; (5) as a protective to the ulcerated, inflamed, or swollen cervix or vaginal walls, to prevent friction and an increase of irritation; (6) as a means of dilating or separating the vaginal walls—a substitute for a hard or distensible dilator—in constriction of the vaginal canal after operation for vaginal atresia or stenosis in vaginismus, and in spasm of the levator ani muscle; (7) as a hæmostatic (I have already considered this subject under the head of *Tampon*, but there is another use of the tamponade or tampon that I deem worthy of special mention, and therefore shall consider it as the 7th, viz., to hasten expulsion in unavoidable miscarriage); (8) as an absorbent of vaginal and uterine discharges, which are thus prevented from touching the external or sound parts, and as a protection of the sound parts from caustic substances applied to the uterus or cervix.

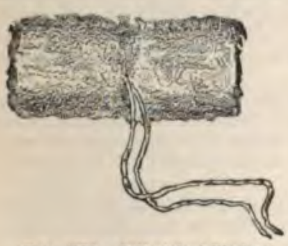

FIG. 4970.—Cylindrical Pledget.

This procedure has its special indications in the application of caustics, such as chloride of zinc, to malignant disease of the cervix or vagina. One or two tampons saturated with the caustic are applied directly to the diseased area, and are then kept in place by one or two dry tampons, after which the healthy portions of the vagina and the external parts are protected by tampons wrung out of a saturated solution of sodium carbonate and packed in the canal in such numbers as to fill the rest of the vagina.

As a carrier of medicinal agents the tamponade has come into almost universal use. The best material is the sterilized non-absorbent cotton or wool. The absorbent cotton, plain or borated, is extensively used. But when saturated with glycerin or moistened with the vaginal discharge it packs together too solidly, and has no elasticity. The absorbent cotton is used mainly as a mop in the dressing forceps for cleansing and drying out the vagina, and as a vehicle, when wound on an applicator, for making intra-uterine applications or for painting the vaginal vault.

Other materials besides cotton are used at times by the medical practitioner. Chief among them are tow, marine lint, wool, oakum, sponges. Of these the sponge is the least desirable. On the other hand, the cotton fulfils every purpose, is easily procured, is cheap, and, in fact, is the most generally used.

If some disinfectant, as carbolic acid, boroglyceride, or iodoform, is always used in the material with which the pledgets are loaded before being applied, the cotton needs no further preparation than to be made up into tampon balls ready for use. These tampon balls should not be made with too great nicety as regards looks. They pack together better and so retain their place in the vagina better if they are somewhat irregular in outline. The best way is to pull or tear off the cotton from the end of the roll, without unrolling it or removing it from its wrapper, in little masses of varying size, about two inches long and an inch thick, and without folding in the edges any more than enough to secure it all with the string. When this string has been made fast to it the tampon will be ready for use. (Fig. 4969.) The purpose of the string is to enable the patient to remove the tamponade herself. It should be long enough to project well out of the vagina, and strong enough not to break when traction is made upon it. For this purpose the neatest and simplest material to use is Clark's white cotton thread, No. 12 or No. 14. When used double it is sufficiently strong to withstand any strain that may be required. A convenient way is to cut off the thread about fourteen inches long; then catching it by the middle point, pass the two strands around the pledget, slipping them through the loop and drawing it up tight enough to hold the cotton securely. It is time-saving to make up a supply of these at convenient moments or to have the nurse do it. A number of these pledgets are saturated with the medicament from day to day, according to the number to be used, and kept securely covered to avoid evaporation.

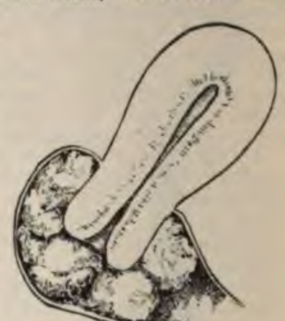

FIG. 4971.—Proper Application of Cotton Pledgets. Ordinarily only two are necessary, viz., the one posterior to the cervix and the one next to it. (After Mundé.)

The old-fashioned kite-tail tampon was made by tying a number of pledgets one after the other on a string. This was easy of removal, and in that respect was a success; but it was apt to get badly tangled and was awkward to handle.

Foster's lamp-wick tampon was a great improvement on this, and is an excellent device. The ordinary old-fashioned lamp-wick, as it comes wound in balls, is the material used. It is cheap, elastic, and absorbent; is readily introduced and has the merit of being as easily removed by the patient. Usually a single strand of the wicking is tucked into the vagina through a speculum; but when the ostium vaginæ is capacious several coils of the wicking may be gathered into wads and inserted one after the other without breaking the strand. When enough has been introduced the wick is cut off at the vulva, leaving the end thus protruding. To remove it the patient pulls on the projecting end and thus unwinds the mass within the vagina, drawing it through the vulva in a single strand.

Medicinal Agents.—Glycerin is the medicament most generally used on the tamponade, and with it are combined alum, ichthyol, fluid extract of eucalyptus, boroglyceride, carbolic acid, boracic acid, according to the indications. The tampon pledget may be dusted with a dry powder, bismuth, alum, tannin, or iodoform, or it may be smeared with an ointment. One or two medicated pledgets are to be inserted, and these are held in place by one or more dry ones.

It is important to bear in mind, in using the tamponade, that the patient must be informed that she has a specified number of pledgets of cotton in her vagina, and instructed how to remove them. The custom is to remove the tamponade at the expiration of twenty-four, thirty-six, or at the most forty-eight hours. No sudden traction should be made upon the thread lest it break. It must be drawn steadily downward toward the perineum, and when any astringent has been used on the pledget it is well to instruct the patient or nurse to pass her finger into the vagina alongside of the cotton and allow a little air to enter as the pledget is withdrawn. Otherwise the cotton acts like a piston in a pump, and may drag down the tissues above, even to the extent of retroverting the uterus. Passing in the syringe tube alongside of the cotton and injecting a little water will also prevent this unpleasant occurrence.

When several pledgets have been introduced it is a good plan to tie a knot in the string of the one to be withdrawn first, two knots in the second, and so on. Unless some distinction of this kind has been made the patient cannot know which string to draw first, and is as apt to make traction on the uppermost pledget as on the lowest.

In the vast majority of cases of peri-uterine trouble and inflammation of the appendages the nearest point of approach to it in the vagina is the part posterior to the cervix. The nearer the medication can be applied to the seat of the disease the more efficacious it will be. The logical deduction of these premises is that the medicated tamponade in the vast majority of cases should be placed behind the cervix, as shown in Fig. 4971.

In spasmodic and inflammatory conditions of the bladder, in acute ovaritis, or in tenderness of the uterine ligaments, the tamponade frequently affords relief by supporting and steadying the uterus, even when it is in normal posture. The most common application of the tamponade as a pessary is that made to retain the uterus in a normal position when first reduced from a retrodisplacement. The uterus, under these circumstances, is apt to be tender, and the surrounding tissues are too sensitive to tolerate a hard pessary. Indeed, where the circumstances will permit, a cure can be attained much more readily by persevering with the tamponade than by resorting to a pessary.

When the retroverted uterus is bound down by adhesions, the frequent applications of the glycerin tamponade, by its pressure and alterative action, will produce a stretching and absorption of the adhesions, and gradually allow replacement of the organ.

In partial or complete prolapse of the uterus a large astringent tamponade will often give more relief than any other support. If the vaginal and uterine supports are much relaxed, it may be necessary to retain the tamponade by a T-bandage. In rectocele and cystocele the tamponade is most serviceable. The astringent puckers up the vaginal walls, and ultimately restores their tone to a greater or less extent.

In 1878 Taliaferro, of Georgia, described a method of using the tamponade for the relief of subinvolution, areolar hyperplasia, descensus, and other dislocations of the uterus, with adhesions, chronic pelvic peritonitis, and cellulitis. His method simply introduced the element of pressure into the treatment already in use, thus stimulating circulation and hastening absorption in the same way that a snug roller bandage hastens the absorption of an exudation in the tissues of the leg. He places the patient in the knee-chest posture, and elevates the perineum with Sims' speculum. A few medicated pledgets are then packed into the fornix vaginæ with long dressing forceps, and upon them a solid column of tightly packed loose balls of wool or cotton is built, down to the floor of the pelvis. This column is flat antero-posteriorly, but reaches from side to side the full width of the vagina; or it may be varied in shape to make pressure where most desired.

Various methods have been devised by which the patient might be enabled to apply the tamponade herself. These methods are all to a greater or less degree deficient. Few women have sufficient dexterity and knowledge of the parts to enable them to apply a tamponade, in their own vaginæ, with any degree of efficiency, either through a special contrivance or a bivalve speculum. The idea is a delusion. If the tampon is to accomplish any beneficial results it must be applied carefully and intelligently, and with an eye single to the object to be accomplished in each individual case.

VIII. VAGINISMUS.—Vaginismus is a painful, involuntary, spasmodic contraction of the constrictor muscles of the vagina, firmly closing its canal and ostium. It may be due to structural changes in the hymen or the carunculæ myrtiformes, contact with which, or even the fear of contact, causing such violent contraction that coitus is precluded and even a digital examination becomes impossible unless the patient is anæsthetized. In such cases it is difficult to locate the source of the spasm. It is common in young, nervous, or hysterical women and is wont to declare itself at the first consummation of the marital rights; or it may develop during one of the following attempts at intercourse, being then due, in all probability, to the inflamed and sensitive state of the remnants of the hymen. It is produced sometimes by an irritable spot in the fossa navicularis, by urethral caruncles, by a vaginal or anal fissure, by the presence of an ulcer in the vagina, or by uterine or ovarian disease. Change of position in bed or washing of the genitals may cause an attack of vaginismus; it may also result from a lascivious dream, the patient awaking in pain from the spasm. In extreme cases convulsions and syncope may follow persistent attempts at coitus; and, on the other hand, nervous irritation with slight spasm may be induced by association with an impotent or partly impotent man.

In most cases the subjects of the disease are women who have been recently married, or women in whom, although perhaps married for several years, sexual intercourse has never been accomplished. In some instances, however, vaginismus first occurs after coitus has been enjoyed freely for months or even years, the symptom suddenly developing in consequence of an infection with gonorrhœa.

Sterility is almost the invariable result of vaginismus, and yet a few cases have been reported in which impregnation occurred without intromission.

In vaginismus superior—so called by Hildebrandt—the contraction occurs at some distance above the vaginal entrance, a sort of hour-glass contraction. In a few instances the contraction is voluntary; that is, the woman at will can prevent complete introduction of the penis, or, after it has entered, she can grasp and retain the organ. Hildebrandt narrates the case of a woman in whom this power was developed to such a degree that she was able voluntarily to grasp the penis below the glans so firmly as to make its withdrawal impossible. The levator ani was the constricting muscle.

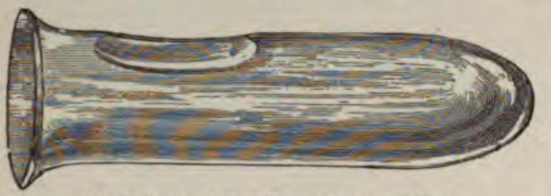

FIG. 4972.—Sims Glass Vaginal Dilator or Plug.

The diagnosis of vaginismus is not difficult. The labia majora and minora may be gently drawn apart, but the moment an effort is made to pass the finger into the vagina the pain, the spasm, and the wriggling of the patient may forbid any further examination without an anæsthetic. If the finger should overcome the resistance and find entrance, it may be so tightly grasped by the contracting muscles as to be benumbed. Frequently the patient is so hysterical that it is useless to make any attempt at an examination without the aid of an anæsthetic. As a rule, the anæsthesia must be very profound to permit of a thorough examination. In such cases it is best not to undertake the examination until arrangements have been made for operative interference, if such should prove to be necessary.

The treatment of vaginismus consists in absolute rest of the genital organs, all attempts at coitus being strictly forbidden. The hyperæsthesia of the parts may in some cases be relieved by hot sitz-baths or by applications of nitrate of silver (ten grains to the ounce), of a solution of chloral (four per cent.), or of carbolic acid (1 in 40). A four-per-cent. solution of cocaine is generally effective, but it must be used with caution. Ointments of belladonna or ichthyol sometimes afford relief. In fissure of the vagina or anus the base must be divided or touched with the thermo-cautery. Ulcers should receive appropriate attention, urethral caruncles removed, and irritable carunculæ myrtiformes snipped off. It may be necessary in some instances to excise the entire hymen and adjacent tissue. The edges of the wound thus made are then stitched with chromicized gut to secure primary union. As a matter of course an anæsthetic is necessary. In fissure of the neck of the bladder the urethra should be dilated to an extreme degree, the base of the fissure touched with a pencil of nitrate of silver or with the actual cautery, and a self-retaining catheter applied and left open for continuous drainage. In cases of obstinate spasm it becomes necessary to dilate the ostium vaginæ and its canal beyond the constrictor muscle. Such dilatation may be forcible and abrupt or gradual. The former is accomplished by introducing the thumbs into the vagina, the patient being anæsthetized, and separating the vaginal walls until the resistance is overcome by the rupture of some of the underlying structures, of which the most important is the sphincter vaginæ. Another method is to use a bivalve or trivalve or quadrivalve speculum as a dilator. The instrument is introduced closed into the vagina and then, after the blades have been opened, it is forcibly withdrawn. Gradual dilatation without anæsthesia may be accomplished in many cases by means of the Sims glass plug or dilator (Fig. 4972). The parts are benumbed by the application of cocaine and the dilator is introduced. It is retained for an hour night and morning. The pain caused by its introduction soon ceases and may be mitigated by anointing the plug before introduction with a medicated ointment. The presence of the plug helps to obtund the sensibility. Day by day an instrument of larger size may be substituted until the vagina is overstretched.

When the dilator cannot be borne by the patient, an operation is the only recourse. With the patient anæsthetized the surgeon introduses two fingers of the left hand into the vagina and then firmly stretches the parts. With the scalpel he next makes an oblique incision about two inches long through the vaginal tissue on each side, extending from half an inch inside the ostium to the raphe of the perineum. More pressure is then made to distend further the vagina. Finally, the vagina is firmly packed with sterile gauze and a **T**-binder applied. Should there be little or no hemorrhage, the glass plug may be inserted at once; otherwise the gauze is left in place until the following day when it is removed and the glass dilator substituted. This instrument is then to be worn for a short time every day for several weeks, *i.e.*, during the healing of the wounds. The constitutional treatment, which should always accompany the local measures, consists in tonics of arsenic, strychnine, and glycero-phosphates, in outdoor exercise, and in change of scene. Complete sexual rest should be enjoined.

VALERIAN.—(*Valeriana*, U. S. P.; *Valerianæ Radix*, B. P.; *Radix Valerianæ*, P. G.) The dried rhizome and roots of *Valeriana officinalis* L. (fam. *Valerianaceæ*).

This perennial herb, native of the temperate parts of Europe and Asia, is a familiar object in our gardens, where it is grown partly as an ornament, partly for medicinal purposes. It is largely grown as

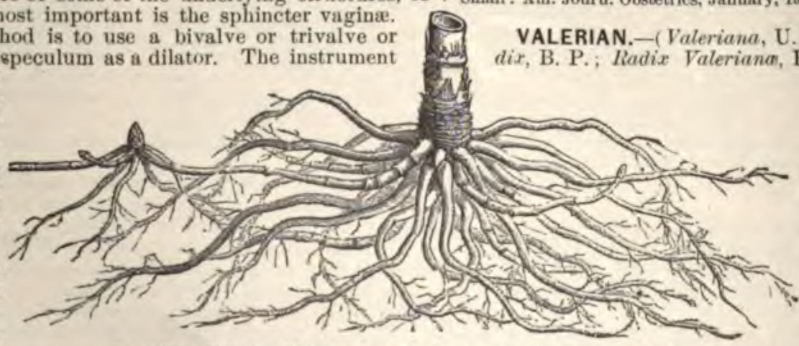

FIG. 4973.—Valerian Rhizome and Roots, about two-thirds natural size.

a drug in England, Holland, and other parts of Europe, though the product of wild plants is said to be superior. It should be collected and dried in the autumn. The rhizome is from 2 to 4 cm. (about 1 to 1.5 in.) long, and 1 to 2 cm. (about 0.5 to nearly 1 in.) thick, upright, subglobular or obconical, truncate at both ends, light-brown or yellowish-brown, internally whitish or pale-brownish, with a narrow circle of white wood under the thin bark; roots numerous, rather coarse, brittle, brown, with a thick bark and slender, ligneous cord; odor peculiar, becoming stronger and unpleasant on keeping; taste camphoraceous and somewhat bitter.

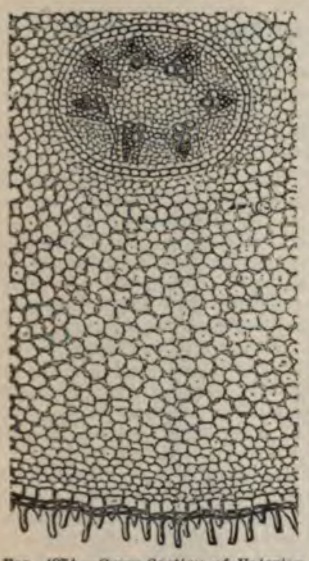

FIG. 4974.—Cross Section of Valerian Root. (Baillon.)

Small, stunted rhizomes, grown upon dry, stony soil, are commonly superior to those of finer appearance.

The important constituents of valerian are: from one-half to two per cent. of volatile oil, and variable amounts of valerianic acid, of a camphor-like body very similar to borneol, and of resin. Both the volatile oil and the resin are mixtures, containing the camphor and valerianic acid. The oil consists chiefly of the terpene *valerin*. The proportion of these different substances varies greatly, according to the age of the drug after collection, the percentage of the oil thus usually decreasing, that of valerianic acid increasing.

Oil of valerian suitable for medical use is described in the Pharmacopœia as follows: "A greenish, or yellowish, thin liquid, becoming darker and thicker by age and exposure to air, having the characteristic odor of valerian, an aromatic, somewhat camphoraceous taste, and a slightly acid reaction. Specific gravity about 0.950. It is readily soluble in alcohol." Valerianic acid is also liquid, but thicker than the oil, colorless, of a strong valerian-like, but also sour and cheesy, odor, and a sour, burning taste. It is an active acid, forming salts with the metals and alkaloids, several of which are in use.

The intoxicating action of valerian on cats, which seem to have an irresistible craving for it, is well known. In very large doses, several drachms several times a day, it may produce, in man, dizziness, disturbance of vision, hallucinations, or active delirium. Nausea and vomiting are also likely to occur from such doses. It appears to be eliminated by the kidneys, which it stimulates slightly.

Its medicinal action is that of an antispasmodic, like musk, asafœtida, chamomile, lavender, etc., as well as ether and the bromides. Like most essential oils, it is also a general and digestive stimulant in moderate doses.

Valerian is frequently given to patients suffering from emotional unbalance, hysterical and "nervous" (in the popular sense) disturbances, headaches, and other pains due to the same causes, as well as wakefulness, with considerable benefit. It is also given in some more serious and obstinate diseases, as chorea or epilepsy, especially petit mal, with occasional benefit.

The most advantageous way of employing valerian is to give either one of the galenical preparations of the drug, or the oil.

The dose of the root is 1–2 gm. (gr. xv.–xxx.), of the official fluid extract an equal number of cubic centimetres or of minims. There is also an official tincture, strength one-fifth, and an ammoniated tincture, of the same strength in aromatic spirit of ammonia.

Henry H. Rusby.

VALERIANIC OR VALERIC ACID ($HC_5H_9O_2$).—Valerianic acid is the active constituent of valerian, whence it was first obtained for study. It is also the chief active constituent of cypripedium, and is found in various other aromatic drugs, such as angelica. Besides these natural sources, it is readily obtained by the chemical change of many organic substances, and is very largely manufactured by the oxidation of amylic alcohol with bichromate of potassium. Thus we have in the market a natural and an artificial acid. The natural acid is obtained by the distillation of valerian with water. The distillate is a mixture of volatile oil of valerian and valerianic acid, and a portion of the oil can be converted into the acid. This acid is divisible into the normal valeric and the iso-valeric acids. The artificial acid produced from amylic alcohol is combined with sodium, from which it is then freed by sulphuric acid. This form is therefore more prone to impurity. If strictly pure, it is the practical equivalent of the natural acid. Valerianic acid occurs as a colorless, transparent, thin, oily, volatile, combustible liquid, with a strong odor, much like that of valerian, and an acrid, burning taste. It is soluble in both alcohol and water, the artificial pure iso-acid being much less soluble in water. The specific gravity of the pure natural acid is 0.940. Acetic acid has been used as an adulterant.

Valerianic acid shares the antispasmodic properties of oil of valerian, but is usually distinctly inferior to it. Its stimulating effect is spurious, it being distinctly weakening. It is capable of poisoning by cardiac and respiratory paralysis, the latter indicated by convulsions. It is used in hysteria and mania, in doses of three to ten minims. It is largely used for the administration of certain bases in the form of valerianates, and the valerianates of ammonium, quinine, iron, and zinc are official.

Henry H. Rusby.

VALERIDIN.—A synonym for sedatin (*q. v.*).

VALIDOL, menthol valerianate, a menthol ester of valerianic acid, is a clear oily liquid of mild aromatic odor and a not unpleasant cooling taste. It contains about thirty per cent. of menthol.

Neustatter gave the remedy in five cases of scintillating scotoma, with prompt disappearance of the flashing and the accompanying headache. Cipriani has employed it as an expectorant in bronchitis, as an anti-emetic in the vomiting of tuberculosis, and in pharyngeal or nasal catarrh as a spray or local application.

Goldmann recommends it in the treatment of nervous headache, migraine, neuralgia, and neurasthenia, and as a stimulating stomachic. Applied externally in hemicrania and such conditions, it exerts a sedative and analgesic action. Dose ten to thirty drops on sugar or in capsule.

W. A. Bastedo.

VANILLA.—U. S. P. (*Fructus Vanillæ*, P. G.) The fruit of *Vanilla planifolia* Andrews (fam. *Orchidaceæ*) peculiarly cured and dried.

The vanilla plant is an epiphytic climber, with fleshy stems and foliage, native of the forest regions of eastern Mexico. It is very extensively cultivated there, as well as in many parts of the Old-World tropics. As grown in these different regions it exhibits distinct varieties, and the products differ considerably in quality and in commercial value. The Mexican variety is still generally preferred in the United States, but the Bourbon article, as improved during recent years, is fast overtaking it in popular estimation.

Natural pollination of the flowers is so scanty that artificial pollination by hand labor is an important industry. Green vanilla fruits are very similar in appearance to green bananas, but relatively only about one-third as stout. They are gathered just when they begin to turn yellow. If left longer, they are apt to split at the ends in drying, which renders them less salable; though some good judges believe that these "splits," as they are commercially termed, are not inferior. The details of the curing process vary greatly in different countries, and even among different operators, but its essential features depend upon the fact that the odorous principle, vanillin, does not exist in the natural fruit and must be developed in the curing process. This usually consists of a sweating or steaming operation in a closed space, followed by alternating exposures in closed containers, or between woollen blankets. The "beans" thus treated gradually shrink in thickness and become darker until they assume the characteristic appearance described below. They are assorted into lengths, the more long and slender ones being preferred and selling higher. They are tied tightly into bundles, wrapped in paraffin paper, and packed in tight tin cans. Because of the loss in weight from over-drying, there is a temptation to underdry them, and many bundles, owing to this mistake, are found mouldy within, on being opened. The finest product is thus described: Bean-shaped fruits, from 20 to 25 cm. (8 to 10 in.) long and 5 to 8 mm. ($\frac{1}{5}$ to $\frac{1}{3}$ in.) thick, straight, except for the short-hooked base, flexible, longitudinally wrinkled, dark chocolate-brown, shining or covered with white crystals of vanillin, giving them a frosted appearance; one-celled, with three fleshy placentæ and innumerable minute seeds; having a strong, pleasant, and characteristic fragrance, and a sweetish, aromatic, and slightly fruity taste.

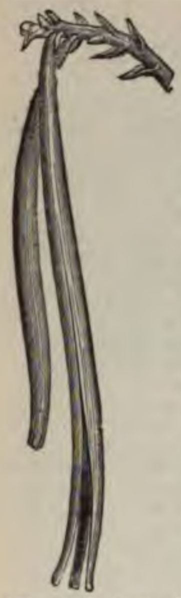

FIG. 4975.—Fruit of "split" Vanilla, one-fourth natural size.

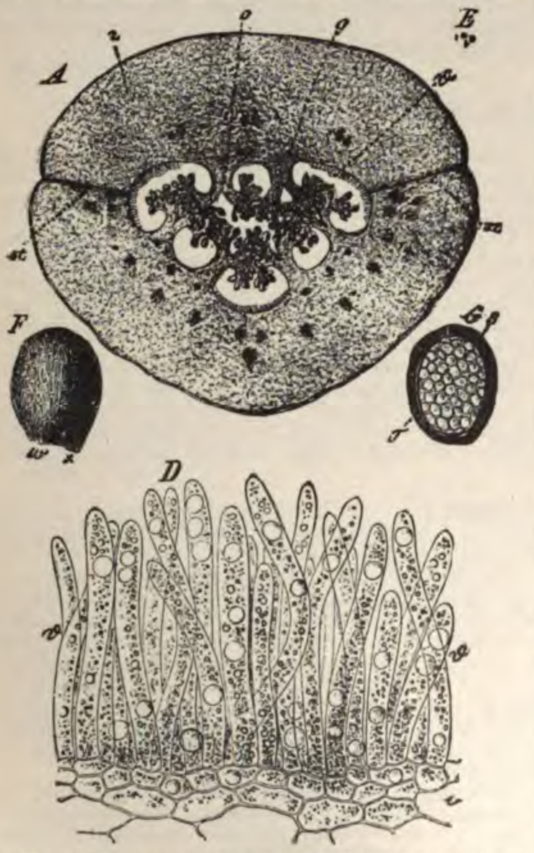

FIG. 4976.—*A*, Transverse section of Vanilla Pod, enlarged; *E*, seed, natural size; *F*, the same, magnified; *G*, section of same; *D*, the papillary gland hairs lining the cavity of the pod. (Berg.)

CONSTITUENTS.—The important constituent of vanilla, and that which represents its odor and taste, is from 1.5 to 2.5 per cent. of *vanillin*, *vanillic aldehyde*, or *methyl-protocatechuic aldehyde*, ($C_8H_8O_3$), which occurs in colorless prisms having the characteristic odor and taste of vanilla in intense degree; they melt at 80° to 81° C., and are soluble in alcohol, ether, and chloroform, and less so in water. With the vanillin, occur a little volatile and about ten per cent. of fixed oil, sugar, and other unimportant constituents.

SUBSTITUTES AND ADULTERANTS.—On account of the high price of vanilla and vanillin, both have been enormously substituted and adulterated. The use of inferior fruits of other species of vanilla, short, broad, flat, and of a strong fruity odor, must be classed as substitution. These usually cost only from one-tenth to one-twelfth as much as the best. The use of tonka beans and other substances containing cumarin is even more extensive. Finally, various compounds of prunes, raisins, and other substances are sold as vanilla substitutes. Cumarin is itself substituted for vanillin. Artificial vanillin is largely prepared from coniferin and eugenol, and, although apparently identical chemically with the natural, it has not been found equal to it in useful properties.

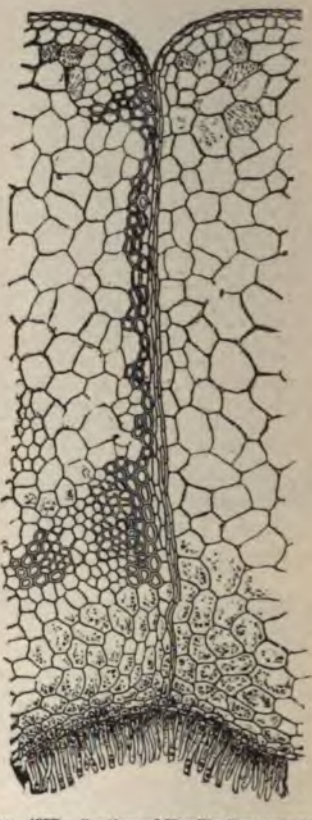

FIG. 4977.—Section of Vanilla through the Commissure where the Fruit splits. (Berg.)

USES.—Vanilla has no active properties as a medicine, though the official ten-per-cent. tincture is sometimes used as an antispasmodic in fluidrachm doses. As an adjuvant for perfuming and flavoring, it has many uses in the pharmacy, as well as in confectionery and pastry.

Henry H. Rusby.

VANILLIN PARAPHENETIDIN, $C_6H_3.OH.OCH_3.CH.N.C_6H_4.OC_2H_5$ is formed by heating vanillin with paraphenetidin. It occurs in the form of crystals which are soluble in water, and in dose of 1 to 2 gm. (gr. xv.-xxx.) it has a hypnotic and antineuralgic action.

W. A. Bastedo.

VARIATION.—In its modern biological sense, *variation* is used to signify a difference or the presence of differences from some *type* taken as the standard of comparison. With a somewhat more limited meaning, the word *deviation* also is used as the name for a difference from the type of any organ or character. By *variability* is meant the extent of the deviations, together with the relative number of individuals possessing each degrees of variation.

What Variation is Not.—Much confusion in regard to variation has arisen from the word having been employed loosely with meanings not in accord with the present usage. Therefore it may be well at the outset to call attention to the more important variations in the use of the word.

In the first place, it is necessary to distinguish between variation and *modification*. Following the suggestion of C. L. Morgan (1897), which has been adopted largely by biologists, we may employ the word *modification* as a technical term, to signify a change in any characteristic of an individual organism in response to some condition of its environment or the process by which such a change is brought about. Modifications were spoken of formerly as *acquired characters*, but the term *acquired* has frequently led to confusion in the minds of persons not perfectly familiar with the facts. It seems best, therefore, to abandon that term. A modification is a change produced in an individual. A variation is any difference in the individual from a certain ideal condition taken as the type. Thus a modification may produce or modify a variation, but modification and variation are two entirely distinct and independent concepts. An electric discharge may produce sound, but sound and electricity are not the same thing, and sound may be produced by other causes. Likewise, modification may produce variation, but they are not the same thing and variation may be due to other causes.

Theoretically we may follow Weismann in making a distinction between blastogenic and somatogenic variations; *blastogenic* variations being those due to differences in the constitution of the germs from which the group of individuals under consideration have developed, while *somatogenic* variations are differences which have arisen in the bodies (*somata*) of the individuals as the result of modification following exposure to different environmental conditions. But as has been pointed out by Vernon (1903), in the practical study of variation by statistical methods, it is generally impossible to make this distinction. This is due, in the first place, to the fact that blastogenic and somatogenic variations may be of the same kind and degree. Thus deafness may result from a pathological lesion, as in scarlet fever, or it may be due to a congenital malformation, which, owing to observed parental correlations, we must suppose to be of blastogenic origin. But even in such an extreme variation as this Fay (1898) found it impossible to determine in many cases to which class a given individual should be assigned. In the second place, every individual and even parts of individuals, are subject to constantly fluctuating environmental conditions from the moment of conception until death. These changes of surrounding conditions are met by corresponding responses, functional or structural, or both, on the part of the organism, but these reactions are themselves probably subject to variations independent of the exciting stimuli, and who can tell, therefore, how much of the similarities and differences in any group of organisms is due to similarities and differences in the structure of their germs, and how much to the various conditions of the environment to which they have been subjected? The importance of modifications in the normal development of organisms has been discussed in another article (see *Differentiation*).

The clearest examples of purely blastogenic variation are to be found in such mammalia as give birth to a considerable number of offspring at one time. For example, in a litter of puppies or kittens, all sired by the same male, all developed at the same time in the same uterus, we have a group of organisms where the conditions of parentage and environment are as uniform as possible, and yet variations in color, form, and mental traits will be readily apparent. These differences appear to be clearly blastogenic in origin, but the very general presence of a "runt" in such a litter indicates that the conditions of nutrition at least have not been quite uniform. Variation, then, as we understand the term at present, is not a broader term than modification, as Vernon (1903) would have it, but is an entirely distinct concept. Modification, on the other hand, may stand toward variation in the relation of cause to effect. Variations so effected are classed as somatogenic, as distinguished from blastogenic variations of purely germinal origin.

Moreover, our idea of variation does not include any change in the individual taking place during the course of its life, no matter whether that change be of blastogenic or somatogenic origin. Thus the changes which an individual insect undergoes in the course of its metamorphosis would not come within our definition of variation. But a group of insects, say the potato beetles in a certain field, would exhibit in each stage of their development variations from the type of that stage, and the degree of variability might differ in the successive stages.

Finally, the idea of variation does not necessarily include the parental relation. It is true that we may select one or the other parent, or both parents combined in an imaginary mid-parent (see *Heredity*) as the type, when dealing with the characters of offspring of identical or like parents. This is done in the study of heredity. But in the ordinary study of variation the investigator is usually ignorant of the parentage of his material. So a variation is not a difference from the parental type necessarily, but is a difference from any type that may be selected.

In fact, variation is a phenomenon by no means confined to organisms. It is shown as well by lifeless objects and events. Thus we may, if we choose, study the variability of the stones on the beach, of snow crystals, of the forms of clouds, of rainfall, of the height of the barometer, or of the price of wheat.

Aim and Method of Study.—Having now clearly in mind what is meant by variation, let us consider what it is that we may expect to gain by the study of this subject and the method to be pursued in such an investigation.

Every one who is at all familiar with modern theories of organic evolution knows that variation is of very great and very fundamental importance from the theoretical points of view. Variation is at the basis of every theory of evolution. Therefore, in order to understand evolution, we must know the facts of variation. (See *Evolution*.)

Variation is an important factor in the classification of animals and plants. Formerly the systematist simply took as the type of a species the individual that was first described. The modern methods enable him, when provided with sufficient material, to define the limits of a species with much greater accuracy and to select as the type a form that is truly representative.

To the physician the study of variation is of great importance. Every practitioner knows that the same disease may be manifested in diverse forms, and that patients vary in their reactions to treatment. A study of the types and variability of diseases and of the effects of treatment may be expected to add much toward a true appreciation of these subjects.

For the surgeon, variation is still more important. He must know what anomalies are likely to be met with and their relative frequency.

Variation has been studied extensively by teachers of gymnastics and the results have had practical application in the determination of the relative rank of the pupils and their degrees of improvement.

The method employed in the modern study of variation is statistical. This, as Pearson (1902*c*, p. 320) has well said, is "because the whole problem of evolution is a problem in vital statistics—a problem of longevity, of fertility, of health, and of disease, and it is as impossible for the evolutionist to proceed without statistics as it would be for the registrar-general to discuss the national mortality without an enumeration of the population, a classification of deaths, and a knowledge of statistical theory." This is true, not only for the problem of evolution, but also for all problems for which a solution may be sought in the phenomena of organic variation.

In order that this method may be employed, the data must be expressed in quantitative terms. We may no longer speak of things as being longer or shorter, heavier or lighter, but we must give the results of observations in exact units of length, weight, and the like. Or, if this be impossible, the observations must be divided into groups, so that each group shall be as nearly as may be equally divergent from the one on either side of it, in order that to each one may be assigned a serial number that can be used as a quantitative expression.

The statistical method for the study of variation was founded by Quetelet (1846), who showed that certain human characteristics follow in their relative frequency the mathematical law of the probability of error, which had been applied previously to astronomical and other physical observations. Darwin (1868) gathered a great many cases of variation, especially among domestic animals and plants, but he seems to have overlooked Quetelet, or, at any rate, he did not employ his method. The first attempt to study the variations of wild animals by exact quantitative measurements appears to have been made by J. A. Allen. But we are especially indebted to Galton (1889) for calling the attention of both socialogists and naturalists to the importance of the statistical method for the study of variation and heredity. He made considerable advances beyond Quetelet's use of the theory of probability, and his methods were quickly appreciated and used by persons interested in anthropometry. Weldon (1890) was the first to apply these methods in the study of variations of animals, and de Vries (1894) applied them in botany. He was quickly followed by Ludwig (1895), who had made previously extensive statistical investigations on plants (1883 *et seq.*).

While others had paved the way, naturalists are especially indebted to Pearson for his mathematical investigations beginning in 1893, which, it is safe to say, will be the foundation for all future work in statistical biology. Unfortunately, however, much of his writing is unavailable to any but those versed in the language of the higher mathematics. Dunker (1899) has done good service in giving an excellent elementary treatment of the subject as it stood at the end of the year 1898, and Davenport (1899) has furnished a useful manual of formulæ and tables. But both of these works are now (1903), in part at least, out of date, and a text-book that will enable the average naturalist or physician to understand and apply the principles laid down by Pearson is still very much to be desired.

Classification of Variations.—Before proceeding with the details of the statistical method it may be well to pause to consider the nature of the material to be studied.

In the first place it should be noted that every individual has many characteristics, and one of the limitations of the method is that it deals primarily, not with individuals as entire objects, but with single characters only. Part of this difficulty may be overcome in some cases by combining two or more characters in a ratio, usually called an *index*, as the *cephalic index*, the ratio of breadth to length of head, or the *strength-weight index*, which is the ratio of the sum of the strength tests to the weight. Such a ratio may then be treated like a single character.

Another difficulty that would be met with in an attempt to appreciate the variability of entire organisms arises from the fact that single characters in one individual differ greatly among themselves in the amount of their deviations from the values typical for the population as a whole. For example, it is very seldom that we meet with a man who has more or less than one nose, two eyes, a mouth, and the like; while, on the other hand, we find within certain limits all degrees of variability in stature, proportions of the face, color of the hair and eyes, and in various mental traits. So at the outset we may divide the characteristics of organisms into (1) those that are *normally stable* and (2) those that are *normally variable*. When a variation is observed in a character that is normally stable, it is so unusual an occurrence as to attract at once the attention of an observer familiar with the normal form. Gardeners call such variations "sports." Nectarines, our seedless fruits, double flowers, and many new varieties of flowers and fruits have arisen in the first place as sports. In animals polydactylism, albinism, and other monstrosities come within this class of unusual variations, which we may designate as *anomalies* in contradistinction to the *normal variations* of normally variable characters. Perhaps the normally variable characters may sometimes show variations that are so extraordinary as to be classed as anomalies, but it is hard to draw a line between these and the extremes of normal variation.

Bateson (1894) has divided variations into substantive, meristic, and homœotic. *Substantive* variations are differences in the substance of the organism, such as variations in size, weight, color, chemical composition, and the like. *Meristic* variations are differences in the number, division, and geometrical position of parts. *Homœosis*, or the occurrence of a homœotic variation, may be seen in a meristic series when a member of one series appears in the form characteristic of another series, as when in a flower one in the series of stamens appears in the form of a petal, or as when in a spinal column a vertebra of the lumbar series develops with the structure of a thoracic vertebra. In a case like the spinal column, however, where several series of structures are closely connected, it is not always possible to distinguish between homœosis and ordinary meristic variation.

It will be seen from this classification that variation opens a wide field for study. It would be useless to attempt to give illustrations of these classes in the present article, for every one will call to mind cases within his own experience, and to summarize the literature on the subject would require volumes. One wishing information in detail should consult Darwin's "Variation of Animals and Plants under Domestication" (1868), Bateson's "Materials for the Study of Variation" (1894), and especially Vernon's "Variation of Animals and Plants" (1903), which is an excellent summary of the results of recent investigations.

From another point of view variations may be classified according to their mode of occurrence into (1) variations between parts of an individual, (2) variations between individuals, and (3) variations between races or other groups of individuals.

In both animals and plants there may be produced in one individual a number of similar parts which show among themselves no differentiation connected in any marked degree with either their time of development, their relative position, or their relation to the environment (Pearson, 1902, p. 335). Such "undifferentiated-like organs" Pearson calls *homotypes*, and we may speak of the variation of such parts within a single individual as *homotypic variation*. Examples are variations in the number of veins in the leaves of a beech tree, the number of seeds in the pods of a pea vine, and the like.

If, instead of comparing similar characters of the same individual, we take like characters of different individuals, we may find what is called *individual variation.** For example, we might count the number of ray flowers on the highest head of each one of a thousand plants in a field of daisies, or we might measure the stature of each man in a regiment of soldiers. Such observations would give us the data for the study of individual variations in these groups.

Finally, if a study of the data of individual variation shows that the observations tend to group themselves, not about a single type, but around two or more types (as determined by appropriate methods to be mentioned later), then each type may be taken as representation of a race or of a species, and we are confronted by the phenomena of *racial variation*. Under this heading would be included differences of type in the same locality as well as differences in different localities. In the first case the material would be said to be *heterogeneous;* in the second case, while it might be *homogeneous*, that is, variable about a single type, in each separate locality, it would likewise be heterogeneous as a whole. The heterogeneity of mixed material in the same locality is difficult to determine, but the presence of racial variability associated with difference of dwelling-place is a familiar phenomenon, especially to American ornithologists. Witness the races of Bob Whites, song sparrows, flichers, Western blue jays, etc. It is important to note the distinction between what we have called individual and racial variation, because a failure to do this leads to confused ideas as to the method of evolution.

---

* Pearson uses the term "individual variation" for what we have called homotypic variation and his racial variation is our individual variation. But our use of the latter term is more in accord with current American usage.

Variation and Chance.—All human knowledge is an estimate of probabilities. But in the statistical study of variation the mathematical theory of probability, or doctrine of chance, is of especial importance, for it forms the foundation upon which the method is erected.

Most persons think of chance as something quite independent of law. They imagine an event occurring by chance as one quite impossible of prediction, and the Darwinian theory has been criticised because it supposes race progress to depend upon the survival of "mere chance variations." On the contrary, while it is perfectly true that we are frequently unable to predict single events, it may be shown, nevertheless, that chance follows very definite laws, which may be expressed by exact mathematical formulæ.

In order that the discussion of statistical methods may be clear, it is necessary to call to mind at this point those principles of probability that especially concern our subject.

In the first place, "the theory of chance consists in reducing all the events of the same kind to a certain number of cases equally *possible*, that is to say, to such as we may be equally undecided about in regard to their existence, and in determining the number of cases *favorable* to the event whose probability is sought. The ratio of this number to that of all the cases possible is the measure of this probability, which is thus simply a fraction whose numerator is the number of favorable cases, and whose denominator is the number of all the cases possible" (Laplace, 1902, p. 6).

This definition of probability, which is the first principle of Laplace (*loc. cit.*, p. 11), may be illustrated by the tossing of a coin. Suppose I drop a silver quarter upon the table: it may come to rest either with the goddess of liberty or with the eagle on the upper side, "heads or tails." We have, then, two equally possible events resulting from the tossing of the coin. Suppose A bets that the throw will be heads, and B takes him up. There are two possible events, of which one is favorable to A, so the probability of his winning is expressed by the ratio one-half, but the other one of the two possible events is favorable to B, and the probability of his winning is also expressed by the ratio one-half. The probabilities for and against heads being the same, the bets on the game should be even. All the equally possible events that may produce or prevent a result are called the *chances* of that result (Quetelet, p. 10). The chances may be favorable or unfavorable; if all favorable, the result is a certainty. It will be noticed that the probabilities for and against the event added together equal unity, which is the mathematical expression for certainty. Thus in mathematics the various degrees of probability are expressed by fractions which may have any value between 0 and 1. It should be noted also that the probability of a given result remains the same no matter how many possible events may affect it, provided that the ratio of favorable events to total events remains the same. Suppose, for example, that A and B play with dice instead of a coin. A cube has six faces, any one of which may rest uppermost. Let A bet that the upper face will show more than three spots, he wins if it shows four, five, or six; that is, there are three favorable out of six possible chances, and the probability of his winning is $\frac{3}{6} = \frac{1}{2}$, as before. But suppose that he wagers on the throw being an ace, then he will lose if any one of the other five sides turns up. His probability of success is then $\frac{1}{6}$, and the probability of the stakes going to B is $\frac{5}{6}$. In making the bets, therefore, B should give odds to A of five to one. What this means is, that, while we cannot predict the result of a single throw of coin or dice (for if we could the probability would be certainty), this calculation enables us to foresee that in the game of heads and tails or in throwing dice for more than three spots, the number of successes will in the long run equal the failures, or in the throwing of aces will be in the proportion of one to five, provided always that the coin or dice are perfectly symmetrical in form and weight.

The closeness of observation to theory is illustrated by an experiment made by Quetelet (*loc. cit.*, p. 93). He placed in an urn 40 white and 40 black balls, and then drew one ball at a time, which was replaced after its color had been recorded. He made in all 4,096 drawings, and according to the theory of probability the result should have been 2,048 white balls and the same number of black. The actual results were 2,066 white and 2,030 black balls, an error of only $\frac{8}{1000}$.

The theory of probability teaches us how to judge of future events by past experience; it is thus common sense reduced to mathematical expression. Suppose, as does Quetelet (*l.c.*, p. 14), that we wish to determine the probability of drawing a white ball from an urn. We upset the urn and count the balls. If we find two white balls, three red, and four black, we answer that the probability of drawing a white ball at the first draw, the balls having been replaced, will be $\frac{2}{9}$.

But let it be impossible to upset or to see into the urn, and let only one ball be drawn at a time, which must be replaced before drawing another. Having no previous knowledge of the contents of the urn, we may suppose it to contain any number of balls of any color mixed in any proportion. The probability of drawing a white ball at the first draw may have any value from 1 to 0. We may suppose this value to be $\frac{1}{2}$. We draw a ball which is white, and it is then replaced. Now we know that the urn contains one white ball, and we may guess as before that the rest of the balls are in equal proportions of white and colored. There would then be on this hypothesis two chances of drawing a white ball to a total of three chances, and the probability would be $\frac{1+1}{1+2} = \frac{2}{3}$. A second draw is made with the same result. Now we know that the urn contains two white balls, and the probability that the third ball will be white becomes $\frac{2+1}{2+2} = \frac{3}{4}$. Similarly after ten white balls have been drawn in succession, the probability that the next ball will be white is $\frac{10+1}{10+2} = \frac{11}{12}$, and after ninety-eight repetitions of this result it is increased to $\frac{98+1}{98+2} = \frac{99}{100}$ (Quetelet, *l.c.*, p. 367). This is but a rough illustration of a principle that mathematicians arrive at by a somewhat different line of reasoning involving the processes of the integral calculus. The rule is: "That an event having occurred successively any number of times, the probability that it will happen again the next time is equal to this number increased by unity and divided by the same number increased by two units" (Laplace, p. 19).

Thus from the analogy of the urn we see how we may judge of the probability of future events in nature. If, for example, I examine one hundred specimens of a certain kind of animal and find that each one has six legs, the probability that the next one examined will have six legs is $\frac{101}{102}$, a value so near unity that I may safely infer that the number of legs in this species is a normally stable character. Putting the extent of historical time at 5,000 years, or 1,826,213 days, during which time the sun is known to have risen regularly during every twenty-four hours, the probability, aside from all other considerations, that it will rise to-morrow is $\frac{1,826,214}{1,826,215}$, or the chances that it will not rise are about one in two million. Thus we see how the factor of doubt in regard to any deduction decreases with the increase in the number of observations upon which the deduction is based. Whatever may be the true value of this unknown factor we may reduce its relative value to any extent we please by continuing the observations to any desired limit. An explorer who upon entering an unknown island should meet two men, both black, would still have considerable doubt as to the color of the rest of the inhabitants. But after he had seen a thousand of the natives and found them all black, he would be justified in thinking that to be the color of the whole population.

Another principle similar to the preceding may be illustrated by returning again to the urn. Suppose that the result of the first nine consecutive drawings was five white and four black balls, the probability of drawing a white ball next time would be expressed by $\frac{5+1}{5+4+2}=\frac{6}{11}$; and if the result of ninety-nine drawings was fifty-five white and forty-four black balls the probability that the hundredth ball will be white is $\frac{55+1}{55+44+2}=\frac{56}{101}$. Thus in such cases in which observations show two possible results, the probability that one of these results will occur again is expressed by a fraction whose numerator is the number of times that result has been observed plus one, and whose denominator is the total number of observations plus two (Quetelet, p. 27). Here, again, we see the factor of doubt decreasing in relative value with the increase of the number of observations, so that, if after a large number of drawings we still get the same relative numbers, we may conclude that the urn contains only black and white balls, and that the proportion of white to black is five to four. Hence with a sufficient number of observations the factor of doubt practically vanishes and we may consider the chances favorable to each of the results to be in the same proportion to the total number of chances that the number of times each result has been observed is to the total number of observations (Quetelet, p. 29). When there are several possible results the calculation is rather complicated, but this rule practically holds good.

This principle is applied in calculating the proportion of the sexes. Thus Quetelet, taking the data from all the rural districts of Belgium during the year 1841, found that there had been born 53,437 male children and 49,788 females, giving a proportion of 1,072 males to 1,000 females. But taking the data for nine years, 1834 to 1842, he found the proportion to be 1,063 to 1,000, which is the same as the result obtained later by Oesterlen from the records of 59,350,000 births gathered from several countries of Europe. (See article *Sex*.)

One of the most important of the principles of probability is that, "If the events are independent of one another, the probability of their combined existence is the product of their respective probabilities." (Third principle of Laplace, *l.c.*, p. 12.) For example, if A toss a coin, the probability of heads is one-half; likewise the probability of B's coin giving heads is one-half. If A and B toss their coins at the same time, there are four possible combinations, but in only one of these do both get heads, thus:

(1)	(2)	(3)	(4)
A—heads	heads	tails	tails
B—heads	tails	heads	tails

So the probability that both A and B will throw heads (1) at the same time is $\frac{1}{4}$, which is equal to the product of the probabilities that A and B will throw heads, respectively, multiplied together, $\frac{1}{2}\times\frac{1}{2}=\frac{1}{4}$. For the same reason the probability that both will throw tails (4) at one time is $\frac{1}{4}$, and $\frac{1}{4}$ is likewise the probability that A will throw heads at the same time that B throws tails (2), and that B throws tails when A throws heads (3). But combinations (2) and (3) give like results, namely, heads and tails. So there are two chances of heads and tails against two that the throws will be either both heads or both tails, and the probability is $\frac{1}{2}$. Thus heads and tails thrown with two coins is a complex combination, and its probability is the sum of the probabilities of the two simple combinations of which it is composed, $\frac{1}{4}+\frac{1}{4}=\frac{1}{2}$. It may be noticed that these values, $\frac{1}{4}$, $\frac{1}{2}$, $\frac{1}{4}$, are the terms of the expanded binomial $(\frac{1}{2}+\frac{1}{2})^2$.

If C comes into the game the number of possible combinations is increased as follows:

(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
A—h	h	h	t	t	h	t	t
B—h	h	t	h	t	t	h	t
C—h	t	h	h	h	t	t	t

The number of possible combinations is now $8=(2)^3$, and of these only one favors the throwing of heads by all three players, the probability of that result being, therefore, $\frac{1}{8}=(\frac{1}{2})^3$. But there are three combinations, giving two heads to one tail. The probability of each of these is $\frac{1}{8}$ and the sum of the probabilities is $\frac{3}{8}=3\times\frac{1}{2}\times(\frac{1}{2})^2$. The probability of two tails and one head is also $\frac{3}{8}$, and of all tails is $\frac{1}{8}$. Again we have a series, $\frac{1}{8}$, $\frac{3}{8}$, $\frac{3}{8}$, $\frac{1}{8}$, which forms the terms of an expanded binomial, $(\frac{1}{2}+\frac{1}{2})^3$.

Now putting these figures into more general terms, we may represent the probability that a single throw will be heads by p, and that it will be tails by q. Let n equal the number of coins used and N the number of throws of the n coins together. Then the *frequency* of each combination of heads and tails will be represented by the terms of the binomial $N\,(p+q)^n$ when expanded. But in order that all the terms may be whole numbers, N must at least be equal to 2^n (greater when p and q are not equal), and the number of terms will be $n+1$.

With the view of illustrating the truth of this formula Weldon (1898) made four series of 4,096 throws of 12 dice ($4,096=2^{12}$), and counted the number in each throw of dice that showed more than 3 spots. The results are as follows:

Number of dice with more than three spots.	Terms of $4096\,(\frac{1}{2}+\frac{1}{2})^{12}$.	OBSERVED FREQUENCIES.			
		i.	ii.	iii.	iv.
12	1	0	1	0	1
11	12	11	13	8	14

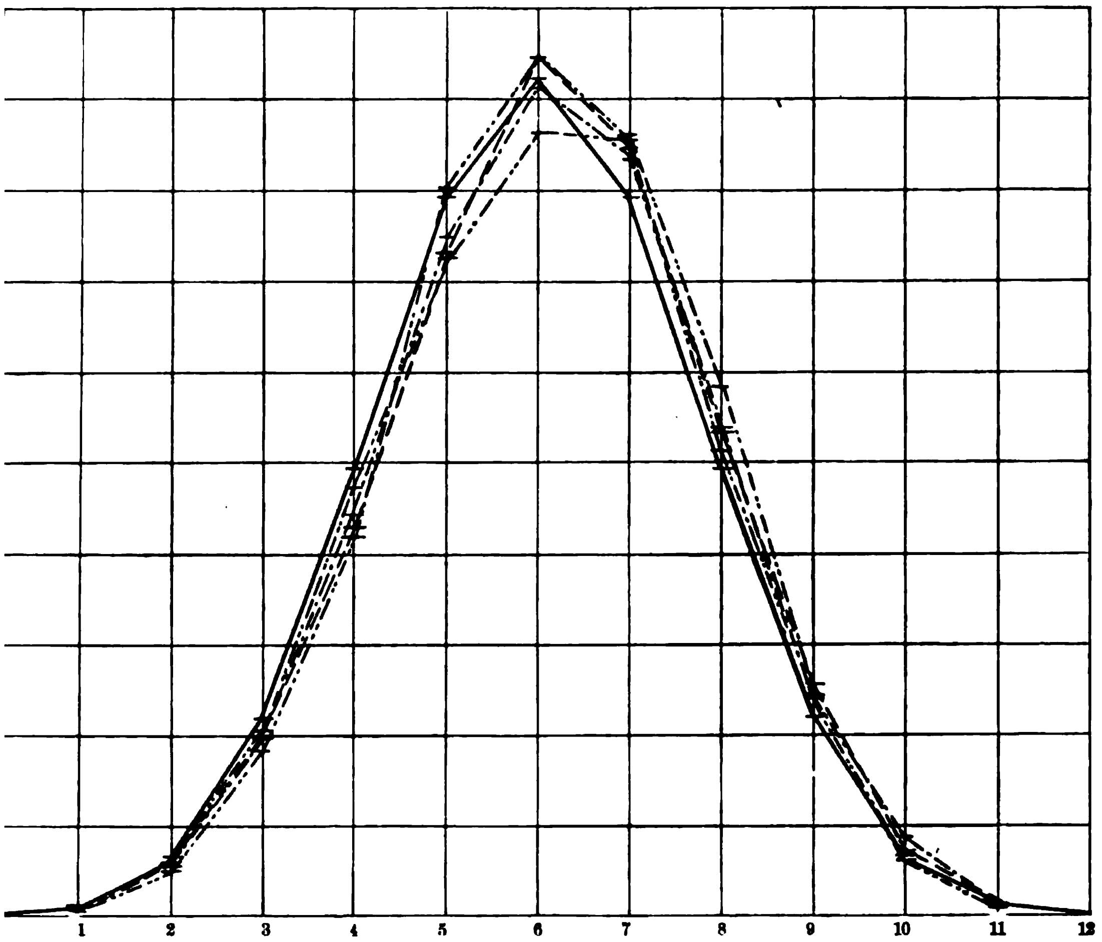
1	12	7	12	13	6
0	1	0	0	1	0

The closeness of observation to theory is more clearly apparent in the diagram (Fig. 4978). The solid line is a polygon of thirteen points, the abscissa and ordinate of each point being proportional, respectively, to a number from the first column and the corresponding number on the same line in the second column of the table. The other polygons are formed in the same way, but with ordinates taken from the columns of observed frequencies. The first polygon is a graphic representation of the result expected on the theory of probability, supposing the dice to be perfectly symmetrical.

It will be noticed that the observed polygons lean slightly toward the side of the greater number of spots. This is readily explained when it is noticed that the dice are slightly excavated at each spot, and the side with six spots is opposite the ace. There is therefore a slight eccentricity of the centre of gravity, which tends to cause the greater number of spots to turn upward. These facts serve as a simple illustration of the way in which the study of probabilities may lead to the discovery of previously unknown causes of observed facts. Thus we see that in this case, in order to make our formula exact-

present the facts, p should be made slightly greater
q.

is is illustrated further in another series of 4,096
vs of 12 dice, in which Weldon counted the number



.—Binominal Curve of Probability, terms of 4,096 $(\frac{1}{2}+\frac{1}{2})^{12}$, compared with the frequencies of the numbers of dice showing more three points, in each of four series of trials with twelve dice, the number of throws in each series being $2^{12} = 4,096$. Binominal ; ——, observations series I — — —, II — . — . —, III — . . — . . —, IV — — . . — — . . — —.

s. Each die having six faces, the probability
of them will turn up is $\frac{1}{6}$, and that it will not is
in this case $p = \frac{1}{6}$ and $q = \frac{5}{6}$. Thus our formula
s $4,096\ (\frac{1}{6}+\frac{5}{6})^{12}$.
alculated and observed results are as follows:

Number of sixes.	Terms of 4096 $(\frac{1}{6}+\frac{5}{6})^{12}$.	Observed frequencies.
	0.58	1

	1,102.56	1,145
	459.52	447

raphic representation of these results in Fig. 4979
ngly different from the curves in Fig. 4978. The
ere symmetrical or nearly so, while in the former
rves are distinctly asymmetrical, or *skew*. Thus
two types of curves, or polygons, of frequency.

When the chances for and against the event to be observed are even, when $p = q$, the curve will be symmetrical about the middle point, which is the highest. When the chances are uneven, when p is greater or less than q, the curve will be skew, and the *skewness* will be greater the greater the difference between p and q.

When we abandon games of chance and seek to apply these formulæ to the study of physical and biological phenomena, the problem is reversed. The measurements made and their "observed frequencies," whose sum $= N$, are our facts, and p, q, and n become unknown quantities. For example, a man's stature depends upon n factors, such as food, climate, ancestry, etc., and p and q are the probabilities for or against an increase or diminution of stature as the result of each of them. The problem of finding a mathematical curve that will fit the facts now becomes too complex to be solved by the binomial theorem and requires formulæ derived by means of the calculus, but which may be used, nevertheless, with the aid of proper tables, by persons not familiar with that important branch of mathematics. When variations are distributed symmetrically on both sides of the type, the curve may be found by the "method of least squares," which was employed originally to determine the range of error in astronomical observations. But when the distribution is skew, Pearson (1902) has shown that it is better to use the "method of moments," borrowed from the science of mechanics.

Collection and Tabulation of the Data.—The object of the statistical method for the study of variation is to represent in intelligible form the facts as they occur in nature. It is of the greatest importance, therefore, that the facts should not be obscured by any personal bias in the collection of the data. The data must be collected methodically at random.

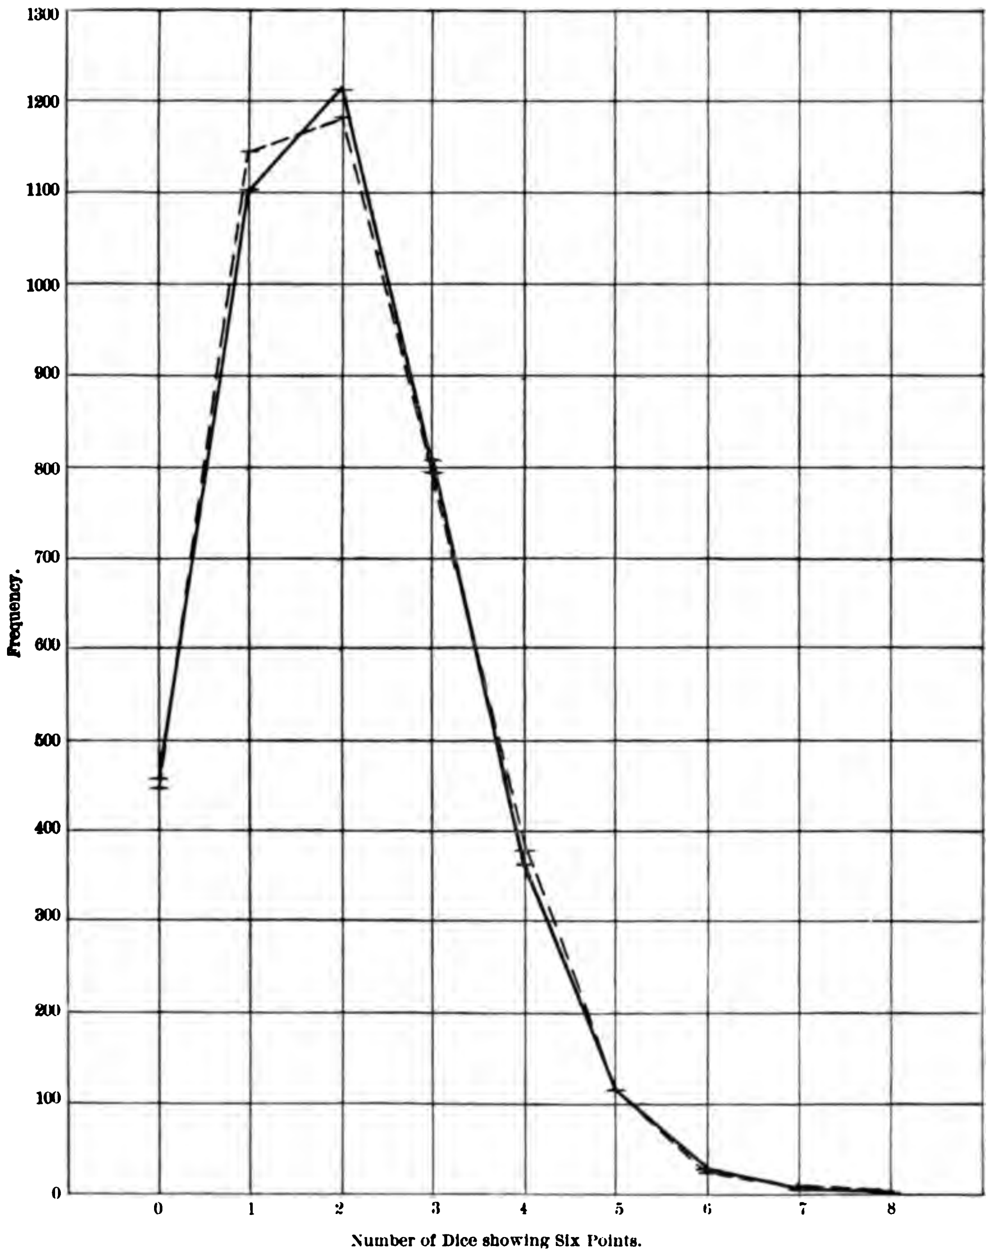

Fig. 4979.—Binominal Curve of Probability, terms of $4{,}096(\frac{1}{6}+\frac{5}{6})^{12}$, compared with the frequencies of the numbers of sixes thrown in a series of trials with twelve dice, the number of throws being $2^{12} = 4{,}096$. Binominal ——, dice — — —.

Sometimes, however, the forces of nature themselves may tend to falsify the results and must be guarded against. For example, if we wish to determine the variability of shells due to the factors affecting growth, we must be sure that the proportions of the shell have not been affected by the erosive action of chemical substances or of parasitic algæ.

Finally, the data may not give true results if the observations are not sufficiently numerous. We must have a fair sample of the population. It has been seen in the case of the dice, that with 12 independent factors we cannot expect to get all the possible combinations in less than 4,096 observations. In practice it is found that usually 1,000 observations give sufficiently close results; 2,000 would be better, but sometimes 500 will do.

For statistical purposes we may divide normal variations into two classes: (1) *discrete* variations, in which the differences between individuals are sharply defined; and (2) *conjacent* (L. *conjacere*, to lie together) variations, in which the smallness of the differences that may be observed is limited only by the precision of our instruments.

Discrete variations are usually observed by counting, as the number of ribs on a shell, the number of ray flowers on a daisy, or of veins in a leaf. Most meristic variations would be in this class.

Observations of conjacent variations are usually obtained by measuring or weighing—as stature (Fig. 4980), strength of pull, and the like. In this class would come the indexes obtained by taking the ratios of two or more measurements. It would include also qualities not quantitatively measurable, like the color of the eye or ability in mathematics. The method of assigning quantitative values to such qualities has been alluded to in a previous paragraph. Thus most of the substantive variations would fall within this class.

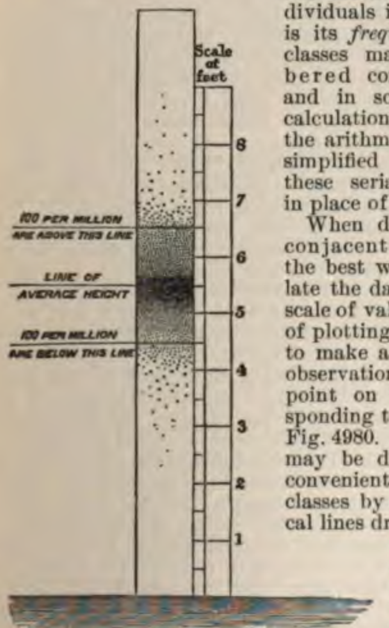
The measurements having been made and recorded, the next step is to arrange the data in a table so as to show the number of times each value has been observed. An example will make this clear. Davenport (1900) counted the number of grooves on the inside of 1,046 scallop shells (*Pecten irradians* Lamarck, right-hand valve). His results may be tabulated as follows:

VARIATION IN THE NUMBER OF GROOVES ON THE SHELLS OF PECTEN IRRADIANS.

Classes	1	2	3	4	5	6	7	8
Values	14	15	16	17	18	19	20	21
Frequencies	2	15	108	515	308	90	7	1

That is, there were 2 shells with 14 grooves, 15 had 15 grooves, 108 had 16, and so on up to 21 grooves, which were found in only 1 shell. Each group of shells having a certain number of grooves forms a *class*, the number of grooves possessed by individuals of each class is its *value*, or magnitude, and the number of individuals in each class is its *frequency*. The classes may be numbered consecutively, and in some of the calculations to follow the arithmetic may be simplified by using these serial numbers in place of the values.

When dealing with conjacent variations the best way to tabulate the data is to lay off a scale of values upon a sheet of plotting paper, and then to make a mark for each observation opposite the point on the scale corresponding to its value, as in Fig. 4980. Then the marks may be divided into any convenient number of classes by a series of vertical lines drawn from points equal distances apart upon the scale. The number of marks between each pair of lines will be the frequency of the class. For example, De Vries gives the results of measuring the length of four hundred and forty-eight common red spotted beans (*Phaseolus vulgaris*), which may be tabulated in the following manner:



Scale of feet
8
7
6
5
4
3
2
1
100 PER MILLION ARE ABOVE THIS LINE
LINE OF AVERAGE HEIGHT
100 PER MILLION ARE BELOW THIS LINE

FIG. 4980.—An Example of Conjacent Variation. A supposed record of the statures of a large number of men. (From Galton.)

VARIATIONS IN LENGTHS OF BEANS OF PHASEOLUS VULGARIS.

Classes	1	2	3	4	5	6	7	8	9
Mid-values, mm	8	9	10	11	12	13	14	15	16
Frequencies	1	2	23	108	167	106	33	7	1

In this case all specimens shorter than 8.5 mm. would go in class 1, those between 8.5 mm. and 9.5 mm. go in class 2, those between 9.5 mm. and 10.5 mm. in class 3, etc. These values, 8.5, 9.5, 10.5, . . . etc., mm. may be called the *class limits*.

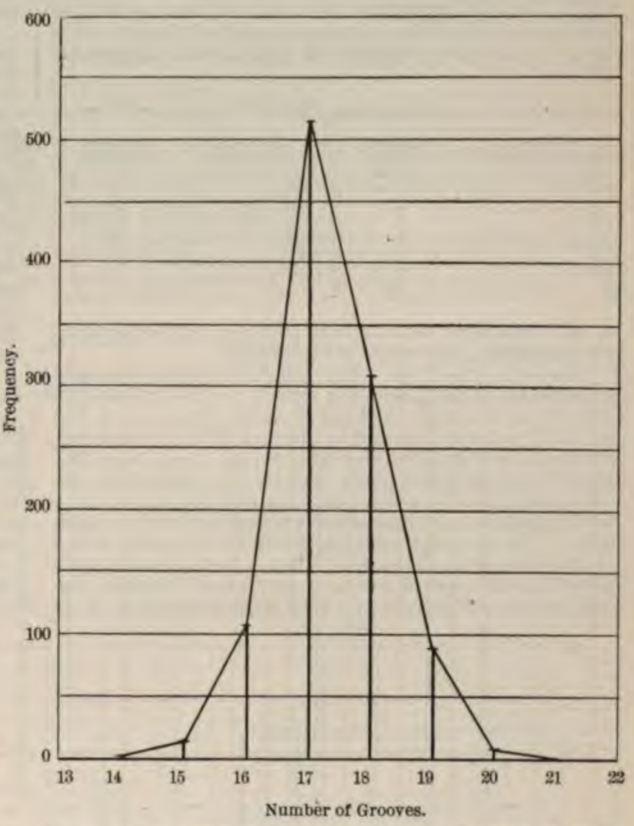


FIG. 4981.—Polygon of Frequency: Grooves on inside of scallop shells. (Data from Davenport.)

The results of these tabulations may be represented to the eye by polygons of frequency similar to those used to illustrate the results of throwing dice. Using plotting paper ruled in squares, we lay off a horizontal scale of values and a vertical scale of frequencies. Then the method of procedure differs according to whether we are dealing with discrete or with conjacent variations. In the case of discrete variations, the value of each class is taken as an abscissa from an imaginary zero point on the left and the corresponding ordinate is raised from zero at the base line to a point on the vertical scale corresponding to its frequency. Then connecting the tops of the ordinates by straight lines gives the polygon of frequency (Fig. 4981).

In the case of conjacent variations where there are many classes, the polygon may be constructed in a similar manner by taking the mid-values as abscissæ for the ordinates. But a more exact method, especially when there are few classes, is to construct the polygon of a series of rectangles, as in Fig. 4982, where the sides of the rectangles have for abscissæ the limiting values of the classes, and their heights are proportional to the corresponding frequencies.

A comparison of Figs. 4981 and 4982 with Figs. 4978 and 4979 show striking resemblances and suggests at once that these variations in shells and beans follow the same general laws of chance that are found in the throwing of dice. This inference is confirmed by the results of a large number of studies of organic variation.

In a case of discrete variation the division of the data into classes presents no difficulties, but with conjacent variations the division is purely arbitrary, and here the theory of probability comes in as an aid to one's judgment. The following table, extracted from one given by Quetelet (1846, p. 90) shows how many observations are required in order that the data may be expected to fall symmetrically into certain numbers of classes. It is based upon the properties of the binomial $N(p+q)^n$ when $p = q$.

Number of observations.	Number of classes.	Number of observations.	Number of classes.
4	3	256	9
8	4	512	10
16	5	1,024	11
32	6	2,048	12
64	7	4,096	13
128	8	8,192	14

It will be noticed that for each additional class the number of observations needs to be doubled.

Discovery of the Type.—The data having been arranged as indicated in the preceding section, we are prepared to determine the type, or typical value, from which the variability of the character in question is to be measured. Referring to Figs. 4981 and 4982, we see in each case that there is a class which has a greater frequency than the others, and from its midordinate the polygon slopes away at first rapidly and then more gradually to zero on each side. The most obvious type would be the value of this class of maximum frequency. But experience and theory show that this would not be a very exact standard, unless our sample comprised a very large proportion of the total population. This is especially true of conjacent variations on account of the artificial character of the class boundaries. For example, in our case of the beans the class of maximum frequency has a medium length of 12 mm. But suppose the classes had been arranged so that the midordinates would fall at 8.5, 9.5, 10.5, etc., mm.; then the maximum frequency might have been found at either 11.5 or 12.5 mm. There is, however, a corresponding type called the *mode*, which is measured by the position of the ordinate of maximum frequency of the *theoretical curve* corresponding to the observed polygon of frequency (Pearson, 1896, p. 345). But the exact calculation of the mode, which is of considerable theoretical importance, involves a rather extended mathematical operation. A less exact, but very easy method will be described later.

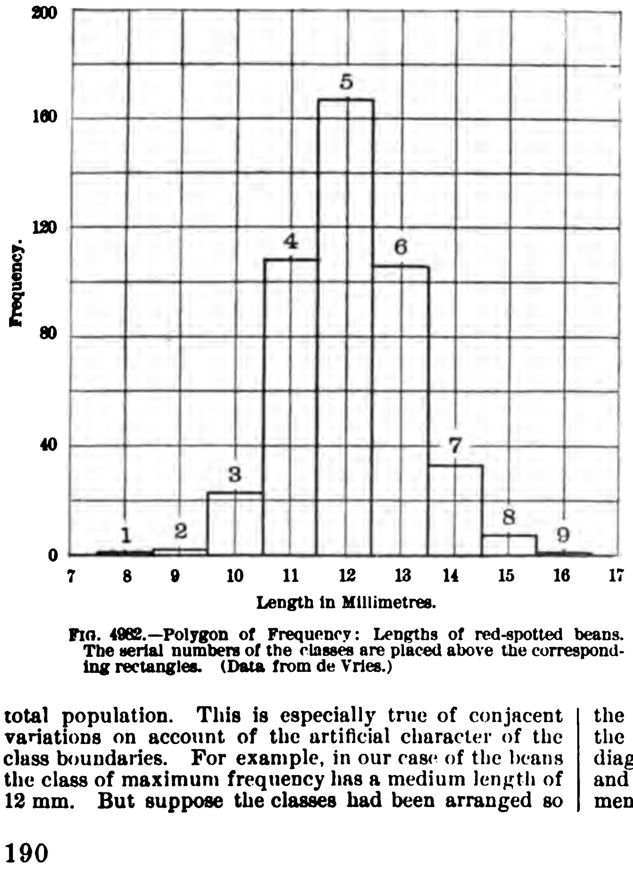

FIG. 4982.—Polygon of Frequency: Lengths of red-spotted beans. The serial numbers of the classes are placed above the corresponding rectangles. (Data from de Vries.)

The type usually employed is the average, or arithmetical mean, commonly called the *mean*. This may be discovered by adding all the observations together and dividing the sum by their number. But in order to avoid this long addition, the usual method is to multiply the value of each class by its frequency, add the products, and divide the sum by the number of observations. This operation is represented by the formula $M = \frac{\Sigma(Vz)}{N}$ where M = mean, V = values, z = frequency, N = number of observations, and Σ is the sign for summation. The same result may be obtained by taking the serial numbers of the classes for the values of V, and, having obtained the value of M in these units, it is easy to substitute the corresponding value in terms of the units of measurement employed in making the observations.

A third type, of considerable importance in certain cases, is called the *median*. This is the middle value, the value above which and below which fifty per cent. of the cases fall. It is easily found by simply counting off half of the observations arranged in order of magnitude. For example, if we have measured four hundred and fifty-one beans and arranged them in the order of their lengths, then the median will be the length of the two hundred and twenty-sixth bean, counting from either end of the series. If there are four hundred and fifty beans, an even number, the median will be intermediate between the length of the two hundred and twenty-fifth and the two hundred and twenty-sixth bean.

The same result may be obtained by a simple geometrical construction. Having for convenience reduced the frequencies to percentages of the total number of observations, the frequency of class 2 is added to that of class 1, to the sum of these class 3 is added, to this sum add class 4, and so on for all the classes, as in the following table. Thus we get a series of "sums from the beginning," which may be plotted as in Fig. 4983, using the method employed in the construction of Fig. 4982. Comparing the two figures, both made from De Vries's measurements of beans, we see that the first rectangle in the two is the same, the second in Fig. 4983 is composed of 1 and 2 in Fig. 4982, the third, of 1, 2, and 3, and so on until the ninth column in Fig. 4983 has the same area as the sum of all the nine rectangles in Fig. 4982. Now, drawing a diagonal from the lower left-hand to the upper right-hand corner of the upper rectangle in each one of the columns of Fig. 4983, we obtain what is called a *polygon of distribution*. It shows the distribution of the variations in our sample of the population. Turning the diagram around so that the scale of frequencies is horizontal, we see that the outline of this polygon is of the same general form as a line that might be drawn so as to touch the tops of the beans if they were stood up side by side in the order of their lengths. First there would be two or three very short beans, then a little row of beans 9.5–10.5 mm. high, then a much longer row, 10.5–11.5 mm. high, etc. Now, with the diagram in its first position, draw a horizontal line from the fifty-per-cent. point on the scale of frequencies to the middle rectangle, cutting the side *ac* at *d* and the diagonal, *cb* at *m*. Then draw a vertical line from *m*, and at its point of intersection with the scale of measurements read off the value of the median. To insure ac-

DATA USED IN CONSTRUCTION OF POLYGON OF DISTRIBUTION (FIG. 4983).

Class numbers.	Mid-values mm.	Frequency.	Per cent.	Sums from beginning per cent.
1	8	1	0.2	0.2
2	9	2	0.4	0.6
3	10	23	5.2	5.8
4	11	108	24.1	29.9
5	12	167	37.2	67.1
6	13	106	23.7	90 8
7	14	33	7.4	98.2
8	15	7	1.6	99.8
9	16	1	0.2	100.0
	....	448	100.0	

curacy, the diagram should be made on a large scale and be drawn with great care. A better way is to calculate the result numerically. Turning to the diagram, it is evident that the triangles *acb* and *dcm* are similar. Hence $dm : ab :: cd : ca$ and therefore $dm = ab \times \frac{cd}{ca}$. Let N be the total number of observations. Then we have the rule: Multiply the range of the middle class (ab) by $\frac{1}{2}N$ minus the sum of the frequencies of all the lower classes ($= cd$), divide by the frequency of the class (ca) and add the magnitude of the lower limit of its range. The result will be the median magnitude. In our example of the beans, $cd = 50 - 29.9 = 20.1$ per cent.; $ab = 1$ mm.; and $ca = 37.2$ per cent. Hence $dm = 1 \times \frac{20.1}{37.2} = 0.54$ mm. The lower limit of class 5 is at 11.5 mm. Therefore the median is $11.5 + 0.54 = 12.04$ mm. This method assumes, of course, that the values in the middle class are evenly distributed.

In the same manner may be determined the value of the measurement corresponding to any other point on the scale of frequencies, as at ten per cent., twenty per cent., etc. These values are called *percentile grades* (Galton, 1889), and they have been used extensively for the study of variations of anthrometric measurements; especially by teachers of gymnastics, who use these grades as a means of determining the standing of their pupils before and after training.

We may derive, then, from each collection of data three values, the mean, the mode, and the median, each one of which may serve as a type from which to measure variability. When the deviations from the mean are distributed symmetrically on both sides of it, all three of these values are the same. But they differ when the distribution is skew, as in throwing sixes with dice and in most variations found in nature. In such cases the median always lies between the mean and the mode, and the deviation of the median from the mean is one-third the deviation of the mode. This rule provides an easy way of calculating the *mode*, which, according to Pearson (1902, p. 261), is quite good enough for practical purposes in most cases, and avoids the tedious mathematics of the more exact method. (Compare *a,c,* and *b* in curves of Type III, Fig. 4986.)

The Measure of Variability.—Taking the mean as the type of any given character or organ, the problem is now to find a quantitative expression for the variability of that character in the group of organisms under observation. The first step is to calculate the deviation (x) of each class from the mean (M) by subtracting the values (V) of the classes from the mean. In the case of the beans, the mean is 12.05 mm. Omitting the small fraction for the sake of simplicity, the deviations of the several classes are given in the fourth column of the following table.

Now if the deviation of each class be multiplied by its frequency (z), the results added without regard to signs, and the sum divided by the number of observations, we obtain the *average deviation*. This is represented by the formula $A\,D = \frac{\Sigma\,(x\ z)}{N}$ and is one measure of variability. But it is rarely used.

CALCULATION OF THE VARIABILITY IN LENGTH OF 448 BEANS, PHASEOLUS VULGARIS (DATA FROM DE VRIES).

Classes.	V.	z.	x.	xz.	x^2z.
1	8	1	−4	−4	16
2	9	2	−3	−6	18
3	10	23	−2	−46	92
4	11	108	−1	−108	108
5	12	167	0	0	0
6	13	106	1	106	106
7	14	33	2	66	132
8	15	7	3	21	63
9	16	1	4	4	16
				$\Sigma\,(xz) = 361$	$\Sigma\,(x^2z) = 551$

$N = 448$

$M = 12$ mm. $A\,D = \frac{\Sigma\,(xz)}{N} = 0.8023$ mm.

$\sigma = \sqrt{\frac{\Sigma\,(x^2z)}{N}} = 1.1065$ mm.

The measure of variability most frequently employed at present is what is called the *standard deviation*. This is the square root of the average of the squares of the deviations, and is represented by the symbol σ, as in the formula: $\sigma = \sqrt{\frac{\Sigma\,(x^2\,z)}{N}}$

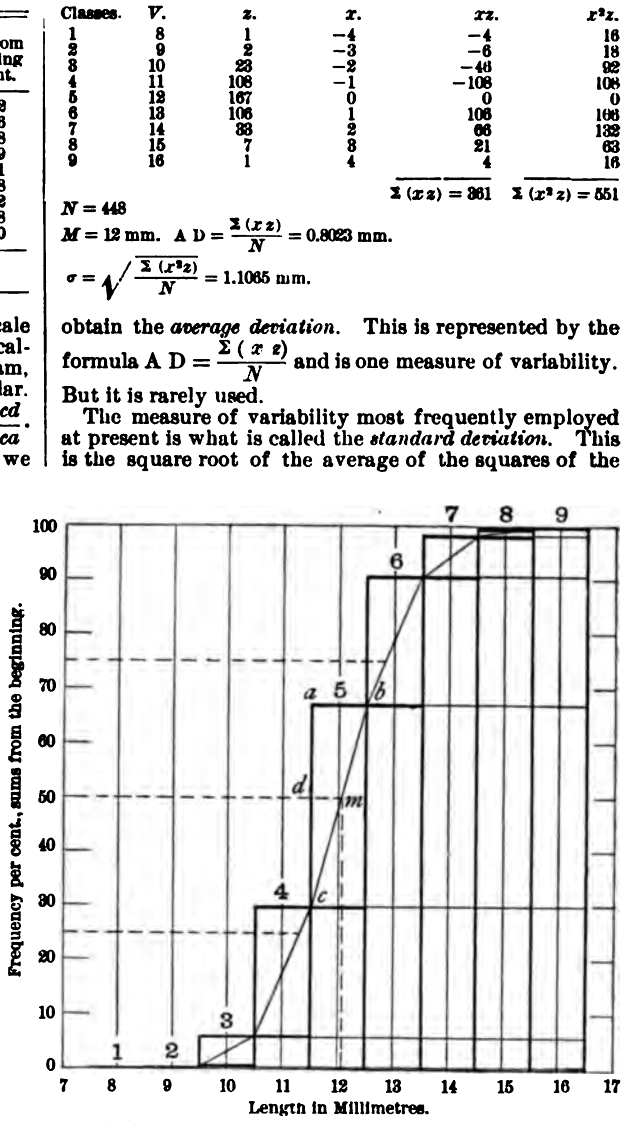

FIG. 4983.—Polygon of Distribution: Length of red-spotted beans. Serial numbers as in Fig. 4982. (Data from De Vries.)

The definition and formula indicate the process by which this quantity is found. Take the square of the deviation of each class, multiply it by its frequency, add the results, divide the sum by N, and extract the square root; all of which is performed easily by the aid of a table of logarithms. An example is given in the sixth column of the preceding table.

A third measure of variability, formerly much used, is the *probable deviation*. It might be called the median deviation, because the deviations that are greater and those that are less than it are equal in number. Galton (1889) has pointed out a method by which it may be obtained graphically from a polygon of distribution, as in Fig. 4983. Using the method employed in finding the median, find the values of the percentile grades at twenty-five and seventy-five per cent., and take half their difference. This will be the probable deviation. It is found as easily and perhaps more exactly by multiplying the standard deviation by 0.6745. PE = 0.6745 σ.

The probable, or median deviation, corresponds to the so-called "probable error" of the mathematicians, and the standard deviations to the "error of mean squares." If we imagine a polygon of frequency to be a horizontal bar loaded with weights proportional to the ordinates and swinging about the mean, which will be the centre of gravity, then the standard deviation corresponds to what physicists call the "radius of gyration," or "swing radius."

It is found by the theory of probability that when $\sigma = 1$, AD = 0.7979, and PE = 0.6745. Thus we see that of the three measures of variability, the standard deviation is the largest. It has also the advantage of being the one most frequently used in mathematical investigations.

It has in common with the other two, however, the disadvantage of being expressed in units of measurement —inches, pounds, etc.; so we cannot compare, for instance, the variability of weight with that of stature while using this measure. A similar difficulty arises with organs of different size. In a thousand men from New York City, for example, we should find the standard deviation of their stature to be several inches, while that of the length of the nose would be only a fraction of an inch. But it would not be fair on that account to regard the noses as so much less variable than the statures.

So it has been proposed to use an abstract quantity called the *coefficient of variability*. This is obtained by dividing the standard deviation by the mean and multiplying by one hundred, as in the formula: $CV = 100 \frac{\sigma}{M}$. In other words, it is the standard deviation expressed as a percentage of the mean. It is frequently useful as a means of comparing variabilities; but, unfortunately, it is not universally applicable, as it gives fallacious results when the data are in the form of ratios or in degrees of an angle, and probably in other cases.

Theoretical Curves.—Having obtained the mean and the standard deviation, we know the type and amount of variability of the material at hand. The plotted polygon of frequency gives a visual idea of the distribution of frequencies on either side of the mean, and with the aid of the median we are able to determine roughly whether the distribution is symmetrical or skew. Taking these results of observation as premises, the next step is to construct a theory as to the most probable distribution of the variations in the whole population, of which our material is a sample.

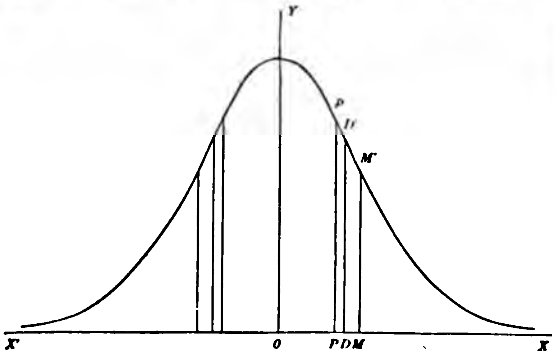

Fig. 4984.—The Normal Curve of Frequency. *YO*, ordinate of the mean; *OP*, "probable" deviation; *OD*, average deviation; *OM*, standard deviation. (From Bartlett.)

In a previous section, we have seen how close the variations in number of spots in throws of dice correspond to the theoretical probability as expressed by the formula $N(p+q)^n$ when this binomial is expanded, and comparison of the polygons (Figs. 4978, 4979, 4981, and 4982) seem to indicate that the same method is applicable with organic variations. It may be used with discrete variations where there are few classes; but in nature N, p, q, and n are all unknown quantities, and with conjacent variations the division into classes is purely arbitrary. So it is better to employ a method that will give a continuous theoretical curve, such as would be obtained if, in the formula $(p+q)^n$, n were infinitely large.

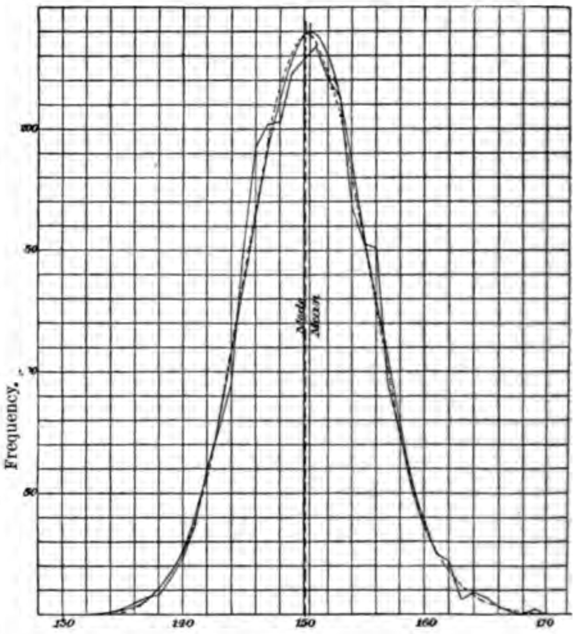

Fig. 4985.—Frequency of the Variations in Breadth of Head of 3,000 criminals. Irregular line, polygon of frequency. Normal curve —; skew curve of Type IV - - - - -. (From Macdonell.)

Now it was shown long ago by Quetelet, Galton, and others that variations in human stature and in other characters follow closely the law expressed by the "normal curve of error" of the mathematicians, or what we should call the *normal curve of frequency* (although other curves more often fit the polygons of organic variation). This is a flowing curve (Fig. 4984), symmetrical about the mean, and theoretically without limit at the ends. The standard deviation marks the point of inflection on the sides. The formula for the curve is $y = y_0 \frac{1}{e^{x^2/2\sigma^2}}$, in which y is any ordinate, x is the corresponding abscissa, or deviation, measured from the ordinate of the mean, or "centroid verticle," y_0 is the height of this ordinate, σ is the standard deviation, and e is the basis of the Napierian system of logarithms, in which $e = 1 + \frac{1}{1} + \frac{1}{1 \times 2} + \frac{1}{1 \times 2 \times 3} + \ldots$ etc. = 2.7182818. The meaning of the formula is, of course, that for any value of x the corresponding value of y will satisfy this equation.

If in our material we find the distribution of variations to be very nearly symmetrical, as in the beans, where the difference between mean and median is only 0.01 mm., we may assume that the normal curve will give the correct theoretical values, and may proceed at once to test this by fitting a normal curve to the observed polygon in the following manner: The mean (M) and the standard deviation (σ) have been found, and in doing this we have found also x_1, x_2, x_3, etc., which are the deviations from the mean of classes 1, 2, 3, etc. Next find the height of the maximum ordinate. This operation is indicated by the formula $y_0 = \frac{N}{\sigma\sqrt{2\pi}}$, in which $N =$ total number of observations and $\pi = 3.14159$. Now turning to Davenport (1899, p. 54) we find a table of the ordinates of the normal curve in which the "argument" is $\frac{x}{\sigma}$ and the corresponding tabular entry is $\frac{y}{y_0}$. So we must find $\frac{x}{\sigma}$, that is, divide the deviation of each class by the standard deviation. Then in the table find the tabular entry corresponding to each value of $\frac{x}{\sigma}$, interpolating, if necessary, and multiply the value thus found by y_0. The result will be the height of the ordinate of the theoretical curve upon the scale of frequency used in constructing the polygon. When these ordinates are plotted and their tops connected by a flowing curve, we have the theoretical curve (as in Fig. 4985), that is, a graphic representation of the distribution of the frequencies of the variations in nature, based upon the sample observed and the assumption that the variations follow the law of probability with $p = q$, and $n = \infty$.

This is the simplest of all the methods for fitting a theoretical curve to an observed polygon. It is especially applicable for discrete variations when the distribution of frequencies is symmetrical. It may be used also, but with less accuracy, for similar polygons of conjacent variations by taking the mid-value of each class as the position of its ordinate.

For greater accuracy with conjacent variation and in all cases of skew variation it is necessary to employ a more complicated procedure, the foundations of which have been laid by Pearson (1896, 1901, 1902). This is the *method of moments*. We return to the analogy between the polygon of frequency and a light rod loaded with balls suspended from it at regular intervals. The tendency of a ball to bend the rod will depend upon the weight of the ball and its distance from the point of support. The product of this distance multiplied by the weight is the *moment*, or first moment, of the ball about the point of support. The square of the distance multiplied by the weight gives the second moment, the cube, the third moment, and so on. Applying this principle to the polygon of frequency, we proceed at once to calculate the first, second, third, and fourth "rough moments" of the polygon as a whole about any convenient ordinate. From these rough moments it is easy to calculate the mean and the moments about the mean. These give us the standard deviation, and by their combination we are able to calculate the skewness and determine the general form of the curve. The actual calculation of the ordinates necessary to plot the curve is quite a different matter.

In practice it is best to use the serial numbers of the classes as their values, then taking the value of a class near the middle as V_m we find the deviations $-x_1$, $-x_2$, $-x_3$, and $+x_1$, $+x_2$, $+x_3$, etc. Then multiplying by their frequencies (z) and adding, being careful to regard the signs, we get a sum which divided by the total number of observations gives $\nu_1 = \frac{\Sigma(z\,x)}{N}$, which is the first rough moment of the curve about V_m with the frequencies of the classes grouped about their midordinates. In the same way we find the second, third, and fourth moments:

$$\nu_2 = \frac{\Sigma(z\;x^2)}{N},\quad \nu_3 = \frac{\Sigma(z\;x^3)}{N},\ \text{and}\ \nu_4 = \frac{\Sigma(z\;x^4)}{N}.$$

Now in the theoretical curve the classes are not represented by rectangles but by trapezia, whose centres of gravity are not on the midordinates (Goodman, 1899, p. 60). This is allowed for and we find the corrected moments about V_m by use of the formulæ (Pearson, 1902*b*, pp. 287–289):

$$\begin{aligned}\mu_1' &= \nu_1\\ \mu_2' &= \nu_2 - \frac{h^2}{12}\\ \mu_3' &= \nu_3 - \frac{h^2}{4}\nu_1\\ \mu_4' &= \nu_4 - \frac{h^2}{2}\nu_2 + \frac{7}{240}h^4.\end{aligned}$$

In these formulæ h is the distances apart of the ordinates and, if we use the serial numbers, $h = 1$.

Now we can find the mean from V_m by adding or subtracting μ'_1, after substituting the true values for those derived from the serial numbers, *i.e.*, $M = V_m - \mu'_1$.

Now the moments of the curve about M will be found as follows (*loc. cit.*, p. 283):

$$\begin{aligned}\mu_1 &= 0.\\ \mu_2 &= \mu_2' - \mu_1'^2\\ \mu_3 &= \mu_3' - 3\,\mu_1'\,\mu_2' + 2\,\mu_1'^3\\ \mu_4 &= \mu_4' - 4\,\mu_1'\,\mu_3' + 6\,\mu_1'^2\,\mu_2' - 3\,\mu_1'^4.\end{aligned}$$

The square root of the second moment is the standard deviation, $\sigma = \sqrt{\mu_2}$.

Now that we know the mean, or *centroid*, the standard deviation, or swing radius, and the moments of the curve about the centroid, we are prepared to determine the form of the curve.

If $\mu_3 = 0$ and $\mu_4 = 3\,\mu_2^2$, the curve is normal. If these equations are not true, the curve is skew and we may proceed to discover whether it will have a range limited at both ends, limited at one end only, or an unlimited range

TYPES OF FREQUENCY CURVES.

Type.	Description.	Formula.	Criterion κ_1.	Criterion κ_2.	References. Pearson.
Normal..	Symmetrical. Range unlimited. (Figs. 4984 and 4985.)	$y = y_0 \frac{1}{e^{x^2/2\sigma^2}}$	$\kappa_1 = 0$ $\beta_1 = 0, \beta_2 = 3$	$\kappa_2 = 0$	
I........	Skew. Range limited both ends.	$y = y_0\left(1+\frac{x}{a_1}\right)^{m_1}\left(1-\frac{x}{a_2}\right)^{m_2}$	$\kappa_1 < 0$ $\beta_1 > 0$	$\kappa_2 < 0$	'96, p. 367. '01 (b), p. 444.
II.......	Symmetrical. Range limited both ends.	$y = y_0\left(1-\frac{x^2}{a^2}\right)^m$	$\kappa_1 < 0$ $\beta_1 = 0, \beta_2$ not $= 3$	$\kappa_2 = 0$	'96, p. 372.
III......	Skew. Range limited at one end. Transition form. (Fig. 4986.)	$y = y_0\left(1+\frac{x}{a}\right)^{\gamma a} e^{-\gamma x}$	$\kappa_1 = 0$ $\beta_1 > 0, \beta_2 > 3$	$\kappa_2 = \infty$	'96, p. 373.
IV.......	Skew. Range unlimited. (Fig. 4985.)	$y = \frac{y_0}{\left\{1+\left(\frac{x}{a}\right)^2\right\}^m} e^{-\nu\tan^{-1}\left(\frac{x}{a}\right)}$	$\kappa_1 > 0$ $\beta_1 > 0, \beta_2 > 3$	$\kappa_2 > 0$ & < 1	'96, p. 376.
V.......	Skew. Range limited at one end. Transition form.	$y = y_0 x^{-p} e^{-\gamma/x}$	....	$\kappa_2 = 1$	'01 (b), p. 446.
VI......	Skew. Range limited at one end.	$y = y_0 \frac{(x-a)^{m_1}}{x^{m_2}}$	....	$\kappa_2 > 1$ & $< \infty$	'01 (b), p. 448.

by calculating the value of $2\mu_2(3\mu_2^2 - \mu_4) + 3\mu_3^2$. If this quantity is greater than zero the range is limited at both ends; if equal to zero, it is limited at one end only; and if less than zero, it is unlimited.

Pearson has distinguished seven types of curves of frequency, the descriptions and formulæ of which are given in the preceding table. In order to determine to which type our curve belongs we must find the values of the following quantities:

$$\beta_1 = \frac{\mu_3^2}{\mu_2^3},\ \beta_2 = \frac{\mu_4}{\mu_2^2},\ \kappa_1 = 2\,\beta_2 - 3\,\beta_1 - 6,$$

$$\text{and } \kappa_2 = \frac{\beta_1\,(\beta_2 + 3)^2}{4\kappa_1(4\beta_2 - 3\beta_1)}.$$

We may call κ_1 and κ_2 the first and second *criteria*. Looking up these values in the table we find there the formula for the curve, from which the ordinates may be calculated. The second criterion serves to differentiate all of the curves except the normal and Type II., in both of which $\kappa_2 = 0$, but Type II. differs from the normal in that β_2 is not equal to 3. The ordinates of the normal curve may be calculated by the aid of the improved tables given by Sheppard (1903), but for the other curves there are no such tables. It would unduly expand this article if we should attempt to explain fully the formulæ for Types I. to VI. and give directions for calculating the values of y, and must, therefore, refer the reader for further details to Pearson's original articles (1896, 1901, and 1902). It should be noted, however, that our curve may be regarded as normal, even if it does not quite satisfy the conditions given in the table. According to Dunker (1899, p. 184), if the product of κ_1 multiplied by by μ_2^3 is within the limits of ± 1, and the value of $\frac{3\,\nu_2^2 - 2\,\nu_1^4\,(+\frac{1}{8}\sigma)}{\nu_4}$ is between 0.8 and 1.25, unity being the value with a strictly normal curve, we may still regard our curve as of the normal type.

Skewness is measured by the deviation (d) of the mean from the mode expressed in terms of the standard deviation. Thus $\mathrm{Sk} = \frac{d}{\sigma}\cdot$ When the value of the mean is greater than the mode, the skewness is said to be positive; when less, negative. The skewness is calculated by a different formula for each type of curve. But it is not difficult to estimate it by the rule given previously for estimating the mode, if we know the mean, median, and standard deviation.

In fact, there is considerable doubt as to how far mathematical analysis of the statistics of variation can be carried with profit. The types of curves grade into one another in such a way that it may happen that in some cases either one of two or more curves will fit the polygon equally well for practical purposes. Thus Miss Heffernan (1900) found a case in which dropping out one extreme individual in a series of four hundred changed the curve from Type IV. to Type I., and the two curves when plotted are practically identical. Pearson (1901, p. 453) gives a case in which two curves of Types V. and VI. plotted from the same data are so close as to be hardly distinguishable to the eye.

Correlation of Variations.—So far we have dealt with variations of single characters only. But every organism possesses many characters and organs, and these are related in many ways, both as to structure and function. Now there may or may not be some definite relation on the average between the variations of any given pair of associated characters.

In the language of Galton (1889): "Two variable organs are said to be correlated when the variation of the one is accompanied on the average by more or less variation of the other, and in the same direction." This is *positive correlation*. When the variation of the second organ is in the opposite direction from that of the first, we have *negative correlation*. Many correlations are matters of every-day observation. Thus the right leg is generally of very nearly the same length as the left leg. There is a similar but less close correlation between the lengths of arms and legs, a man with light hair usually has blue eyes, and so on.

We may find correlations also between similar characters in associated individuals, as fathers and sons (see *Heredity*), or husbands and wives; also between characters of organisms and factors in their environment or their previous treatment or condition, as between color of plumage and latitude of habitat, susceptibility to disease and age, immunity against smallpox and vaccination.

Such correlations are clearly of great theoretical importance for the study of evolution and heredity, and they have very practical bearings upon medical and social questions.

Therefore it is important that we should have some means of expressing the amount of correlation in quantitative terms. This means has been furnished by Galton (1889) who showed how to find the *coefficient of correlation*, or what is often called Galton's function.

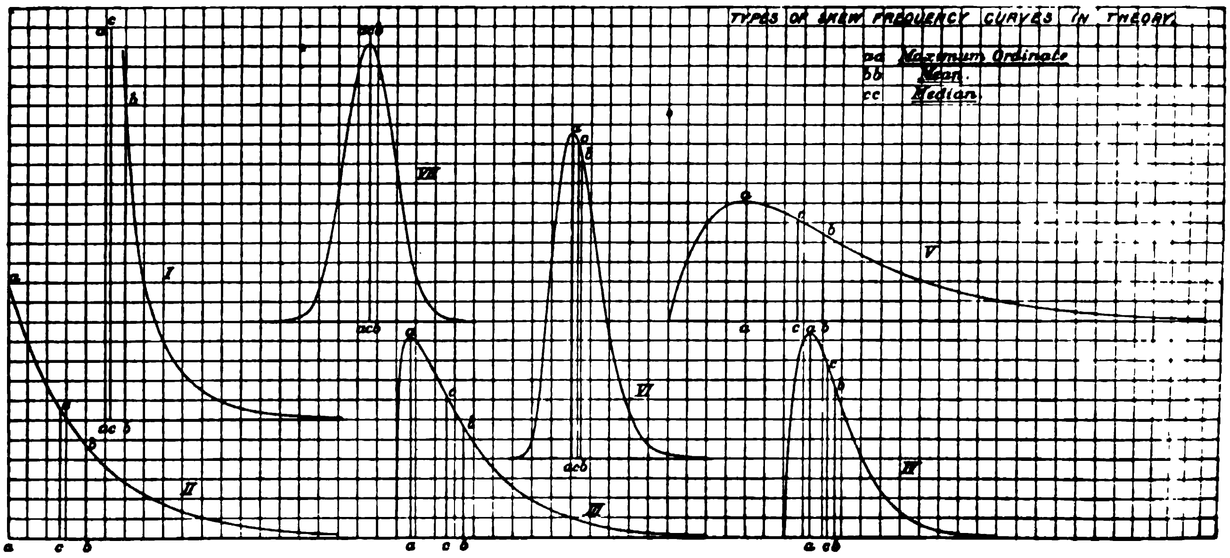

FIG. 4986.—The Various Sub-Types of Transitional Skew Frequency Curve of Type III. *aa*, Maximum ordinate; *bb*, ordinate of the mean; *cc*, ordinate of the median. (From Pearson.)

Suppose we have measurements of the length and breadth of the heads of one thousand men. The data may be arranged in a *correlation table*, like the one given below. This is constructed in the following manner: At the top is a horizontal scale of length, and we will call this the selected character, or "subject." Likewise at the left is a vertical scale of breadth, which is the associated character, or "relative." The entries in the body of the table are the frequencies of individuals in which this pair of characters have the values given in the corresponding positions in the horizontal and vertical scales, respectively. For example, there were 21 men whose head length was 7.1 inches. Of these 1 had a width of 5.7 inches, 4 were 5.8, 4 were 5.9, 6 were 6 inches broad, and so on. The columns and rows of frequencies are added up at the bottom and at the right. Each column forms an *array*, which shows the variations of breadth associated with the value of the length given at the head of the column. In the same way breadth may be taken as the subject, and then the rows of frequencies are the arrays, giving the variations of the associated length.

the axis of x; and the position of the mean of all the head breadths is similarly represented by the intersecting horizontal line, the axis of y. Now the horizontal distance of a circle from the axis of x will give the deviation (x) of the selected character, and the vertical distance of the same circle from the axis of y will give the mean deviation (y) of the associated array from the mean of all the arrays. Now if x and y are expressed in equivalent units, the ratio $\frac{y}{x}$ will give a measure of the correlation of the two characters in this particular array. If the ratio $\frac{y}{x}$ were the same in all the arrays, the zigzag line in Fig. 4987 would become a straight line. As it is, we see that it has a general trend which is represented by a straight line that may be drawn so that the sum of the distances of the small circles from it shall be as small as possible. This line will meet the axes of x and y at their point of intersection. Now the slope of this line may be measured in the same way that the grade of a railway track is measured, by the rise or fall in a certain unit of horizontal distance, as ten feet in a mile, or in our case by the height y_a of any point a at the distance x_a from m_1 (Fig. 4988). The slope of the line may be

The means and standard deviations of the subject and relative may be calculated from the total frequencies given at the bottom and right side of the table, respectively, by the methods previously described. In the same way the mean may be determined for each array. Now transferring our horizontal and vertical scales to plotting paper, the positions of the means of the arrays may be plotted as in Fig. 4987, which is made from a correlation table of head breadth and stature in three thousand criminals. In this diagram the position of the mean of an array, is indicated by a small circle, and the circles are connected by a zigzag line. The position of the mean of all the statures is represented by a vertical line drawn through the middle of the diagram: call this

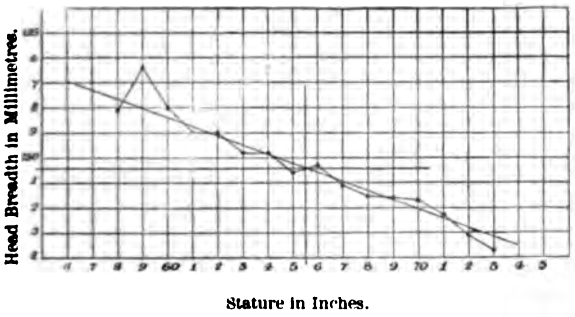

FIG. 4987.—Diagram of Correlation Table. Stature, subject; head breadth, relative. Three thousand criminals, mean height = 65.5 inches, mean head breadth = 150.4 mm. Coefficient of regression = 0.3612. (From Macdonell.)

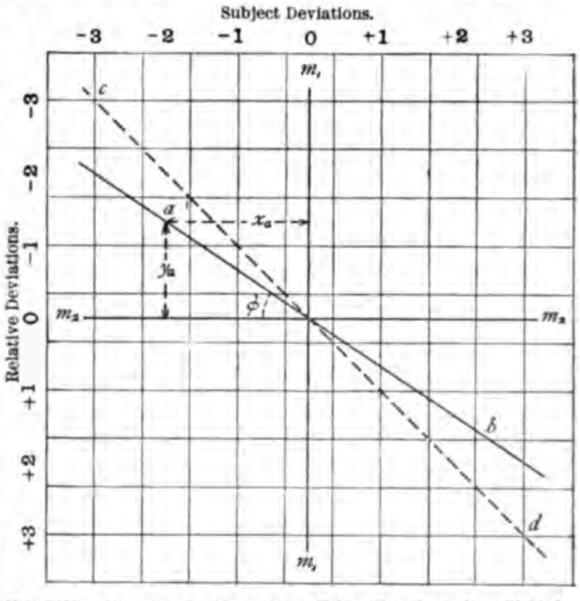

FIG. 4988.—Diagram of a Correlation Table with Deviations Plotted in Terms of Standard Deviation. m_1, Position of mean of subject; m_2, mean of relative; $a\ b$, regression line.

measured also by the angle ϕ which it makes with the line m_2, and the ratio $\frac{y_a}{x_a}$ is what mathematicians call the tangent of that angle, $\frac{y_a}{x_a} = \tan \phi$. It may be shown by the principle of least squares that, taking all the observations into consideration, the most probable value of $\tan \phi$ will be $\tan \phi = \frac{\Sigma\,(x\ y\ z)}{\Sigma\,(x^2\ z)}$, where x and y are the deviations of each pair of observations from the means of the subject and relative, respectively, z is the number of pairs, or frequency of each class in the arrays, and Σ is the sign for summation. But in a diagram like Fig. 4987 the ratio $\frac{\Sigma\,(x\ y\ z)}{\Sigma\,(x^2\ z)}$ will not give a constant measure of the correlation between the two characters, because, in the first place, x is expressed in inches while y is in millimetres. If we changed these units, we would change the ratio. Moreover, stature and head breadth have different standard deviations, so that the diagram is longer in one direction than in the other, and the slope of the diagonal would differ according as to whether head breadth or height were taken as the subject.

Galton overcame this difficulty by expressing all the deviations of each character in terms of its probable deviation. Then his correlation table took the form represented in Fig. 4988, when $\frac{y_a}{x_a}$ gives the coefficient of correlation no matter which character is taken as subject. If there is perfect correlation the line *ab* will coincide with *cd* and $\frac{y_a}{x_a} = 1$. But if there is no correlation *ab* coincides with m_2 and $\frac{y_a}{x_a} = 0$. So the coefficient of correlation is a fraction which may have any value between 0 and 1, in Fig. 4988 its value is $\frac{2}{3}$, and, if A be the selected character and B the relative, then this coefficient expresses the probable proportion of the mean deviation of B to the corresponding selected deviation of A. In general the deviations of B will be found to be less than the corresponding deviations of A. Galton first noticed this phenomenon in his early studies of heredity and he called it *regression*.

But regression is not peculiar to heredity. It is found in all statistics concerned with two associated variable quantities which are not perfectly correlated. What we mean by regression, then, is "that in associated or correlated pairs, if we select one member with a given value for its character, the second has on the average a less value, regressing somewhat to the mean of the general population" (Pearson, 1900, p. 394). Regression is thus the reverse of correlation.

In a diagram like Fig. 4987, in which the positions of the means of the arrays are plotted in the units of actual measurement, the zigzag line drawn through the means is called the *polygon of regression*, and the straight line that best fits this polygon is called the *line of regression*. For want of a better name, the slope of the line of regression has been called the *coefficient of regression*, although it does not measure regression directly, but inversely. It is a peculiarly unfortunate choice of name, because it has led to much confusion and misunderstanding through the natural tendency of recent writers to speak of it simply as "the regression."

We have seen that the slope of the regression line is given by the ratio $\frac{\Sigma\,(x\ y\ z)}{\Sigma\,(x^2\ z)}$. But $\Sigma\,(x^2\ z) = N\sigma_1{}^2$ and we may make $\Sigma(xyz) = Nr\sigma_1\sigma_2$, where N is the total number of pairs, σ_1 the standard deviation of the subject, σ_2 the standard deviation of the relative and r is an unknown quantity. Then $\frac{\Sigma\,(x\ y\ z)}{\Sigma\,(x^2\ z)} = \frac{Nr\,\sigma_1\,\sigma_2}{N\sigma_1{}^2} = r\frac{\sigma_2}{\sigma_1}$. Thus the formula for the *coefficient of regression* becomes $r\frac{\sigma_2}{\sigma_1}$, and then it may be shown that $r =$ the *coefficient of correlation*. They both measure the same phenomenon. The former gives the probable ratio of the deviations as they are actually observed. The latter gives a corrected value of this quantity after due allowance has been made for differences in units of measurement and in standard deviation. In cases in which $\sigma_1 = \sigma_2$, then $\tan \phi = r\frac{\sigma_2}{\sigma_1} = r$.

There is one more property of the correlation surface, as it is called, that should be noted. If x and y are plotted in terms of σ_1 and σ_2, as in Fig. 4988, and the distribution of frequencies is normal, then when $r = 0$, a series of contour lines drawn through the classes of equal frequency will be perfect circles. When the regression line, *ab*, moves from m_2 toward *cd*, the contour lines become ellipses with *cd* as their major axis. As *ab* approaches *cd* the ellipses become more and more narrow until when *ab* coincides with *cd*, that is, with perfect correlation, the frequency of each array would be concentrated along the line *cd*. Now the range of each array is measured by its standard deviation, which with perfectly normal distribution would be given by the formula $\sigma_3 = \sigma\sqrt{1 - r^2}$. It is evident that as r approaches the value of 1, $1 - r^2$ will become smaller and smaller until finally $\sigma_3 = 0$, that is, until the distribution of frequencies of the arrays is concentrated along the major axis of the ellipses. This shows that the accuracy with which one can use the value of a character to predict the value of its associated character will depend to a great extent upon the amount of correlation existing between them.

There are two methods at present in use for calculating the coefficient of correlation. The first method depends on the formula $r = \frac{\Sigma\,(x\ y\ z)}{N\sigma_1\,\sigma_2}$, which has been shown by Pearson to give the best value for r. The formula indicates the method of procedure, which is simple but laborious. Having constructed a correlation table and found the means and standard deviations of subject and relative, the deviations x and y for each array class are found, and then multiplied together and by the frequency of the class. All these products are added and the sum is divided by the product of the whole number of pairs multiplied by the standard deviations of subject and relative. The result is the coefficient of correlation.

Dunker (1899, p. 154) has devised a modification of this method, which is intended to lessen the labor, and is fully described by Davenport (1899, p. 33).

The second method is more complex in theory, but is shorter in practice. Theoretically it is not so good as the first, but it has the advantage of saving a great deal of time and labor, and it is the only method that can be used with characters that are not quantitatively measurable. It was for this purpose that the method was invented by Pearson (1901). Macdonell (1902) has made a careful comparison of the two methods, and concludes that the new method gives a value of r with an accuracy fairly comparable to that obtained from an ordinary frequency table containing about one-third the number of frequencies. The results obtained in three cases by the two methods are compared in the following table:

COMPARISON OF THE TWO METHODS.

	COEFFICIENT OF CORRELATION.	
	First method.	Second method.
Head length and head breadth	.4016 ± .0103	.3977 ± .0176
Head breadth and stature	.1831 ± .0119	.1811 ± .0210
Left middle finger and stature	.6608 ± .0069	.6633 ± .0142

The theory of this second method is explained in untechnical language by Pearson in the "Grammar of Science" (1900, pp. 432–436). We will proceed at once with a description of the manner in which the theory is applied in the calculation of r.

The material is arranged in a fourfold correlation table like the following:

CORRELATION OF STATURE AND BREADTH OF HEAD. 3,000 CRIMINALS. (Macdonell.)

Head breadth (centimetres).	Stature in Feet and Inches.		Totals.
	5′ 4$\frac{3}{16}$″ and under.	Over 5′ 4$\frac{3}{16}$″.	
14.8 and under	455	622	1,077
Over 14.8	599	1,324	1,923
Totals	1,054	1,946	3,000

CORRELATION OF PREVIOUS TREATMENT AND RESULT OF SMALLPOX. HOMERTON AND FULHAM HOSPITALS (DOUBTFUL CASES EXCLUDED). (Macdonell.)

	Recoveries.	Deaths.	Totals.
Vaccinated	8,207	692	8,899
Unvaccinated	1,424	1,103	2,527
Totals	9,631	1,795	11,426

Let the correlation table be represented by the following diagrams:

TABLE OF FREQUENCIES.

a	b	$a+b$
c	d	$c+d$
$a+c$	$b+d$	N

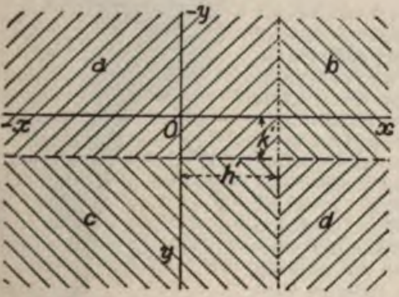

FIG. 4989.—Diagram Showing the Theoretical Relation of the Table of Frequencies to a Normal Correlation Surface. The shaded rectangles a, b, c, d represent the divisions of the table of frequencies, h' and k' the deviations of the lines of division from the means of subject and relative represented by the axes of y and x. (From Pearson.)

Calculate the values of a_1 and a_2 by the formulæ

$$a_1 = \frac{(a+c)-(b+d)}{N}.$$

$$a_2 = \frac{(a+b)-(c+d)}{N}.$$

Now we need a table of the "probability integral," which gives the "sums from the beginning" of the normal curve of frequency. In "Biometrika," vol. ii., pp. 182–190, is a series of tables of this kind prepared especially for our purpose. Turning to Tables III. and IV., pp. 189–190, we find in the a column our value of a_1 and in the x column read off the corresponding tabular entry, interpolating if necessary, and the value thus obtained is called h. Continuing to the z column we find the tabular entry and call that H. In the same way for a_2 we find the corresponding entries under x and z and call them k and K.

Then find ε by the formula $\varepsilon = \frac{ad-bc}{N^2 H K}$, and r, the coefficient of correlation, may be found from the equation.

$$\varepsilon = r + \frac{r^2}{2} hk + \frac{r^3}{6}(h^2-1)(k^2-1) + \frac{r^4}{24} h(h^2-3)k(k^2-3) + \ldots \text{etc.}$$

(Pearson, 1901*a*, p. 6).

Or, if we wish to be a little more exact, we may find r by the following equations:

$$\varepsilon = \theta + \tfrac{1}{2}hk\theta^2 - (h^2+k^2-h^2k^2)\frac{\theta^3}{6} + hk\left\{h^2k^2 - 3(h^2+k^2) + 5\right\}\frac{\theta^4}{24} + \text{etc.}$$

$r = \sin\theta$ (Fig. 4990). (Pearson, *loc. cit.*, p. 8.)

The equations for finding r and θ may be solved by Newton's method of approximation, or better by Horner's method (see Wells, "College Algebra," p. 520); or Burnside and Panton, 1892, p. 212). In the second equation the value of the angle θ is given in radians, ratio of arc to radius. As $\frac{1}{2}\pi = 90°$, the value of θ in seconds is given by the equation $A = 206{,}265\ \theta$ (De Morgan, 1902, p. 276). Reducing A to degrees, minutes, and seconds, $r = \sin\theta$ is found easily in any table of natural sines (*e.g.*, Jones, "Logarithmic Tables," pp. 60 *et seq.*). A still easier method of finding r from θ is to take a table like Jones's Table II. (*loc. cit.*, pp. 15–19) where the angles are given both in degrees and in radians, and $\log r = \log \sin\theta$ can be read off directly, and r, found from a table of logarithms.

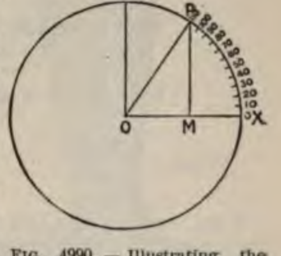

FIG. 4990. — Illustrating the Meaning of $r = \sin\theta$. If the angle $POX = \theta$ is measured by the arc PX, then $r = \sin\theta = PM$, OP being taken as unity. (From Pearson.)

Pearson has given (1902 *b*, pp. 13–14) a graphical method for fitting a straight line to a set of observations that seems applicable in the plotting of regression lines and the calculation of coefficients of correlation. But it is doubtful if this method would have any advantage over the one just described.

It will be interesting to note at this point some of the results that have been obtained by the study of correlation. The following coefficients of correlation were obtained by Macdonell from three thousand criminals:

CORRELATIONS	COEFFICIENT.
Stature and head length	0.33993
Stature and head breadth	.18308
Stature and face breadth	.34527
Stature and finger	.66084
Stature and cubit	.79986
Stature and foot	.73636

From the results of which these form a part he has arrived at important conclusions concerning the identification of criminals.

Some correlations of especial interest to physicians are:

DIPHTHERIA, Pearson (1901)—Correlation of antitoxin treatment and recovery .... $r = 0.2451 \pm 0.0205$

SMALLPOX, Macdonell (1902)—Effectiveness of vaccination and strength to resist the disease.

For six towns	$r = 0.6561 \pm 0.0092$	Doubtful cases included in the vaccinated.
For Sheffield	$.7694 \pm .0124$	
For Leicester	$.6112 \pm .0728$	
For Gloucester	$.5897 \pm .0198$	
For Homerton and Fulham	$.5760 \pm .0089$	
For Homerton and Fulham	$.6615 \pm .0083$	Doubtful cases excluded.
For Glasgow	$.7783 \pm .0365$	
For London, 1901	$.5779 \pm .0311$	
For London, 1892–93	$.5954 \pm .0272$	

Precision of the Constants.—The constants of our curves of variation and correlation—mean, median, standard deviation, coefficient of correlation, and the like—are the predictions made from observations as to the probable condition of the given character in the whole population. Our data are like the balls drawn from the urn which we cannot see into nor upset. We can only guess at what is in the urn by what has been drawn out of it. We have seen that the probability of our guess being right depends upon the number of observations. This is expressed by the, so-called, probable errors of the constants, which, preceded by the ± sign, are written after the constants, as in the examples given in previous sections. We will now give the formulæ for calculating the probable errors (P.E.) of some of the most important constants. When distribution is normal:

$$\text{P. E. of mean} = .6745\frac{\sigma}{\sqrt{N}}.$$

$$\text{P. E. of median} = .8454\frac{\sigma}{\sqrt{N}}.$$

$$\text{P. E. of } \sigma = .6745\frac{\sigma}{\sqrt{2N}}.$$

$$\text{When } r = \frac{\Sigma(xyz)}{N\sigma_1\sigma_2}. \qquad \text{P. E. of } r = .6745\frac{1-r^2}{\sqrt{N}}.$$

When r is calculated by the second method, its P. E. has a very complex formula (Pearson, 1901, p. 14). But, according to Macdonell, it will be about the same as if r were calculated by the first method with one-third the number of pairs. Yule gives a table (1897, p. 854) of the P.E. of r by the first method for various values of N.

Biologists are indebted to Elderton for a useful table ("Biometrika," vol. i., part ii.), by which it is possible to determine whether the differences between a polygon of frequency and the corresponding theoretical curve are greater or less than the probability of random sampling should lead one to expect. If they are not greater, the curve chosen may be regarded as a satisfactory representation of the relative frequencies of the variations in nature.

We will now bring to a close this description of the methods employed in statistical biology, which we believe to be the first one that is both fairly complete and in a language that can be understood by the ordinary American biologist or physician; and we venture to express the hope that it may lead to a wider investigation in the fields that these new methods make available for study.

VARICOSE VEINS.—ETIOLOGY.—Dilated and tortuous veins are spoken of as varices, or varicose veins. This abnormal condition is dependent in some way upon an interference with the flow of blood in the veins. Thus gravity plays its part, since the trouble is most common in the veins of the legs, and since it is more often seen in tall people than in short ones. Age and disease of the heart, producing imperfect valvular action, are also potent factors. As instances of local venous obstruction may be mentioned abdominal tumors, pregnancy, and the wearing of constricting clothing, such as circular garters. The left spermatic vein empties into the left renal vein at a right angle, being crossed by the sigmoid flexure. The pressure exerted upon it by an accumulation of fæces is thought to be one reason why varicocele is common on the left side.

However, the reasons just stated are not of themselves sufficient to explain the occurrence of varicose veins. Thus the veins begin to dilate in the early months of pregnancy before the uterus is sufficiently enlarged to exert any pressure upon the iliac veins, while varicose veins are wanting in many patients with large abdominal tumors. Nor is the change due to the atrophy of old age, as it is usually noticed before the fortieth year, and in a great many instances before the twenty-fifth year. It is equally difficult to explain why the veins of one leg should be much dilated and tortuous, while those of the other are scarcely affected; or why in certain persons the large veins are chiefly affected, and in others the smaller radicles in the skin. As muscular contraction and muscular relaxation constitute the chief aids to venous flow, it is not surprising that persons who are obliged to stand for hours at a time (washerwomen, car motormen, etc.) suffer more from this trouble than those who are constantly changing their position.

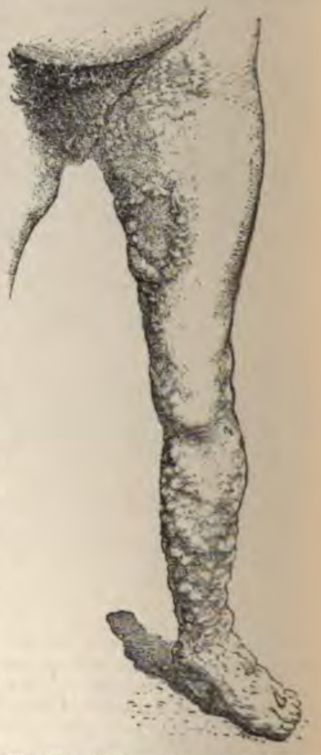

FIG. 4991.—Varicose Veins of the Lower Limbs and Genital Organs in the Case of a Woman soon to be Delivered of her Tenth Child. (Duplay et Reclus: "Traité de Chirurgie.")

While any of the veins of the lower extremity may be affected, the trouble is most often found in some of the radicles of the internal saphenous vein. The tortuous and dilated vessels are easily recognized on inspection, and if they lie near the surface their bluish color is visible through the skin. If they are not or have not been inflamed, they collapse under moderate pressure and disappear almost entirely when the foot is elevated. In some places their channels through the skin feel like a break in its continuity; while here and there they lie so near the surface that they seem to be covered with little more than epithelium. The deep veins of the leg may be affected as well as the superficial ones. If the dilatation goes on to a still greater degree a distinct thin-walled sac filled with fluid blood is formed. Such a large varix is shown in Fig. 4992.

As a result of the dilatation many of the valves become insufficient. This can be tested in the following manner: After the veins of the lower extremities have been emptied by elevation of the foot and stroking of the limb toward the body, the thumb is placed upon the main saphenous trunk and the patient is directed to stand. The varicose veins will fill slowly and only to a moderate degree. The moment the thumb is removed the column of venous blood falling into them from above instantly distends them to their fullest capacity if the valves are incompetent. Such are the conditions of simple varicosity. Sooner or later one or more complications are likely to arise, such as thrombosis, rupture, periphlebitis, œdema, eczema, and ulcer.

Complications.—Thrombosis may occur in dilated veins of the leg exactly as it may occur in the dilated vein of an external hemorrhoid. It is accompanied by a good deal of pain and tenderness, by slight redness and by œdema plainly limited to the immediate vicinity of the vein involved. Thus if a not very tortuous vein be affected for a distance of five or six inches its course can be accurately mapped out as an indurated strip about three-fourths of an inch wide. If the vein is tortuous, the indurated area will have an irregular outline.

The nutrition of the parts drained by varicose veins is often seriously affected, so that a wound may become infected. The result may be erysipelas, cellulitis, abscess, or suppurative thrombophlebitis, although the last-mentioned condition is by no means common.

When the vein lies near the surface it is easily ruptured by a blow from a sharp object, and as there is little elastic tissue about the opening, the hemorrhage is profuse and may be serious if it is not stopped by pressure or ligation.

A fourth complication, more often seen in older individuals, is an extensive œdema. At first this is of the usual type, revealing itself by pitting on pressure; but after it has existed for many months the production of fibrous tissue may be sufficient to prevent much indentation on pressure. This condition may be due to other causes than varicosity of the veins, and it greatly interferes with the nutrition of the parts, and especially with the repair of a chronic ulcer, whether varicose or not.

Eczema is another complication due to an imperfect nutrition which is apt to lead to ulcers starting in the small scratches made by the patient in the vain attempt to relieve himself from the intolerable itching.

Not every ulcer occurring in a patient whose veins are varicose is to be attributed to such varicosity. A long-standing ulcer of the leg of a non-malignant, non-syphilitic, non-tuberculous character is better spoken of as a chronic ulcer. It may be the direct or indirect result of varicose veins, but it may also be due to traumatism or eczema, or œdema, or anæmia. It is misleading to call all such ulcers varicose ulcers. They are all due to poor local nutrition, of which varicosity of the veins is simply one cause.

When varicose veins have existed for a considerable time there will often be noted a brown pigmentation of the skin, occurring more or less in patches, and due either to small subcutaneous ruptures of the venous radicles or to transudation of red blood cells through the dilated venous walls. In either case the blood pigment becomes permanently fixed in the fibrous tissue of the skin, giving it a characteristic yellow-brown color.

Symptoms.—Varicose veins often give rise to no symptoms whatever. Such is apt to be the case in young and healthy persons, and also when the veins are dilated throughout a small area—for example, over one-half of the vulva, or around the saphenous opening.

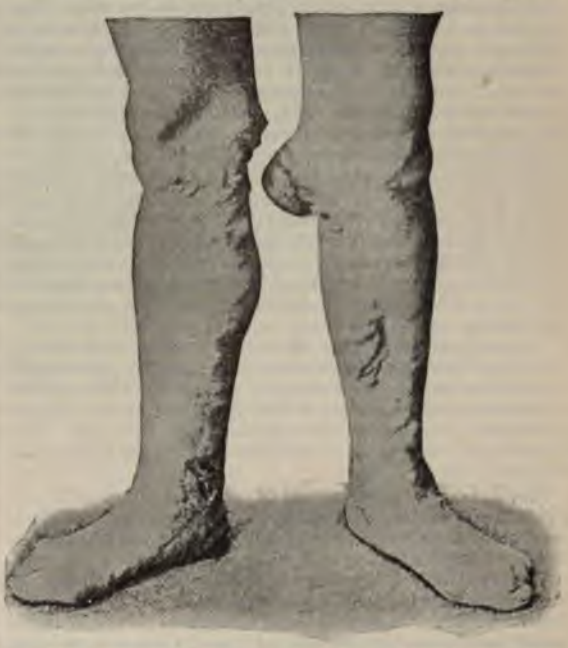

Fig. 4992.—Varicose Veins of Both Legs with a Large Varicose Vein below the Left Knee and a Varicose Ulcer just above the Right Ankle. (Von Bruns.)

The symptoms in uncomplicated cases are: A sense of weight and more or less dull aching relieved by elevation of the affected extremity.

The symptoms of thrombosis are: Marked tenderness on pressure, acute local pain, which is considerably but not wholly relieved by a recumbent position, and a rise of temperature of one, two, or three degrees.

The symptoms of the inflammatory complications mentioned above are such as accompany these processes wherever they occur in the body.

The diagnosis of varicose veins and of the different complications above enumerated is easy for any one who is able to recognize the different forms of inflammation and ulceration. The inflamed strip of a varicose vein is broader than that of infection in a lymph vessel, and the overlying skin is not so red. A sharply localized varix can hardly be mistaken for any sort of a cystic growth, as it is collapsible on pressure, refills slowly, and has less tension than most cysts. It does not pulsate like an aneurism.

Treatment.—Palliative treatment of uncomplicated varicose veins consists in attention to the general health; in the avoidance of such occupations and such clothing as tend to interfere with the venous flow; in the elevation of the feet as much as possible when the patient is sitting down, and in the wearing, during the daytime, of an elastic bandage or stocking extending from the toes to the knee. Even though the varicose veins extend well into the thigh, firm compression of the leg will usually relieve the symptoms, and it is difficult to apply a stocking or bandage with comfort above the knee-joint.

A woven elastic, cotton or silk-web stocking costs from $2.50 to $8. Its advantages are the ease with which it may be applied and the firm pressure which it exerts when new. A thin white lisle thread stocking should be worn next the skin to protect the elastic stocking from perspiration. With the best of care an elastic stocking loses its tone in a few months, so that the expense is no inconsiderable item to a poor person. Various kinds of elastic bandages have been devised, such as pure rubber, rubber webbing, cloth webbing, stockinette, etc., but nothing is more satisfactory than pure coarse white flannel cut on the bias in strips about three inches wide, a sufficient number of which are sewed together to make a bandage six or eight yards long. Such bandages can be washed and ironed as often as they become soiled, and they will last a long time. They should be applied before the patient gets up in the morning. In the beginning this is a considerable trouble, as it is by no means easy to bandage one's own leg. But most patients soon learn to apply them in five or ten minutes, and many put them on as neatly as a professional could hope to do. No one who has once become accustomed to apply such bandages would willingly exchange them for an elastic stocking, since he can always regulate the pressure according to his own comfort, aside from the fact that they are cleaner and cheaper.

The radical treatment of varicose veins may be (1) their multiple ligation, either subcutaneously or through short incisions, (2) the excision of portions or of the whole of the dilated veins, or (3) the double ligation of the saphenous vein at its entrance into the femoral. The injection of substances to produce clots in the veins is no longer in vogue.

The subcutaneous ligation of the vein consists in the passage of a needle threaded with catgut first beneath the vein and then between the vein and the skin (Fig. 4993).

The ligation of the main trunk of a saphenous vein was recommended by Trendelenburg in an article published in 1891. The good results then reported and those which have since been obtained by others, have given this operation a considerable renown. It is worth remembering, however, that a thrombus may form in the proximal portion of the vein and that it may reach up into the femoral and cause embolism. For this reason a patient ought to remain in bed for at least ten days after the operation. The vein can be exposed under the influence of cocaine at its termination in the femoral vein, or, in case its higher branches are not varicose, it may be exposed just below the centre of the thigh. It should be ligated in two places and divided between the ligatures.

The excision of a considerable length of a varicose vein is an operation which usually requires some little time and which can best be performed under a general anæsthetic. The limb should be allowed to hang over the edge of the operating table for a minute or two for the purpose of distending the veins, and then a constricting band or rubber tube is placed around the thigh, not tight enough, however, to obstruct the arterial flow. The dissection of the veins should be made from above downward, since in this manner they will remain full of blood and will thus be easily found. As long as the vein is not cut into it is clearly visible and the dissection is easily performed; but often, in spite of his resolve not to do so, the operator will cut a hidden branch which extends from the superficial vein to some deeper one, and the wound will then become filled with a flow of blood which is sometimes stopped with difficulty. When the tissues are once stained with blood the veins are less easily recognized. When the affected veins have been removed the wounds in the skin are sutured, and if they heal primarily the patient should be able to go about in ten days or two weeks. The ultimate recovery is not hastened by getting the patient out of bed before there is firm union of the skin.

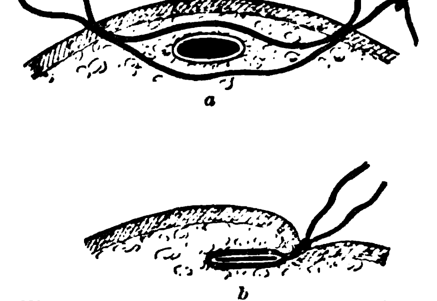

FIG. 4993.—Subcutaneous Ligation of a Vein (Trendelenburg's Method). *a*, Shows how the ligature is to be applied; *b*, shows the condition of the parts after the ligature has been drawn taut and tied.

These operations are of service not only in relieving the patient of his troublesome varicose veins, but in tending to cure such complications as eczema and ulcer.

Excision may also be applied to a thrombosed vein. The time of recovery will not be much greater than that required for excision of an uncomplicated varicose vein, while the non-operative method of treatment of thrombosis often requires four or five weeks for effecting a cure. The risk is said to be no greater than that following excision of simple varicose veins.

The non-operative treatment of a thrombosed varicose vein consists in rest in bed and the application of moist wet dressings or an ice-bag to relieve the pain. In from two to four weeks the acute symptoms will have subsided, and the patient may again go about. It is better to apply, for a time at least, a firm bandage from the toes upward, so as to relieve the veins from the strain of a column of blood to which they have grown unaccustomed during the rest in bed. An annoying feature of thrombosis is its tendency to spread in spite of treatment. An extension upward along the vein may occur at any time, and the course of the trouble in the new situation will be exactly like that of the original thrombosis. Excision has been lately advised as a method of curing thrombosed veins, as stated above.

VEINS, ANOMALIES OF.—The anomalies of veins, though of great morphological interest, are, with a few exceptions, of no great surgical importance. The most important variations of the venous system are found in the great veins entering the heart, and in their large tributary branches in the thorax and abdomen.

Although variations of veins are more frequent than those of arteries, they have been much less studied, one reason being that veins are rarely injected with paint for purposes of dissection. Their variations also are of much less surgical importance than those of arteries. When arteries are anomalous, so are their accompanying veins; an exception to this rule is seen in the obturator vein which empties into the internal iliac vein, even when the artery is abnormal.

Abnormal communications by aberrant vessels are much more common in the venous than in the arterial system. Many veins which are normal in the lower animals occur as anomalies in man. Many varieties which occur in man are really persistent fœtal conditions, and these are permanent conditions in animals lower in the scale. An example of this is seen in the occurrence of a double vena cava, the supernumerary vessel (the left cava) being merely a persistent left duct of Cuvier.

The following account of the anomalies of veins is necessarily incomplete; the reader who is interested in the subject is referred for further information to W. Krause's "Varietäten der Körpervenen" in vol. iii. of Henle's "Anatomie des Menschen," the various articles in the *Journal of Anatomy and Physiology*, and R. Quain's "Commentaries on the Arteries," 1844; and, for an excellent account of the development of the veins, to vol. i., Part I., of Quain's "Anatomy," 1890.

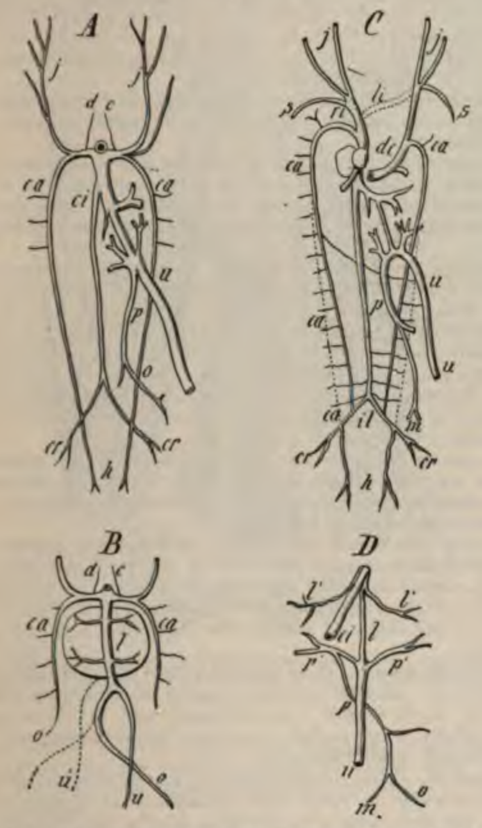

FIG. 4994.—Diagram Illustrating the Development of the Great Veins. (After Kölliker.) *A*, Plan of the principal veins of the fœtus of about four weeks or over, after the first formation of the vessels of the liver and the vena cava inferior; *B*, veins of the liver at a somewhat earlier period; *C*, principal veins of the fœtus at the time of the first establishment of the placental circulation; *D*, veins of the liver at the same period; *dc*, the right and left ducts of Cuvier; *ca*, the right and left cardinal veins; *jj*, jugular veins; *s*, subclavian; *az*, azygos; *u*, umbilical; *o*, omphalo-mesenteric vein; *p*, portal vein; *p' p'*, venæ advehentes; *l*, ductus venosus; *h*, hypogastric or internal iliac veins in the line of continuation of the primitive cardinal veins; *li*, transverse innominate.

CARDIAC VEINS.—*Coronary Sinus.*—The coronary sinus and the small oblique vein connected with it must be regarded as the persistence of a fœtal condition which will be described in connection with the superior cava; it is really the termination of the left duct of Cuvier, or left superior cava. The vena azygos minor has been seen emptying into the coronary sinus; in this case the left superior cava was persistent as a small branch.

It is not uncommon for one or more of the cardiac veins to be absent. When the left superior cava persists, it may receive veins which normally enter the coronary sinus. The *great coronary vein* may end in the auricle itself, as may also the *middle cardiac vein;* this is the normal condition in the horse, camel, etc.

PULMONARY VEINS.—The pulmonary veins occasionally communicate with other veins, as the innominate (Hyrtl); the right upper pulmonary has been seen to empty into the superior cava, and the left upper into the innominate. The two pulmonary veins of one side may unite into a single trunk (more commonly on the left side) before emptying into the left auricle.

There may be three pulmonary veins on the right side, the third coming from the middle lobe of the right lung. Hepburn[1] records a case of double vena cava in which there were three right pulmonary veins, the upper opening into the superior cava of the right side, and the two lower into the *right* auricle; there was also a separate foramen (quite distinct from the foramen ovale) between the right and left auricles. Peacock[2] records a similar case in a child six years of age.

I have on two occasions seen the upper pulmonary vein of the right side emptying into the superior vena cava. The left vein may open into the innominate. Shepherd[3] reports a case of a single right pulmonary vein opening into the vena azygos major.

DEVELOPMENT OF THE GREAT VEINS.—In order to understand more thoroughly the variations of the great veins which return the blood to the heart, the following description, abridged from Quain's "Anatomy," 9th edition, vol. ii., will be of service:

"At the time of the commencement of the placental circulation two short transverse venous trunks, *ducts of Cuvier*, one on each side, open into the auricle of the heart; each is formed by the union of a superior and an inferior vein named the *primitive jugular* and the *cardinal vein*. The *primitive jugular* receives the blood from the cranial cavity by channels in front of the ear, which are subsequently obliterated; in the greater part of its extent it becomes the external jugular vein, and near its lower end it receives small branches which grow to be the internal jugular and subclavian veins."

The *cardinal veins* are primitive vessels which return the blood from the Wolffian bodies, the vertebral column, and the parietes of the trunk. The inferior cava is a vessel of later development, which opens into the trunk of the umbilical and omphalo-mesenteric veins above the *venæ hepaticæ revehentes* (Fig. 4994).

The iliac veins, which unite to form the inferior cava, communicate with the cardinal veins. The inferior extremities of the cardinal veins are persistent as the internal iliac veins; above the iliac veins the cardinal veins are obliterated in a considerable part of their course; their upper portions then become continuous with two new vessels, the *posterior vertebral veins* of Rathke, which receive the lumbar and intercostal twigs.

As development proceeds, the direction of the ducts of Cuvier is altered by the descent of the heart to the thoracic region, and then it becomes continuous with that of the primitive jugular veins. A communicating branch makes its appearance between the two jugulars, directed obliquely downward from left to right; further down in the dorsal region, between the posterior vertebral veins, another communicating branch is developed.

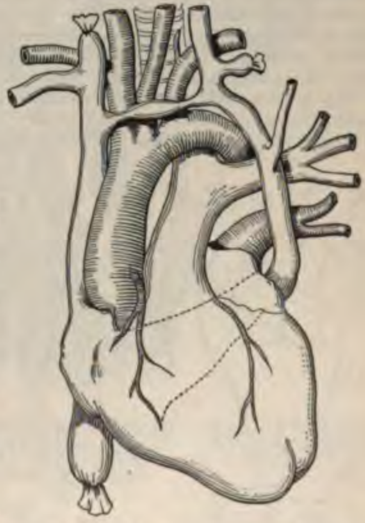

FIG. 4995.—Double Vena Cava seen from the Front, with Small Transverse Innominate Veins. (R. Quain.)

The communicating branch between the jugulars is converted into the left innominate vein (see Fig. 4996). The portion of the primitive jugular below the communicating vein, together with the right duct of Cuvier, forms the superior vena cava, while the cardinal vein opening into it (*az*, Fig. 4994) is the extremity of the great azygos vein. On the left side, the portion of the primitive jugular placed below the communicating branch, and the cardinal and posterior vertebral veins, together with the cross branch between the two posterior vertebral veins, are converted into the left superior intercostal and left superior and inferior azygos veins. The left duct of Cuvier is obliterated, except at its lower end, which always remains pervious as the coronary sinus. Traces of this vein are recognized in the adult as a fibrous band or a small vein (see Fig. 4996, *A*). The variability in the adult arrangement of these vessels depends on the various extent to which the originally continuous vessels are developed or atrophied at one point or another.

VARIETIES OF THE SUPERIOR CAVA AND INNOMINATE VEINS.—*Double Vena Cava.*—This anomaly is rather a rare one, and is due to the persistence of the left duct of Cuvier. When the left duct of Cuvier persists, the transverse innominate vein is absent or of a very small size, and the vein formed by the junction of the left internal jugular and subclavian is continued down in front of the arch of the aorta and root of the left lung to the heart (see Fig. 4995), where it receives the great cardiac vein, and then passes outward to become continuous with the coronary sinus, and thus opens into the right auricle (see Fig. 4996, *B*).

The explanation of this anomaly is simple, if the description of the development of the great veins, given above, be referred to. It is merely a persistence of the fœtal condition. The left duct of Cuvier is not obliterated, and in consequence the transverse branch between the two primitive jugulars has been developed but slightly or not at all. The persistent left cava has been seen in a few cases to open into the left auricle (Hyrtl, Gruber, and others).

In birds and some mammals, as the rabbit, etc., the left duct of Cuvier persists normally as well as the right.

R. Howden[4] reports a case of double vena cava in which the left vein was joined by a large left azygos vein; the right azygos was broken up into several veins; the most inferior one joined the left azygos, and the superior the vena cava. This is a reversal of the usual condition, and the left azygos in this case must be looked upon as a persistence of the left cardinal vein.

The writer has met with no less than six cases of persistence of the left duct of Cuvier. They all occurred in adults (four males and two females), and were of the usual form; in four the transverse innominate was of considerable size. In the third and fourth cases it was very small, and formed chiefly by the inferior thyroid veins. Instances have been recorded in which the right superior cava was absent and the left persisted; in such cases there was a right transverse innominate vein. This variation occurred without transposition of the arch of the aorta or any of the viscera. In cases of transposition of the viscera this is the normal arrangement.

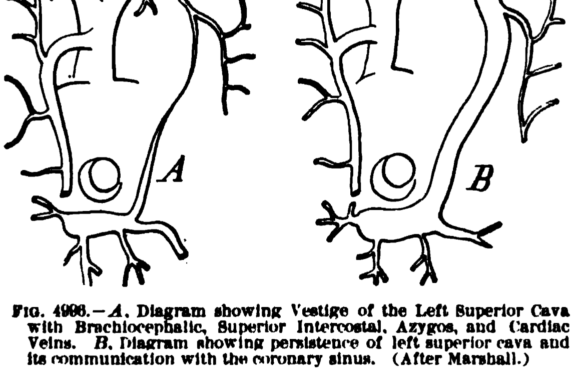

FIG. 4996.—*A*. Diagram showing Vestige of the Left Superior Cava with Brachiocephalic, Superior Intercostal, Azygos, and Cardiac Veins. *B*. Diagram showing persistence of left superior cava and its communication with the coronary sinus. (After Marshall.)

In some cases the transverse innominate vein is of normal size, and yet there is a persistence of the left duct of Cuvier in its whole length, either as a good-sized canal or as a very small, but patent, vein.

In some cases in which two superior cavæ are present, the left has been seen to enter the left auricle instead of the coronary sinus.

Gruber reports a case in which the principal veins of the heart terminated in a trunk which opened into the left innominate vein, the opening of the coronary sinus into the right auricle being occluded (*Virchow's Archiv*, xcix.).

Connection between the Vena Cava and Pulmonary Veins.—Cases are on record of the upper right pulmonary vein emptying into the superior cava (Meckel, Gegenbauer); of the left pulmonary vein joining the innominate (Bachhammer); and also of the right pulmonary vein opening into the vena azygos major (Shepherd). Hyrtl reports a case in which there was a communication between a rudimentary left cava and the left inferior pulmonary vein.

Transverse Innominate.—This vein may be placed higher up than usual—so high, in fact, that in children with short necks it might be accidentally wounded in the low operation for tracheotomy.

Cooper[5] reports it as passing through the thymus. Gruber examined many embryos of children, and found that in certain cases the vein passed behind the left and in front of the right lobe of the gland, and in others in front of the left and behind the right lobe (quoted by Krause).

Coronary Sinus.—This has been seen to open into the left auricle. Gruber reports a case in which the opening into the right auricle was occluded, and the principal veins of the heart ended in a trunk which passed up to join the left innominate vein.

Vertebral.—This vein not infrequently passes behind the subclavian to reach the innominate, or it may embrace the subclavian by dividing above and reuniting below. It occasionally passes through the transverse process of the seventh cervical vertebra, or sends a branch through the foramen to join the deep cervical vein.

Internal Mammary.—This may be double, and may anastomose with the upper intercostal. The writer has seen it empty into the superior cava. It may empty into the azygos major on the right side (Portal).

SUPERFICIAL VEINS OF THE HEAD AND NECK.—The arrangement of the superficial veins of the neck often varies greatly from that described in text-books of anatomy.

The two divisions of the *temporo-maxillary* vein are frequently very unequal in size; the branch joining the facial may be of large size, and that going to the external jugular very much diminished, or *vice versa*. In some cases the branch joining the facial returns all the blood into the internal jugular, and in other cases the internal jugular receives no branch from the temporo-maxillary. When the latter arrangement exists all the blood empties into the external jugular.

The *facial vein* sometimes passes back over the sternomastoid muscle to join the external jugular. It may pass across the sternomastoid to its posterior border, and then join the internal jugular beneath that muscle. It sometimes joins the internal jugular behind the posterior belly of the digastric and stylohyoid muscle, or it may be continued downward to the anterior jugular (see Fig. 4998).

External Jugular.—This vein may be double. In those cases in which the posterior division of the temporo-maxillary trunk is wanting, and all the blood goes to the internal jugular, the external jugular is very small, being formed altogether by the posterior auricular.

When the posterior auricular joins the temporo-maxillary trunk, the external jugular is wanting altogether in the upper part of the neck. Gruber describes a case in which a loop was formed in this vein through which passed the transverse cervical nerve. The lower end of the external jugular may divide into two branches, one of which joins the subclavian vein or, transversus colli, and the other the anterior jugular, subclavian, or internal jugular.

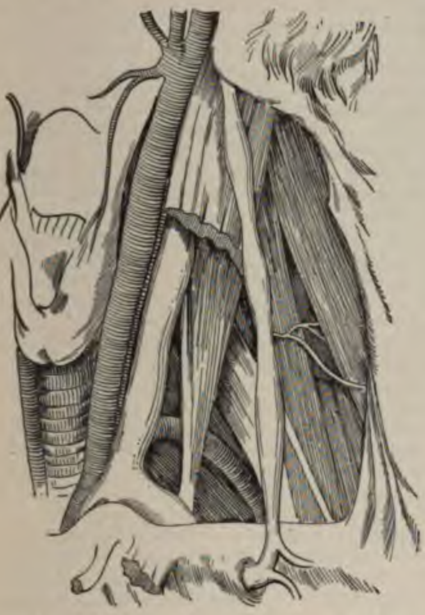

FIG. 4997.—External Jugular passing over the Clavicle and going up between that Bone and the Subclavius Muscle to join the Subclavian. (Richard Quain.)

Occasionally the vein may pass over the clavicle and join the cephalic vein, or the cephalic may join the external jugular beneath the clavicle, and communicate with it at the same time by a loop line above the clavicle (Nuhn). (See Fig. 4999.)

The writer has seen several cases in which the external jugular passed over the clavicle and then turned up between that bone and the subclavius muscle to join the subclavian (see Fig. 4997). A knowledge of these anomalies is important in operations on the clavicle and subclavian artery.

According to Hallett, the external jugular is absent once in ninety-three subjects.

Anterior Jugular Veins.—These veins are not constant. One may be much larger than the other. Occasionally the two join to form a single median trunk. The two veins may be united by a large trunk over the trachea, which may give rise to troublesome hemorrhage if wounded in the operation of tracheotomy.

Pilcher says that when one of the veins is absent it is compensated for by a large obliquely transverse branch which comes from the external jugular and crosses the neck at its lower third to join the anterior jugular which persists.[6]

Pilcher also describes a deep anterior jugular of large size which is occasionally seen. It has its origin in the subhyoid region, passes down directly in the median line, deeply seated beneath the muscles; it passes over the cricothyroid space, and, going down the middle of the neck over the trachea, receives the superior and inferior thyroid veins, and finally empties into the transverse innominate vein.

The anterior jugular may in rare cases pass outward over the sternomastoid muscle.

Transverse cervical and suprascapular veins not infrequently empty into the subclavian vein independently. Occasionally they join the internal jugular (R. Quain).

Internal Jugular.—This vein frequently covers the common carotid artery to such an extent that the artery cannot be seen until the vein is drawn aside (see Fig. 4998). According to R. Quain[7] this occurs most frequently in the left side. The left vein is occasionally of very small size, its place being taken by the external jugular (W. Krause). This is a persistence of an early fœtal condition, for in early fœtal life the primitive or external jugular returns all the blood from the heart. This is the normal adult condition in many mammals, as rabbits, squirrels, etc. The internal jugular is altogether absent in fishes, many amphibia, birds, and some mammals, as the horse and ruminants.

A case is reported by J. W. Williams[8] in which the right omohyoid muscle, instead of passing over the vein, "played by means of its intermediary tendon through a slit in the vessel."

In some cases the temporo-facial trunk fails to empty into the internal jugular, the external receiving all its blood.

R. Quain reports a case in which a very large anterior jugular vein communicated with the internal jugular over the carotid artery (see Fig. 4998).

The internal jugular may receive the vertebral, the transverse cervical, and the suprascapular veins. A superior intercostal has been seen to empty into it (Lauth); or a large bronchial vein (Weber). The external jugular has been seen to empty into the internal about the middle of the neck (Führer).

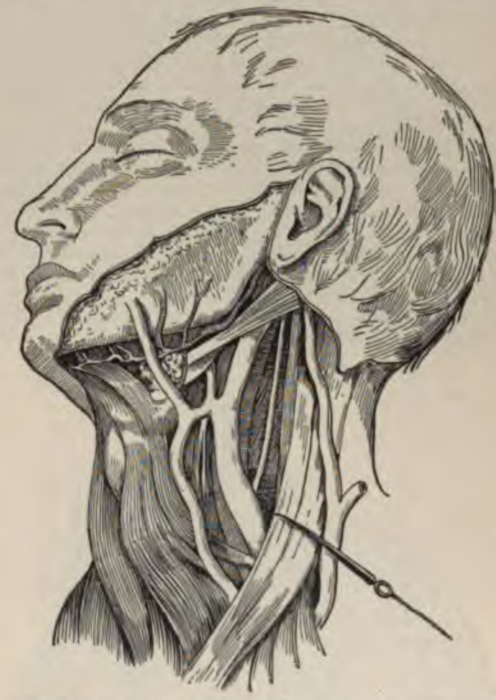

FIG. 4998.—Facial Vein, continuous with the Anterior Jugular, which is Joined to the Internal Jugular by a large Communicating Branch over the Carotid. The internal jugular is seen covering the upper part of the carotid artery. (R. Quain.)

VARIETIES OF CEREBRAL SINUSES.*—The sinuses about the *torcular Herophili* are subject to considerable variation. A true confluence of the sinuses is not always found at this point. The torcular may be placed to one side or other of the median line. The connecting branch between the torcular and straight sinus may be of large size and convey the blood from the superior longitudinal sinus.

---

* J. F. Knott has given an excellent account of the variations of the sinuses in the Journal of Anatomy and Physiology, vol. xvi.

Superior Longitudinal Sinus.—This sinus may be completely absent (Portal). Knott[9] describes it as being occasionally so small as hardly to represent a normal sinus. It may join the straight sinus; it may bifurcate posteriorly a little behind the coronal suture, and reunite about an inch posteriorly (Knott and Vicq d'Azyr). Malacarne reports a case of bifurcation of the sinus near the apex of the occipital bone, each branch following the lambdoidal suture of its own side and joining the lateral sinus.

Lateral Sinus.—The right is often very diminutive. Lieutaud has recorded a case of complete absence of the left lateral sinus. Both lateral sinuses may be of small size; in such cases the occipital sinuses are much enlarged, and empty their blood into the internal jugular.

Sometimes one or both sinuses are divided into two by a septum (Hallett). Verga describes an aberrant vein going from the cavernous sinus or ophthalmic vein to the left lateral sinus. One sinus may be of large size and the other small. The left is usually the larger. A case is reported[10] in which both lateral sinuses were small, especially the right, which became quite minute after the exit of a large vein through the mastoid foramen. In this case three large emissary veins were present at the anterior extremity of the superior longitudinal sinus, also three others opening into the torcular, one into the commencement of the right lateral sinus, and one into the posterior extremity of the superior longitudinal.

Inferior Longitudinal.—Knott[11] reports a case in which this sinus, instead of joining the straight, turned up between the layers of the falx and ended in the superior longitudinal sinus, one-quarter of an inch above the internal occipital protuberance.

Straight Sinus.—Sometimes absent. In a case reported by Knott the vein of Galen and the inferior longitudinal sinus met at the anterior edge of the tentorium, formed a trunk three-quarters of an inch long, and then divided into three veins, one of which passed up between the layers of the falx to join the superior longitudinal, and the other two passed between the layers of the tentorium to the left side to join the lateral sinus.

Cavernous Sinus.—Complete absence of this sinus is reported by Santorini. There is sometimes a vein from it going through the foramen rotundum with the superior maxillary division of the fifth cranial nerve (Nuhn).

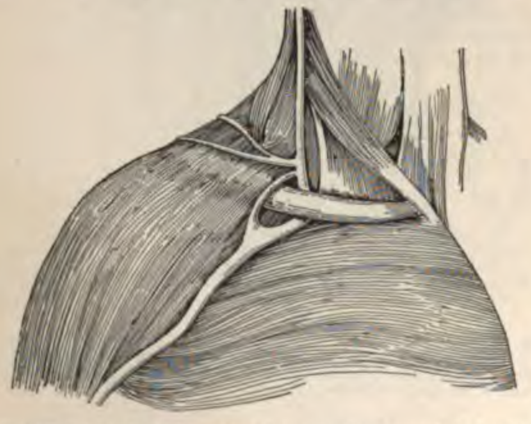

FIG. 4999.—Cephalic Vein passing up under the Clavicle to Join the Subclavian. The cephalic is connected with the external jugular by a loop line which passes over the clavicle. (Nuhn.)

Superior Petrosal.—Sometimes absent; may communicate with the ophthalmic vein (Verga).

Inferior Petrosal.—Sometimes terminates within the skull above the margin of the jugular foramen.

Circular Sinus.—May receive the ophthalmic vein.

Occipital Sinuses.—Sometimes wanting, occasionally of large size; in such cases the lateral sinuses are small; they may be very small. The sinus is often much larger than its fellow, and may groove the occipital bone as it passes forward to join the lateral sinus.

Petrosquamous Sinus (Luschka, W. Krause).—This additional sinus is sometimes present, lying in a small groove along the junction of the petrous and squamous portions of the temporal bone, and opening behind into the lateral sinus. In rare cases it is found passing through an aperture (*foramen jugulum spinosum*) in the squamous portion of the temporal bone, between the orifice of the external auditory meatus and the glenoid cavity, and joins the temporal vein. In the dog and many other animals a similar vessel forms the principal outlet for the intracranial blood. In the human subject also, at an early period of fœtal life, the lateral sinus is continued forward in this course, and opens into the primitive (afterward the external) jugular vein; the occurrence of the petrosquamous sinus is due to the persistence of this channel, which usually becomes obliterated after the development of the internal jugular.[12]

VEINS OF THE UPPER LIMB.—The superficial veins of the forearm are subject to considerable variation, both as to arrangement and as to size. At the bend of the elbow the arrangement varies greatly.

The *radial* vein may be very small or absent, and in such cases the cephalic vein is wanting, the outer branches from the radial side being collected into the median vein, which goes directly to form the *median basilic.* This latter is occasionally double.

The *cephalic* vein may be absent (Hallett found it absent in two out of ninety-three cases). It may be double. It sometimes empties near the insertion of the deltoid into the brachial vein. Sometimes it anastomoses with the brachial vein by an aberrant branch. It may pass up over the clavicle to join the external jugular, or it may be connected with it by a branch called the jugulo-cephalic (see Fig. 4999). In two cases this branch has been seen to perforate the clavicle (Allen Thompson). This vein may pass up between the clavicle and subclavius muscle to join the subclavian vein; the writer has seen several examples of this anomaly (see Fig. 4999).

The *median cephalic* vein is not infrequently absent.

Basilic Vein.—May be double in its whole course. May anastomose with the ulnar vein. May be separated from the brachial artery by only a very thin fascia; this fact should be kept in mind in bleeding from this vessel. The basilic may anastomose by a large branch with the cephalic vein (Theile).

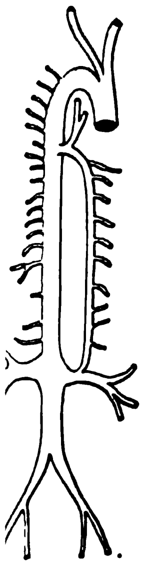
Axillary Vein.—This vein may be double, from a failure of the venæ comites to unite with the basilic. R. Quain has repeatedly seen the axillary vein perforated by a branch of the internal cutaneous nerve.

Subclavian Vein.—This vein may be placed at a higher level than usual, overlapping the artery at the outer edge of the scalenus anticus. In rare cases the vein passes *behind* the scalenus anticus muscle with the artery, or, in cases in which the artery passes in front of the muscle, the vein may pass behind. Luschka has several times seen the subclavian vein passing between the clavicle and the subclavius muscle. The same anatomist also reports having seen the vein divide and embrace the scalenus anticus muscle, and reunite and follow its usual course. The two venæ comites have been seen to empty into the subclavian; also a left bronchial vein (Weber.)

Double Subclavian.—Morgagni (quoted by R. Quain, p. 182) in one instance found on both sides of the same body two venous trunks placed side by side, instead of the usual single subclavian vein. On the right side the two veins were of equal size, about five inches long, and reached to a point where the internal jugular ends. On the left side one of the veins was of very small size.

The *anterior jugular, suprascapular,* or *transverse cervical* may empty into the subclavian separately. Weber reports the subclavian receiving a large bronchial vein. The *cephalic* vein may empty into the subclavian above below the clavicle. An aberrant vein may unite the per end of the cephalic vein with the subclavian by sing behind the clavicular portion of the pectoralis jor (W. Krause).

zygos Veins.—The variations of the azygos veins are siderable, the veins on the left side being especially ble to variation. Two or three of the middle intertal veins of the left side not uncommonly unite into a gle trunk which passes directly into the azygos major. e left superior (hemi-) azygos vein may be absent, the rcostal veins emptying separately into the main trunk. e hemiazygos may empty into the subclavian (Wris-) or into the left innominate, joining with the supe- intercostal. A case has been reported (Cerutti) in ich the hemiazygos joined the internal jugular vein. the intercostal veins on the left side may be collected a single trunk which empties into the left innominate, stribution somewhat similar to that on the right side. writer has reported an example of this arrangement.[13] By referring to the short account given above of the development of the great veins it will be seen that this anomaly is due to a persistence of the left cardinal vein. A case is recorded by Gruber in which the left azygos opened into the coronary sinus, and was met by a small vein descending from the union of the subclavian and jugular. In this case the jugular vein had been developed in the usual way, while the left vena azygos continued to pour its blood into the left duct of Cuvier (Quain).



00. The Inferior continued into Thorax as the Azygos, and the d from it Enter- he Heart through uperior Cava. In case the hepatic opened into the auricle in the situation of the ior cava. (R. n.)

The azygos veins may be transposed, the larger vessel being placed on the left side and being joined by the right azygos; the trunk formed by these veins then arches over the root of the right lung and opens into the left coronary sinus (Gruber). This is the normal arrangement in the sheep and some other animals.

R. Howden[14] reports a case of double vena cava in which a single large left azygos, after being joined by some of the right intercostal veins, emptied into the left cava near the coronary sinus. The upper right intercostals formed a trunk which emptied into the right cava.

There may be a single azygos vein ascending in front of the spinal column and receiving the intercostal veins of both sides (Wagner). The azygos major may empty into the right innominate (Meckel) or r up than usual into the superior cava. Wrisberg escribed a case in which the azygos major passed gh a canal by grooving the upper lobe of the right

Most of the varieties mentioned above may be explained by studying the development of the for they are all persistent fœtal conditions. The ava inferior has been seen continuous with the major. (See Fig. 5000. This will be more fully ed with the vena cava inferior.)

right spermatic has been noted as emptying into gos vein, also the left renal and suprarenal veins).

berrant branch has been seen going from the angle ction of the left renal and inferior vena cava to the zygos (W. Krause). The right pulmonary vein en seen to join the vena azygos major (Shepherd, *rnal of Anatomy*, vol. xxiv.).

rior Vena Cava.—R. Quain[15] divides the peculiari- this vein into two classes: (*a*) Where the vein has the usual mode of termination in the heart; (*b*) where it terminates in the superior vena cava.

The common iliac veins may not join at the usual place; the left common iliac, after sending a branch across to join the right, may pass up on the left side of the aorta and join the left renal. This is not a very uncommon anomaly, and has been seen several times by the writer. It is sometimes called an example of double vena cava inferior. A case is reported by William Osler[16] of occlusion of the vena cava as it entered the liver. There was in this case a double cava arranged as above described (see Fig. 5001); the circulation was carried on by a large branch from the left renal, which probably joined the splenic.

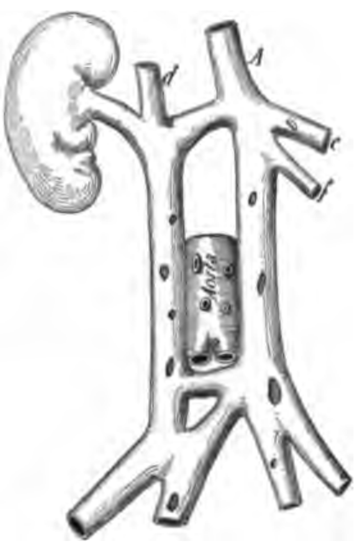


FIG. 5001.—Case of Double Inferior Vena Cava, the Two Common Iliacs being Joined by a Transverse Branch. *A*, Occluded vena cava; *e*, right renal; *f*, right spermatic; *d*, large branch, probably joining the splenic, through which circulation was carried on. View taken from behind. (W. Osler.)

In some cases there is no transverse branch below between the two common iliacs (see Fig. 5002). These cases are examples of the persistence of the lower part of the cardinal veins.

Another somewhat similar anomaly is that in which the two common iliac veins join to form a common vein which passes up on the left side of the aorta, but, after receiving the left renal, crosses over (rarely under) the aorta and from there on takes its usual position.

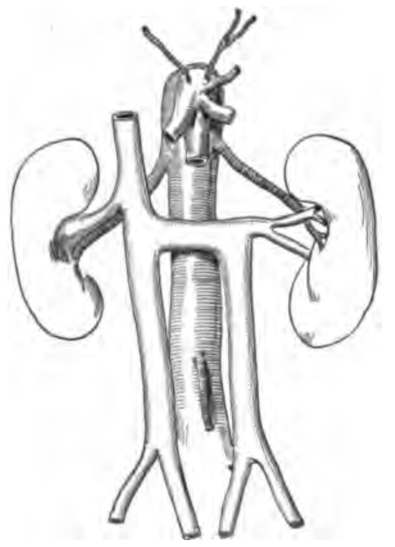

FIG. 5002.—Example of Double Inferior Vena Cava. The left cava is joined by the left renal and then crosses the aorta to join its fellow, and below, the inferior cava proper. Each cava is really a continuation upward of the common iliac vein of that side. (R. Quain.)

The explanation of this anomaly is that the right cardinal vein has been obliterated while the left persists. In cases of transposition of the viscera the vena cava inferior passes up the whole distance on the left side of the aorta, grooves the transposed liver, and joins the right auricle of the heart in its transposed position on the left side. A case of transposition of the viscera is recorded (Hernholdt) in which the inferior cava passed up on the right of the aorta, pierced the diaphragm, and then crossed over to join the transposed superior cava.

In some rare cases the inferior cava passes up normally to the diaphragm without receiving the hepatic veins, it then pierces the diaphragm, and goes over the root of the right lung to join the superior cava, thus taking the place of the vena azygos major; the hepatic veins in these cases form a trunk, which opens into the right auricle at the usual place of termination of the inferior cava (Fig. 5000). Again, the inferior cava may pass up on the left side of the aorta and, after piercing the diaphragm on that side, go behind the aorta and thoracic duct to join the superior vena cava, thus following the course of the left azygos vein. The hepatic veins, as in the former case, open into the right auricle (see Fig. 5003). These cases are explained on the supposition that the normal inferior cava has never been developed, and that the blood is returned from the lower part of the body by a persistent cardinal vein.

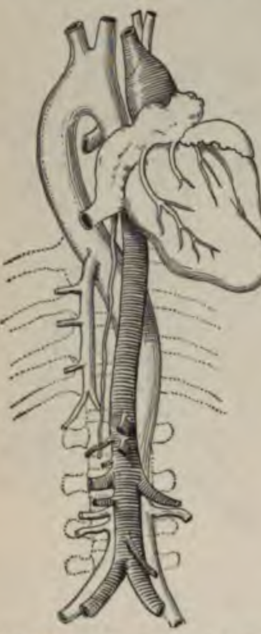

FIG. 5003.—Vena Cava to Left Side of Aorta; below, but crossing behind that vessel above, and, passing up the thorax on the right side; it empties its blood into the superior cava. (R. Quain.)

W. Gruber[17] reports a case in which the inferior cava was formed by the junction of three trunks—right and left external iliacs and a common iliac formed by the junction of the two internal iliacs; this arrangement is seen in some of the lower animals, as the bear, etc. The vena cava inferior is occasionally formed by a common iliac vein and the veins of the other side, not opening by a common trunk, but separately.

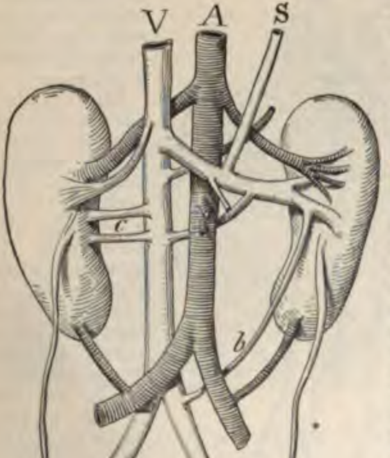

FIG. 5004.—Anomalous Renal Vessels. *A*, Aorta; *V*, vena cava; *b*, communication between the left renal and the left common iliac; *S*, vein from left renal going to join the splenic; *c*, supernumerary renal veins. (Shepherd.)

Renal Veins.—The left renal vein, in order to reach the inferior cava, may pass *behind* instead of in front of the aorta. Supernumerary renal veins are not so common as supernumerary renal arteries, but they not infrequently occur. One of these supernumerary vessels of the left side may open into the azygos of that side.

Walsham[18] reports a case of double left renal vein embracing the aorta, one passing in front and the other behind. The posterior branch received the spermatic and also the third lumbar vein. The writer has seen a somewhat similar case, referred to below. When the kidney is placed lower than normal, a vein from it usually empties into the common iliac.

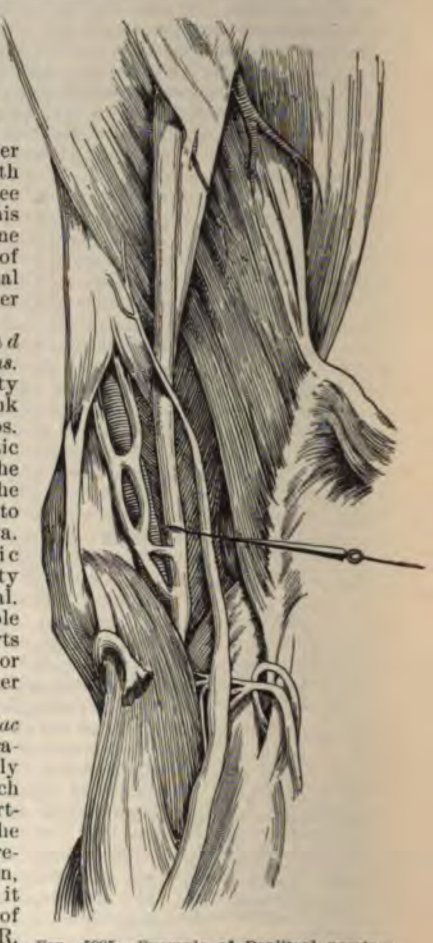

FIG. 5005.—Example of Popliteal passing up the Thigh to Join the Profunda. In this case the lower end of the femoral artery is accompanied by a very small vein. (R. Quain.)

In the museum of McGill University is a beautiful specimen of abnormal renal veins obtained by the writer. Both kidneys were placed lower down than normal, reaching to the intervertebral substance between the fourth and fifth lumbar vertebræ, and each received a supernumerary artery from the common iliac artery. On the right there were two renal veins, on the left one large vein proceeded from the hilus of the kidney in front of the aorta, and a smaller one passed behind the aorta to join the inferior cava lower down. This communicated below, by a large branch which passed beneath the left common iliac artery, with the left common iliac vein, and above, by another large branch, with the splenic vein (see Fig. 5004). This case is probably one of persistence of the left cardinal vein in its lower part.

Spermatic and Suprarenal Veins.—These may empty by a common trunk into the azygos. The right spermatic may empty into the right renal and the left spermatic into the inferior cava. The spermatic vein may empty into the suprarenal. It may be double in the upper parts of its course or may be altogether absent.

Common Iliac Veins.—A perforation is occasionally seen through which passes a small artery. Sometimes the vein divides and reunites farther on, thus making it double in part of its course (R. Quain). The left common iliac vein has been seen passing in front of the right common iliac artery (Zaaijer). Absence of the common iliac vein of one or both sides has been met with by Gruber; the left external and internal iliac veins in one instance being continued upward to enter the commencement of the inferior cava, and in another the two internal iliac veins were joined into a common trunk which united with the right and left external iliac veins to form the vena cava.[19]

Obturator Vein.—Often double, one accompanying the artery and the other coursing around the inner side of the femoral ring. It may open by two mouths into the external iliac.

Internal iliac vein of the *right* side has been seen to empty into the *left* common iliac vein. The internal iliac may be double (Quain).

VEINS OF THE LOWER LIMB; SUPERFICIAL VEINS.—*External Saphenous.*—This vein may empty into the long saphenous or femoral instead of the popliteal. It may communicate with the gluteal veins beneath the gluteus maximus muscle.

A case is reported[20] in which the external saphenous, after piercing the deep fascia in the popliteal space, ran up on the posterior surface of the adductor magnus, perforating it near the second perforating artery, and then joined the profunda vein. In the same paper another case is mentioned in which the venæ comites of the posterior tibial, instead of uniting to form the popliteal, continued up as two veins, being joined by the external saphenous, and going up on the adductor magnus to open into the profunda vein near the first perforating artery. The writer has seen the external saphenous empty about the middle of the thigh into an abnormal popliteal vein which passed up the back of the thigh to join the profunda. The external saphenous may empty into muscular branches in the adductor magnus. Branches of communication have been seen between the perforating and ischiatic veins and the external saphenous.

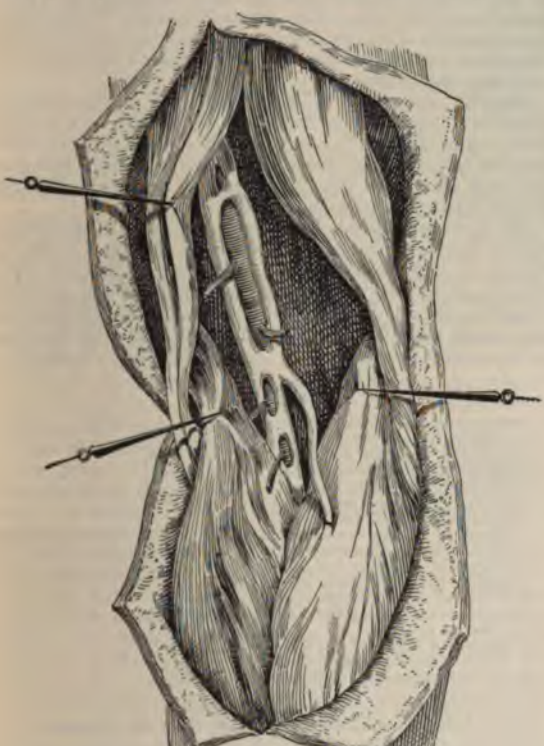

FIG. 5006.—Case of Double Popliteal Vein. (R. Quain.)

Internal Saphenous Vein.—This vein may pierce the fascia lata higher or lower than usual. It may be doubled, or may form an island. It may receive the superficial epigastric, circumflex iliac, an accessory saphenous, or the external saphenous. It is in some cases very large, and in others of no great size. There is frequently an accessory internal saphenous.

DEEP VEINS OF THE LOWER LIMB.—*Popliteal Vein.*—The veins which form the popliteal occasionally unite farther up than usual, so that the lower part of the artery is accompanied by two veins. In some rare cases the vein is double in its entire length. It may be double as high up as the profunda vein. Sometimes the popliteal vein passes up the thigh and joins the profunda; in such cases the external saphenous empties into this vein high up on the thigh. When the popliteal vein does not accompany the artery to become the femoral, a small vein is occasionally seen with the artery (see Fig. 5005).

The popliteal vein may lie deeper and more internal than the artery and next the bone.[21]

Femoral Vein.—Occasionally double in part and, more rarely, in the whole of its course. When double, the femoral artery lies between the two veins (see Fig. 5007). In some cases one of the veins may cross the artery. Small veins are occasionally observed passing over the artery in various directions, sometimes in transverse loops (see Fig. 5008), or obliquely; these transverse branches usually connect various parts of the double vein. The femoral vein may be much diminished in size when the popliteal vein empties into the deep femoral and pierces the adductor magnus at a higher point than usual. In these cases the femoral vein proper first comes in contact with the artery in the groin. R. Quain mentions a case in which he could find no femoral vein accompanying the lower end of the artery; the writer has seen one such case.

PORTAL SYSTEM OF VEINS.—*Hepatic Veins.*—Rothe, a German surgeon, reported many years ago (1787) a case in which one of the large hepatic trunks from the right lobe of the liver terminated, not in the inferior cava or right auricle, but in the base of the right ventricle. Its entrance was guarded by three valves (quoted by W. Krause). In cases in which the inferior cava, as already described, joins the superior cava, the hepatic veins may open separately (Horner) or by a single trunk (Abernethy) into the right auricle. This arrangement is normal in some animals. The writer has described[22] a case in which the vena cava inferior, after piercing the liver and being joined there by a few small hepatic veins (principally from the left side), passed as usual to the diaphragm, and as it pierced that muscle it was joined by a large vein, the size of one's finger, and with walls as thick as those of an artery. This vein, when traced back, proved to be a common trunk formed by two large hepatic veins which came from the right lobe; the common trunk measured one inch in length (see Fig. 5009).

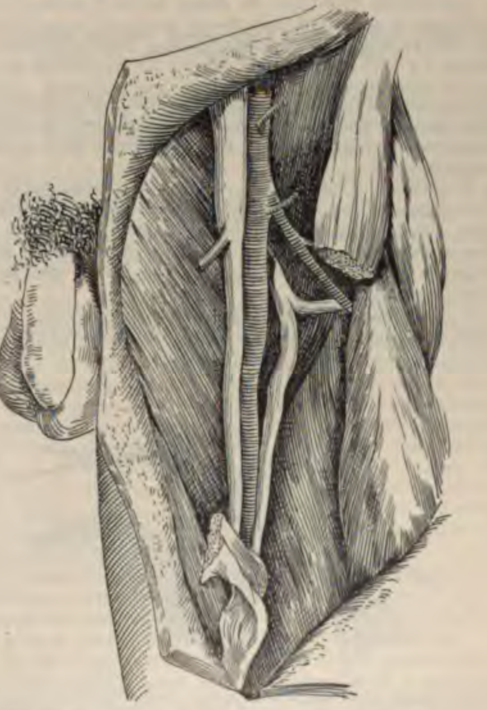

FIG. 5007.—Case of Double Femoral Vein. (R. Quain.)

Morgagni reports a case of the hepatic veins joining the vena cava inferior after it had pierced the diaphragm (quoted by W. Krause). Hyrtl has seen the hepatic veins empty by a common trunk into the right auricle to the inner side and separately from the inferior cava; this, as mentioned above, is the normal course when the vena cava is absent or its place is taken by a persistent cardinal vein.

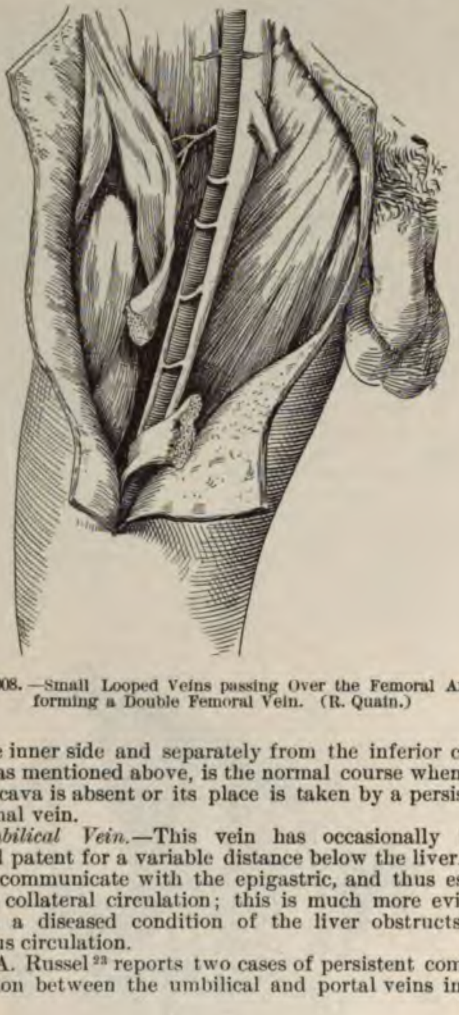

FIG. 5008.—Small Looped Veins passing Over the Femoral Artery, forming a Double Femoral Vein. (R. Quain.)

Umbilical Vein.—This vein has occasionally been found patent for a variable distance below the liver. It may communicate with the epigastric, and thus establish a collateral circulation; this is much more evident when a diseased condition of the liver obstructs the venous circulation.

J. A. Russel[23] reports two cases of persistent communication between the umbilical and portal veins in the human subject. F. Champneys[24] describes a communication between the external iliac and portal veins through the epigastric and umbilical veins.

This was due, probably, to fusion of Luschka's *par-umbilicalis* (which, according to him, always exists normally as a communication between the portal and epigastric veins), and the channel was afterward increased in size by obstruction, due to enlarged liver. A communication of large size between the umbilical and epigastric veins is the normal arrangement in many of the lower animals, as the rorqual, seal, sheep, pig, etc., and in man is an early fœtal condition. Numerous examples have been recorded of communication between the veins of the abdominal parietes, as the phrenic (azygos, etc.) and the portal vein. The writer has already described, in connection with the renal vein, a case in which a large branch of communication existed between the left renal vein and the splenic.

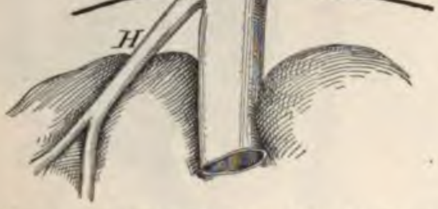

FIG. 5009.—Hepatic Veins from Right Lobe of the Liver Opening by a Common Trunk near the Entrance of the Inferior Vena Cava through the Diaphragm. *R*, Right auricle; *D*, line of diaphragm; *L*, liver; *V*, vena cava; *H*, abnormal hepatic veins. (Shepherd.)

Menière has described a case in which a large vein, as thick as a finger, went from the portal vein to the right iliac. And Brigidi[25] has reported a case of free communication between the umbilical vein, which was patent, and the right iliac by means of a branch of large size in a case of cirrhosis of the liver.

W. Krause[26] mentions a number of cases of communication between the portal vein and the iliac veins by means of a patent umbilical, connected directly by a branch or through an epigastric vein.* These communications are all due to persistent fœtal conditions, and are much more apparent when there is any obstruction to the portal circulation. *Francis J. Shepherd.*

VEINS, PATHOLOGY OF.—In general, the same pathological processes are found in the veins as in the arteries, though varying in degree and importance in the two sets of vessels, some conditions being more pronounced in the arteries, others in the veins. Thus, for example, inflammatory changes are of much more frequent occurrence in the veins; sclerosis and calcification in the arteries. Thrombosis of veins and thrombophlebitis are among the most common and important of pathological conditions; while, on the other hand, from the nature of things, arterial embolism holds a like important place in pathology. In addition to the pathological processes common to both sets of vessels there is a number of morbid conditions peculiar to the veins, among the most important of which may be mentioned varices and phlebectasias.

ANOMALIES.—*Congenital anomalies* in the number, branching, course, and distribution of veins are very common. They are rarely of clinical importance, though at times causing temporary embarrassment during surgical operations. Congenital dilatations or varices are also of very frequent occurrence. They may vary in size from a slight local increase in the prominence of the veins (*venous nævus*) to extensive dilatations of the superficial veins involving an entire extremity, or the greater portion of the trunk or body. Heredity is an important factor. As a rule the condition does not become especially noticeable until about the age of puberty when there is usually a rapid increase in the degree of the abnormality. The superficial veins alone may be affected, or anomalous communications may exist between these and the deep venous trunks, or the entire venous system of an extremity may be over-developed without a corresponding development of the artery. (See *Veins, Anomalies of*.)

---

* Sappey is of opinion that all recorded cases of free communication between the umbilical and epigastric veins rest on errors of observation; he holds that the dilated vein is not the umbilical vein, but one of the accessory portal veins. Professor Giacomini is also of the same opinion, saying that the umbilical vein, in its course from the umbilicus to the portal vein, neither gives nor receives any branch normally. Professors Bordoni and Romiti, however, have investigated the subject afresh, and find that the umbilical vein anastomoses with the epigastric, not only in infants a few days old, but in those five and six months of age. In bodies of infants several days or months old they never failed to demonstrate the anastomoses between the branches of the epigastric and umbilical veins by means of Richardson's injecting medium (see London Medical Recorder, July, 1888, p. 274).

Retrograde Changes.—*Atrophy*.—A thinning of the wall of a vein may result from long-continued overdistention, or from a lessened function, as in the case of an amputation stump. As the result of such thinning of the vessel wall there may follow a dilatation of the lumen, formation of varices, insufficiency or rupture of the valves of the veins, or even rupture of the vessel itself. The atrophy may be confined to one venous system or may be universal. The latter occurs particularly in the case of extreme general venous congestion, as in chronic valvular lesions of the heart. A secondary atrophy of the walls of veins appears also as a frequent accompaniment or sequela of a variety of primary conditions affecting the veins, such as phlebitis, etc. Hypertrophy of the vein wall is usually followed by a secondary thinning, which may be associated with retrograde changes, such as fatty degeneration, hyaline change, calcification, etc. A secondary thinning of the vein wall is also of common occurrence in varices.

Fatty degeneration occurs in the intima of veins under the same conditions as in that of arteries (anæmia, intoxications, infections, etc.). In the intima of the affected vein there are seen whitish or yellowish spots or patches which are usually slightly elevated above the general surface of the intima. The degeneration is usually confined to the endothelium, and the affected cells are more easily scraped from their basement membrane than are the normal cells. In long-continued and severe intoxications, as in sepsis, chronic nephritis, icterus, pernicious anæmia, etc., extensive fatty degeneration may be found in the intima of the veins. Similar marked changes may also be found in very severe cases of certain of the acute infections, such as diphtheria and pneumonia, also in severe anæmia due to hemorrhage, and in poisoning with phosphorus, arsenic, etc.

Hyaline degeneration of the connective tissue of the walls of veins, while not so common as in the walls of arteries, is nevertheless of relatively frequent occurrence. The radicles of the portal vein are most often affected, but the process is common enough in the femoral veins and in the veins of the lower extremities. The spermatic and ovarian veins, and the veins of the broad ligament not infrequently show this change. It may be primary or follow secondarily upon a chronic phlebitis. The change may be diffused or localized. In the majority of cases it is the sequela of a fibroid thickening of the intima, the new connective tissue formed beneath the endothelium soon becoming hyaline in character (phlebosclerosis). Calcification and fatty degeneration may follow, but are much less common than in the case of the arteries. The portal radicles, hepatic veins, and the veins of the lower extremities are most frequently affected. When occurring primarily and not as a sequela of phlebitis, hyaline degeneration of the wall of veins is usually dependent upon a chronic intoxication, as in the case of syphilis. The media and adventitia are rarely involved. After thrombosis of a vein and subsequent organization of the thrombus the newly formed connective tissue replacing the thrombus may become hyaline in character. In extreme chronic passive congestion of the lungs (mitral stenosis) the pulmonary veins as well as the arteries may become greatly thickened and present a hyaline change of greater or less degree.

Calcification.—This is on the whole relatively rare in veins, and is usually localized to small areas. Only rarely are veins calcified throughout any considerable portion of their wall. The deposit of lime salts most frequently follows hyaline or fatty changes, or is a sequela of thrombophlebitis. In cases of chronic phlebitis true bone may sometimes be formed in the walls of veins. This event occurs particularly in the femoral and its branches and in the radicles of the portal vein. The writer has observed a number of cases of calcification of the femoral and saphenous veins following thrombophlebitis of these vessels. In two cases osteoid and true osseous tissues were found in the vein walls and in the adjacent tissues. Calcification of the portal vein is of not infrequent occurrence. Virchow, Spiegelberg, and others have described such cases. The lime salts are deposited in the form of thin laminæ, usually in the media of the vein, but at times also in the intima and adventitia. Evidences of a chronic pylephlebitis are usually present in the form of sclerotic changes, irregular thickenings of the wall, bridges of connective tissue crossing the lumen of the vein, etc. The mesenteric and splenic veins may show similar changes. In two cases of Banti's disease studied by the writer there was a marked stenosis of the portal vein with extensive sclerosis and calcification, involving chiefly the middle coat of the vessel. The irregular character of the vein wall, the roughened intima, and the strands of connective tissue crossing the lumen in one of the cases made it very probable that the stenosis and the accompanying sclerosis and calcification were the sequelæ of an old thrombopylephlebitis. In both cases the splenic and mesenteric veins and their radicles were greatly dilated and showed marked sclerotic changes. Deposits of lime salts were also present in the sclerotic walls of many of the smaller branches of the mesenteric veins. Several similar cases have been reported under various heads in the older literature. In connection with these cases the question arises if the symptom complex now known as splenic anæmia may not be secondary to portal obstruction due to various causes. Sclerosis and deposits of lime salts are not rare in the portal vein and its branches in the late stages of cases of hepatic cirrhosis. Calcification of the vein walls in other parts of the body is of rare occurrence, except in the case of local deposits at the site of calcified thrombi.

Amyloid change is much rarer in the veins than in the arteries, and is usually found in but slight degree. It is extensive only in the case of extreme general amyloidosis.

Progressive Changes.—*Hypertrophy* of all three coats of the vein wall with dilatation of the lumen occurs in athletes and in individuals accustomed to heavy labor. The degree of hypertrophy bears no constant relation to excessive muscular activity, and such an enlargement of the veins may be entirely absent in individuals in whom such conditions are present. It must, therefore, be assumed that some inherent peculiarity in the structure of the vein walls lies at the foundation of such hypertrophy. This view is further supported by the fact that individuals not given to marked muscular activity may also show such a venous hypertrophy. In the latter case the hypertrophy is usually congenital and often inherited, particularly from the paternal side. It is probable that such congenital hypertrophy of the veins is due to a primary weakening of the walls or to a lowered tension in the tissues surrounding the vessels. The loss of the aid given to the venous circulation by muscular activity may also play a part in the production of the condition.

A hypertrophic condition of the veins occurs also in the vessels taking part in the formation of a collateral circulation. In general it may be said that stagnation of the blood-flow in veins leads to a thickening of their walls. A general hypertrophy of the venous system may therefore be the result of a general venous stasis, as in the case of heart lesions without proper compensation. In mitral stenosis there is almost always a marked thickening of the walls of the pulmonary veins, and, in case the right ventricle is not compensating fully for the lesion, a similar thickening of the systemic veins also results. A local venous stagnation may give rise to a local venous hypertrophy. Such enlargement of the veins and thickening of their walls are frequently seen in the neighborhood of tumors. A secondary atrophy follows sooner or later in all cases.

The increase of thickness may involve all three coats, but often the muscularis is alone hypertrophic. At other times the intima may show the most thickening, and in other cases still the adventitia. In the case of collateral anastomoses, particularly in arterio-venous anastomoses and behind obstructions, the vein wall may show a very marked degree of thickening. In the majority of cases such hypertrophies are in reality connective-tissue hyperplasias due to chronic hyperplastic phlebitis. A true muscular hypertrophy and hyperplasia do occur, however. The new connective tissue formed in the vein wall is usually of the character of scar tissue. Secondary atrophy, contraction and thinning, in association with sclerotic changes, fatty degeneration, calcification, etc., follow the hypertrophy. The hyperplasia of the muscularis in the case of collateral anastomoses is to be regarded as purely compensatory in nature, though often associated with inflammatory changes. In all organs in which there has been for some time a condition of marked chronic congestion the number of large veins appears to be greatly increased. It is due to the fact that the walls of the smaller veins become thickened in proportion to the dilatation of the vessel lumen. In these cases the muscle does not become increased in amount, the thickening of the wall being due to a new formation of connective tissue which later becomes more or less hyaline in character.

INFLAMMATION. PHLEBITIS.—Inflammation is a much more common occurrence in the veins than in the arteries. Though analogous in structure to the latter, the walls of the veins are thinner and weaker, and their coats less sharply differentiated. For this reason it is hardly possible to separate inflammatory processes of the vein walls into endo-, meso-, and periphlebitis. In the great majority of cases all three coats are coincidently affected, the process extending quickly from the intima to the adventitia, or in the opposite direction, so that the entire vein wall becomes equally involved. A further and more important difference between the arteries and veins is the part played by the latter in inflammations of the tissues. In such conditions the arteries present no recognizable anatomical changes; the veins, on the other hand, present the phenomena of a marginal disposition of the leucocytes and diapedesis of the same. In purulent inflammations the smallest veins may become so involved that the elements of their walls suppurate or show signs of proliferation. Such changes should be included under phlebitis in a broad sense, but the term is usually restricted in its application to inflammatory processes involving the large veins.

According to Köster, phlebitis is to be regarded as a *lymphangitis* of the vein wall, the inflammatory process extending along the lymph spaces and lymph vessels with which the wall is richly supplied. The extension upward along the vein (*ascending phlebitis*) is due to an ascending lymphangitis. The vasa vasorum likewise play an important part in the extension of the process. The connection between peripheral lymphangitis and phlebitis is very close. In the case of infected wounds of the extremities the signs of an ascending lymphangitis precede those of phlebitis, the infection of the vein wall following that of the lymphatics.

In all cases of phlebitis in which the intima of the vein is damaged thrombosis results. The combination of thrombosis with phlebitis is known as *phlebothrombosis*, and is to be regarded as one of the most important features of the process. In the case of hæmatogenous infection (intravascular) the formation of a thrombus may constitute the first step of the process, the inflammation of the vein wall following upon this. In the case of periphlebitis (extravascular infection) the thrombosis follows the extension of the process to the intima. By some writers the term *thrombophlebitis* is applied to the first condition, *phlebothrombosis* to the second. This distinction is not commonly observed, however, and the term thrombophlebitis is used to designate both processes. Thrombosis may be associated with either acute or chronic phlebitis.

Etiology.—The infection of the vein may be either intra- or extravascular. In the first case the infection is either of metastatic or of cryptogenic origin. More frequently the vein is involved by an extension (lymphangitis) from neighboring suppurative processes. Infected wounds (trauma, operation, childbirth, etc.) form the most common causes of phlebitis. The primary infection may be of slight degree, or the infection may take place through uninjured tissues (hair follicle). Phlebitis due to infection following abortion or childbirth is of frequent occurrence. In the majority of the infectious diseases phlebitis occurs often, being due either to the direct action of the specific infectious agent, the intoxication, or to a secondary infection. In smallpox, typhoid fever, influenza, erysipelas, diphtheria, dysentery, scarlatina, pneumonia, and gonorrhœa phlebitis not infrequently occurs. In the milder infections, such as measles, it is a more rare complication. Chronic intoxications, syphilis, gout, alcoholism, etc., are regarded by some writers as causal agents in chronic phlebitis. Obliterating endophlebitis in particular has been ascribed to syphilis. By other writers the existence of a specific rheumatic or gouty (alcoholic) phlebitis is denied. Of the micro-organisms causing phlebitis, the streptococcus, staphylococcus, pneumococcus, gonococcus, typhoid bacillus, and the colon bacillus play the chief rôles.

Varieties.—As mentioned above, it is rarely possible in the acute forms of phlebitis to differentiate endo-, meso-, and periphlebitis. In chronic phlebitis such a classification is often possible, the chronic forms being more often confined to the inner and middle coats. According to the chief characteristics of the inflammatory process, there may be distinguished the following varieties of phlebitis:

Phlebitis.	Acuta (hæmatogenous or extravascular).	1. Exudativa. (a) Purulenta. (b) Suppurativa.	Phlebothrombosis or thrombophlebitis.
		2. Dissecans.	
		3. Productiva, s. adhæsiva, s. organisatoria.	
		4. Gangrænosa.	
	Chronica (hæmatogenous or extravascular).	1. Hyperplastica.	
		2. Atrophica.	
		3. Obliterans.	

Various other terms have been applied by different authors to designate especial features of given cases: *ascending phlebitis, diffuse phlebitis, universal phlebitis, panphlebitis*, etc. *Phlebitis circumscripta* is also applied to a localized phlebitis, more particularly to areas of localized inflammation in the walls of the cerebral sinuses.

Acute Phlebitis.—The vein wall may be infected from the blood (*hæmatogenous*) or from the tissues (*extravascular*). The latter occurrence is probably the more common.

(*a*) *Extravascular Origin.*—In this case the adventitia is first affected, and the early stages of the process appear as a purulent periphlebitis. The lymphatics and the small veins of the vessel wall become filled with leucocytes, and these may collect in such numbers as to give the process the character of a purulent infiltration of the vein wall (*phlebitis exudativa* or *purulenta*). Œdema and liquefaction of the elements of the wall may also take place as the process increases in severity (*phlebitis suppurativa*). Inasmuch as the connective-tissue sheath of the vein wall is very resistant the exudate collects beneath it and extends along the vessel for some distance, giving rise to other abscesses. In this way the vein may become surrounded by a mantle of pus, which may be so great as to separate the vessel from its neighboring tissues and lead to the complete necrosis of the elements of its wall. The media and intima are usually quickly involved by direct extension and also through the lymphatics and vasa vasorum. Ultimately the entire vessel wall may present a dense purulent infiltration; in some cases only traces of the original tissues of the wall can be made out. The thickness of the wall may become greatly increased.

ten to twelve times as great as normal; and the lumen of the vein may be obstructed or wholly obliterated as the result of the swelling alone. In large veins or in the case of a lesser degree of infiltration the intima may show circumscribed areas of bulging corresponding to the points of greatest infiltration. In addition to the swelling caused by the œdema and cellular exudate, hemorrhages of varying size may occur.

The elastic tissue of the media plays an important part in the extension of the infiltration toward the intima. The advancing exudate pushes the elastic fibres toward the intima, and finally breaks through them at the points of least resistance. The elastica interna remains preserved for the longest time, but finally gives way, and the exudate presses through the point of rupture. Finally, the elastic fibres become involved in the complete dissolution of the vein wall.

The damage to the intima results constantly in thrombosis. The thrombus thus formed may be obturating or parietal; in both cases it serves to prevent further entrance of the exudate into the lumen of the vein. In the formation of the thrombus the elements of the blood circulating through the vein may take part, or, as affirmed by Köster and others, the *intravasation* of red and white cells and fibrinogen-containing exudate from the affected wall into the vessel lumen may aid in the formation of the thrombus, or be alone concerned in its production. The inflammation of the vessel wall is, therefore, the primary process, the thrombosis the secondary, the entire process being regarded as analogous to the formation of exudates upon serous membranes, the exudate containing red blood cells, blood plates, leucocytes, fibrinogen, etc., these being poured out from the vasa vasorum over the intima of the affected portion of the vessel. With the formation of the thrombus upon the intima the process may be appropriately designated phlebothrombosis (*phlebothrombosis purulenta*). By Hunter it was termed *phlebitis pseudomembranacea*. By the majority of writers no distinction is made between thrombophlebitis and phlebothrombosis, but by others the distinction as given above is favored. Inasmuch as the thrombosis is in one case the primary process and in the other a secondary, it would seem well to retain the distinction.

The œdema and infiltration of the coats of the affected vein may lead to their separation from each other (*phlebitis dissecans*). In the case of an involvement of a vein in a gangrenous process the phlebitis may also assume a gangrenous character (*phlebitis gangrænosa*). With the advent of thrombosis and the partial or complete obturation of the vessel on the one hand and the cessation of the inflammation on the other, organization of the thrombus may take place (*phlebitis productiva, s. adhæsiva, s. organisatoria*) and healing may result. The sequelæ of such healing may be thickening of the vessel wall, obliteration of the lumen, formation of connective-tissue bridges, calcification, etc. During the healing process or subsequently thereto a regeneration of elastic fibres may take place, and newly formed fibres may also be found in the organized thrombus.

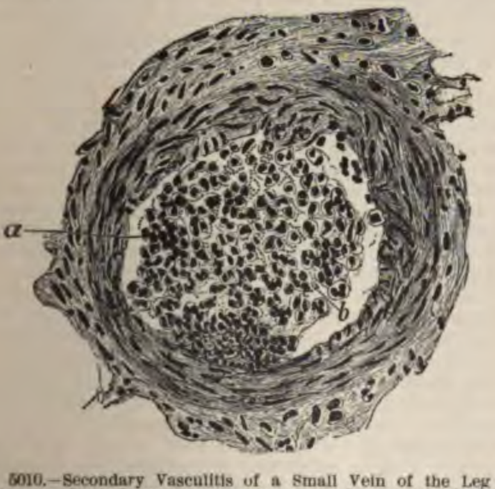

FIG. 5010.—Secondary Vasculitis of a Small Vein of the Leg in Phlegmon due to Streptococcus pyogenes. *a*, Leucocytes; *b*, Streptococci. (After Welchselbaum.)

(*b*) *Hæmatogenous Origin.*—The phlebitis caused by intravascular excitants of inflammation runs a different course. There is usually a primary thrombosis followed by a secondary inflammation. As a result of changes produced in the intima of the vein by toxins, or by the direct action of bacteria, or by the direct action of heat, freezing, trauma, etc., there results a thrombosis. If micro-organisms capable of exciting suppuration are not present in the thrombus (so-called benign thrombus), the only effect upon the vein wall is the slight reactive inflammation caused by the presence of a foreign body. Organization of the thrombus takes place, and it is replaced by newly formed connective tissue and blood-vessels (*phlebitis productiva, s. adhæsiva, s. organisatoria*). The sequelæ of calcification, obliteration of the lumen by connective tissue, thickening of the vessel wall, formation of connective-tissue bridges, etc., likewise occur in this connection. Irregular dilatations and stenoses of the affected vein result; the newly formed connective tissue in its lumen may become channelled by new vessels, and the circulation partly or wholly re-established. As the result of such changes the vein may come to have a structure suggesting that of the longitudinal sinus of the dura mater. (Fig. 5011.)

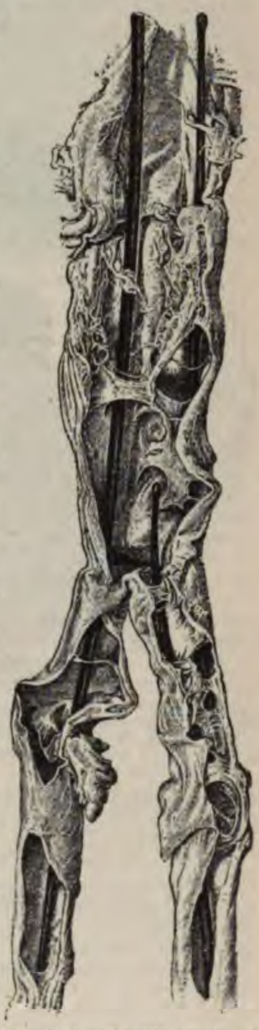

FIG. 5011.—Changes Produced in the Inferior Vena Cava and Iliac Veins by the Organization and Contraction of a Thrombus Resulting from the Involvement of the Vessels by a Retroperitoneal Abscess. The irregularities of the intima and the connective-tissue bridges crossing the lumen cause the vessel to resemble the superior longitudinal sinus. (After Schrötter.)

Much more unfavorable is the course if the original thrombus contains pyogenic micro-organisms capable of multiplication. These exert their characteristic effects upon the intima and upon the elements of the thrombus; necrosis, liquefaction, and infiltration of the vein wall follow, the process extending outward toward the adventitia (*thrombophlebitis purulenta s. suppurativa*). The infection of the lymphatics and blood-vessels of the vein wall leads to a further extension of the process, and the surrounding tissues become secondarily involved. The thrombus and the entire vein wall at the seat of infection may be completely destroyed by the suppurative process. Healing and organization may take place; but in the majority of cases the softening of the thrombus leads to embolism of infected material, and the suppurative process repeats itself at the site of lodgment of the emboli.

The presence of pyogenic organisms in the circulation leads to a general pyæmia which is frequently fatal. In the pre-aseptic days this form of phlebitis was much more common than the secondary phlebothrombosis, but it is now relatively more rare. Childbirth, abortion, infected wounds from trauma or operation, malignant endocarditis, acute infections, and secondary infections following the acute infectious diseases are most often followed by hæmatogenous phlebitis. Cryptogenic infections are also common. In the case of infection by certain organisms the phlebitis may assume a gangrenous character (*thrombophlebitis gangrænosa*). This is more rare than in the case of an infection of the vein from the tissues.

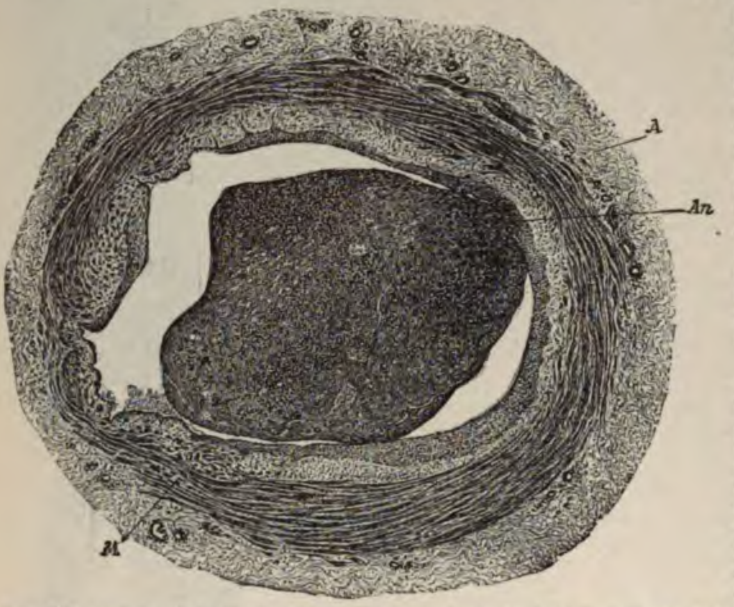

FIG. 5012.—Chronic Phlebitis, with Beginning Organization of the Thrombus. *A*, Adventitia: *M*, Media: *An*, thickened intima at point of attachment of organizing thrombus. (After Schrötter.)

Should organization of the thrombus and healing of the phlebitis occur the process assumes the character of a *thrombophlebitis organisatoria*. An *acute productive phlebitis* (*phlebitis prolifera*) without thrombosis may be associated with inflammatory processes in the neighborhood of the affected vessel, as shown by a fibroblastic thickening of the vein wall, dilatation, and thickening of the vasa vasorum, etc. It is also possible that similar changes may be of hæmatogenous origin.

Chronic Phlebitis.—The processes of organization, repair, etc., following an acute phlebitis are often regarded as of the nature of a chronic phlebitis. They are more properly sequelæ. A true chronic phlebitis, however, occurs as the result of chronic inflammations in the neighborhood of veins, and possibly also as a result of chronic intoxications. In hepatic cirrhosis the branches of the hepatic veins usually show chronic inflammatory changes. The veins in the neighborhood of chronic ulcers or abscesses, chronic tuberculous or actinomycotic foci usually show marked changes of the nature of a chronic inflammation. These are characterized by a connective-tissue thickening of the vein wall (*phlebitis hyperplastica*), enlargement of the vasa vasorum, and thickening of their walls, and either a dilatation or stenosis of the vessel lumen. The thickening of the vessel wall may depend to some extent upon a chronic infiltration. Secondary thinning of the wall frequently follows (*phlebitis atrophica*). By many writers varices are regarded as a sequela of chronic phlebitis. Sclerotic changes or calcification may also occur. Thrombosis may or may not be associated with the process. The organization of the thrombus or the proliferation of the intima may lead to an obliteration of the vein at the affected point (*phlebitis obliterans*). (Fig. 5012.)

An *endophlebitis obliterans* (*endophlebitis prolifera*) occurs coincidently with or under the same conditions as endarteritis obliterans. As a result of the proliferation of the intima the lumen is partially or completely filled with a newly formed connective tissue, often resembling myxomatous tissue, and containing numerous new blood-vessels, giving it a certain amount of vascularization. In the majority of cases the condition may be ascribed to syphilis, but similar changes may follow the ligation of veins, thrombosis, and possibly various chronic intoxications. The veins of the lower extremities, the portal radicles, and the branches of the hepatic veins appear to be the most frequently affected. In three cases described by Chiari the proliferation of the intima of the hepatic veins led to a marked stenosis of their lumen, in some vessels even to a complete obliteration, as a result of which secondary changes occurred in the liver, accompanied by overdistention of the portal vein and ascites. Death took place from thrombosis of the obstructed veins. Chiari regarded syphilis as the most probable causal factor in these cases.

Symptoms.—Phlebitis may occur without any individual signs or symptoms; or these may be obscured by the general symptoms of the primary disease. Particularly in the case of the deeply lying veins may symptoms be absent, and the condition may become evident only through the occurrence of thrombosis or of other sequelæ. In acute phlebitis there is usually an irregular fever, which at times may reach a high degree. The course of the vein, if superficial, may be revealed by the presence of a dark blue, or reddish, thick cord, which is very tender on pressure. In the event of thrombosis the cord becomes more firm and hard. If the surrounding tissues are markedly œdematous and infiltrated it may not be possible to feel the vein. Pressure over deep-seated veins is also painful. The pain is also spontaneous, not only along the course of the vein, but also in its neighborhood. An œdematous swelling of the vein or of the tissues surrounding a vein does not necessarily indicate a phlebitis, as the condition may result from a non-infected thrombus. The distention of the superficial veins may in both cases be regarded as evidence of the establishment of a collateral circulation. The symptoms of chronic phlebitis are in general similar to those of the acute, but are less severe. Acute exacerbations are common in the infected cases, the symptoms being those of an acute phlebitis. In the case of superficial vessels the thickening remains permanent, while the redness and tenderness disappear. The development of the collateral circulation is usually more pronounced, and the distention of the superficial vessels lasting in the case of chronic phlebitis.

It must be noted, however, that the symptoms of phlebitis may vary greatly in different cases, according to the cause, location, sequelæ, and the nature of the general or local disease with which it is usually associated.

Diagnosis.—From the above it is clear that the diagnosis of phlebitis is often not possible, the condition being completely concealed under the symptoms of the primary or accompanying disease, the two forming a symptom complex usually designated as *cryptogenic septicopyæmia*. The diagnosis is, however, easy in many cases, particularly when superficial veins are involved. The differentiation between phlebitis with secondary thrombosis (phlebothrombosis) and thrombosis with secondary phlebitis (thrombophlebitis) is in the majority of cases impossible. Neither the nature of the primary affection, the character of the fever or pain, nor the late appearance of the symptoms in the course of another disease can be used as differential points. Both thrombosis and phlebitis may occur late in an infectious disease, even during convalescence. The persistence in the body of virulent bacteria may lead to phlebitis and thrombosis long after the original attack of the disease.

Occurrence.—The veins of the lower extremities are most frequently affected. The reasons for this are largely anatomical, these veins being more likely to suffer from stasis and consequent dilatations. Trauma with infection is also of frequent occurrence in this region. Varicose ulcers of the legs very often lead to phlebitis of the *saphenous veins.* The *venæ spermaticæ* and *uterinæ* may become infected after abortion or childbirth. Retention of the placenta leads frequently to an infection of the *uterine veins.* The thrombophlebitis beginning in these vessels may extend to the *vena cava* or the *femoral vein* (phlegmasia alba dolens). The *femoral vein* itself is very often affected primarily in the acute infections and in marasmic conditions. Phlebitis of the *hæmorrhoidal* and *vesical veins* follows cystitis, prostatitis, gonorrhœal infections, rectal and perirectal abscesses. Infection through hemorrhoids themselves is also common. In all of these cases the colon bacillus doubtless plays an important rôle. Phlebitis of the *mesenteric veins* and *pylephlebitis* occur in connection withdy sentery, perityphlitis, and other inflammatory conditions of the intestines. In infections of the umbilical cord in the new-born the *umbilical vein* usually presents the picture of a thrombophlebitis purulenta which may extend into the vessels of the liver and into the portal veins. The *veins of the upper extremities* are less frequently the seat of a phlebitis, but show the condition often enough. Infected wounds of the hands and boils are the most common sources of infection. Cryptogenic infection through an uninjured hair follicle may take place. Venesection was formerly the most common cause of phlebitis of the upper extremities. The *meningeal veins, sinuses,* and the *veins of the diploë* are very frequently the seat of phlebitis. Infected wounds of the head, mastoid or middle-ear disease, caries of the petrous bone, etc., give rise to thrombophlebitis of these vessels and further to meningitis and encephalitis. The *internal jugular* may ultimately be affected. The *sinus sigmoideus* plays an important rôle in the extension of infections from the ear. Phlebitis of the meningeal veins and sinus thrombosis may also follow infections through the orbital or nasal cavities. In rare cases carious teeth may be the primary lesion from which sinus thrombosis ultimately results. Phlebitis of the *pulmonary veins* may result from septic infarcts, abscesses, gangrene, and other inflammatory conditions of the lungs. In osteomyelitis the *veins of the bone marrow* present the picture of thrombophlebitis.

Sequelæ.—The most favorable sequela of thrombophlebitis or phlebothrombosis is the organization of the thrombus and the partial or complete obliteration of the affected vessel with the development of an adequate collateral circulation. Embolism of infective material from the primary focus in purulent phlebitis is the most unfavorable sequela. Such an embolism may be direct, retrograde, or paradoxical. In general, it may be assumed that from every phlebitic focus portions of material are set free into the venous circulation. If these contain pyogenic bacteria the emboli given off may cause an endocarditis of the right side of the heart, septic infarcts and abscesses of the lungs; or they may pass through the pulmonary capillaries and give rise to a mitral or an aortic endocarditis, or to pyæmic abscesses throughout the arterial system. Phlebitis in the regions tributary to the superior vena cava may give rise to liver infarcts and abscesses through retrograde embolism. Phlebitis of the pulmonary veins in particular leads to the production of embolic infarcts and abscesses throughout the general circulation, especially of the brain, spleen, and kidneys. Pylephlebitis may lead to infarcts and abscesses of the liver and lungs. In general the sequelæ of thrombophlebitis depend upon the location of the vein, the character and extent of the thrombosis, the presence of bacteria and the variety of the same, the possibilities of embolism, and the vital importance of the affected organs.

Prognosis.—This depends upon the size and location of the affected vein, the bland or infectious nature of the process, the occurrence of embolism, and the importance of the affected organ. In the less severe cases of phlebitis of the lower extremities the prognosis is relatively favorable, even in the case of pulmonary embolism, since the emboli are likely to be of small size. The more severe cases with marked œdema of the extremity (*phlegmasia alba dolens*), in which the principal veins are affected, are very dangerous because of the possibility of emboli of large size or the growth of the thrombus into the vena cava. Sudden death from pulmonary embolism may occur. The etiological factors in phebitis of the larger veins are in themselves of grave significance. The prognosis in the septic cases is always grave because of the possibility of embolism and the occurrence of general pyæmia and septicæmia. The persistence of fever is the most important indication to be followed. As long as there is a daily rise of temperature the danger of fresh thrombosis and embolism or of an extension of the phlebitis is present.

Treatment.—The old methods of treatment with mercurial ointments, iodine, etc., have been entirely abandoned. The local massage employed in their administration made their application a source of danger.

Prophylaxis is of prime importance. Asepsis or antisepsis at all times is the chief means by which the complication of phlebitis and its attendant thrombosis may be avoided. A small boil or even the slightest infected scratch may lead to a dangerous phlebitis. The pernicious habit of "paring corns" with domestic instruments is also a source of infection, which may sometimes run a dangerous and fatal course. The puerperium is obviously a time when modern aseptic precautions should be carefully observed. Abortion with retention of placental fragments is likewise of the greatest danger. Infection through carious teeth should be avoided by prompt attention to the condition. Mastoid and middle-ear disease should receive proper operative treatment. As a result of modern prophylactic measures the dictum of Cruveilhier that "la phlébite domine toute la pathologie" no longer applies. With the almost universal adoption of aseptic and antiseptic measures, pyæmia and puerperal sepsis have become much less frequent, and thrombophlebitis in consequence is a much more rare complication.

In the case of an established thrombophlebitis the most important indication is the avoidance of embolism by means of absolute rest until no doubt exists as to the subsidence of the process and the complete organization of the thrombus, and the establishment of the collateral circulation. This is particularly the case in thrombophlebitis of the extremities, especially the lower ones. Elevation and fixation of the affected limb may be of service in promoting the return flow from the obstructed area. In the event of severe pain the application of cold, etc., may be useful. The dangers of embolism and the results of moving the limb should be thoroughly impressed upon the patient.

Many cases of phlebitis are now treated surgically. The opening and drainage of periphlebitic abscesses should be carried out as soon as possible. Ligation of the efferent veins, exposure of the affected vein with direct antiseptic treatment of the same, or resection of the diseased portion, etc., are recent operations performed with great success. In the case of mastoid and middle-ear disease with extension to the meninges and sinus thrombosis the jugular may be ligated. As the result of these operations the duration of the process is shortened, the dangers of embolism are removed, and recurrences rendered impossible. The more severe the case the greater the indications for such operative interference.

The local and general conditions should receive appropriate treatment also. Septic and pyæmic conditions should be treated according to the conditions.

WOUNDS OF VEINS.—*Ruptures, lacerations, bruises,* and *erosions* of veins are of common occurrence. They take place much more frequently in the case of small veins than in the case of the arteries. Aside from direct trauma, an increase of intravenous pressure plays the most important part in the rupture of veins. Hemorrhage from the conjunctival veins may result from spasmodic coughing and vomiting. The same cause may lead to rupture of small veins in the mucosa of the larynx and trachea. The veins of a collateral circulation frequently burst, particularly in the case of œsophageal varices in hepatic cirrhosis. The pressure of a tumor or aneurism upon the great cervical veins may lead to a rupture of the meningeal veins. Ruptures of the veins of the lower extremities are of frequent occurrence. Increase of pressure, fatty degeneration of the vein wall, etc., are causal factors. Rupture of varices and hemorrhoids occurs very frequently. Intense cramps of the muscles of the calf may cause the rupture of small veins. In a case reported by Frerichs fatty degeneration of the wall of the portal vein led to the rupture of this vessel. Rupture of the superior and inferior venæ cavæ may be caused by falls, crushing of the body, etc. A fall upon the head may cause a rupture of a cerebral sinus even without external signs of injury. Bullet wounds of all kinds may occur in the veins in any part of the body. The wound may be caused by the direct action of the projectile or by pieces of bone. Cases have been reported in which the bullet remained embedded in the vein wall.

The sequelæ of such injuries are hemorrrhage into the tissues or body cavities (hæmothorax, hæmatopericardium, etc.), hæmatoma formation, thrombosis at the point of injury, healing, and the formation of a collateral circulation. If the artery is injured at the same time with the vein an *anastomosis arterio-venosa* may be formed. Embolism of air or of portions of the thrombus may also follow. The aspiration of air into the veins is particularly likely to happen in injuries of the veins of the neck, but is seen more rarely in the case of injuries of the veins of the extremities, uterus, head, and possibly through the veins of the stomach in the case of erosions, ulcerations, etc. Repeated small hemorrhages from hemorrhoids or eroded varices may give rise to the severest grades of anæmia. In the case of the loss of large quantities of blood on a single occasion, death may follow immediately or later, as the result of fatty degeneration of the heart and other organs. In the case of injury of the large veins death usually follows at once from the large amount of blood lost, but even in these cases spontaneous recovery may take place. Surgical interference reduces greatly the mortality in these cases. Ligation of the jugular, innominate, axillary, and femoral veins, as well as of the inferior vena cava, has been successfully performed, and a collateral circulation established. Successful healing has also followed the suturing and resection of the femoral and the vena cava.

The treatment of rupture of veins is chiefly surgical. Compression, clamping, ligaturing, and suturing are resorted to according to the conditions. Even in the case of hemorrhage into the body cavities (pericardium, etc.) the bleeding veins may be found and successfully ligatured. In some cases ligature of the corresponding artery may be necessary to subdue the hemorrhage. The occurrence of after-hemorrhage should always be anticipated. General principles of absolute rest, proper position, etc., should also be applied according to the indications.

Perforation of the veins occurs in the case of aneurism, abscess, tuberculosis, actinomycosis, and new growths. Abscesses of the liver may rupture into the inferior vena cava. Erosions are of importance particularly in the case of the stomach veins; in cirrhosis of the liver, splenic anæmia, stenosis of the portal vein, etc., fatal hemorrhage may follow the erosion of the greatly dilated branches of the coronary or œsophageal veins.

THROMBOSIS.—Thrombosis of veins is of very common occurrence. In general the causes are: Changes in the vessel wall (phlebitis, intoxications, etc.); changes in the lumen (phlebectasias, varices, obstruction, etc.); changes in the composition of the blood (intoxications, anæmia, cachexia, hydræmia, presence of agents causing coagulation, etc.); changes in the blood current (stagnation, retrograde currents, etc.).

According to their location venous thrombi may be divided into *parietal* and *valvular.* A thrombus completely obstructing the vein is called an *obturating* thrombus. Parietal and valvular thrombi are found particularly in the veins of the extremities; obturating thrombi in the uterine, vesical, and hemorrhoidal veins, in the pampiniform plexus and in the dural sinuses. An *autochthonous* thrombus is one arising at the place in which it is found. A thrombus may, however, originate in the saphenous or the femoral, and growing upward by continued accretions finally reach the right heart. This process is spoken of as a *progressive* or *continued* thrombosis.

According to their structure venous thrombi may be divided into *white, red, mixed,* and *laminated.* The red ones are composed chiefly of red cells, and are formed as the result of the stasis of the venous flow. The white or gray thrombi are composed of blood plates, fibrin, or leucocytes, or contain these elements in varying proportions. They are formed during the circulation of the venous blood, and represent substances which are thrown out of the blood. In the case of alternating rates of current the thrombus may be formed of alternate layers of white and red clot (*laminated thrombus*), or the white and red portions may be mixed in varying proportions.

Venous thrombi may undergo simple, purulent, or gangrenous softening, organization, and calcification, or the elements of the thrombus may be loosened from their attachment to the vein wall and be carried away as emboli. Simple softening without embolism, organization, and calcification are the most favorable terminations of thrombosis; purulent and gangrenous softening the most unfavorable. The last two are due to infection, either hæmatogenous or extravascular. Embolism of portions of the thrombus is of importance according to the size of the transported material, and its origin from a bland or infected thrombus. Bland emboli may, if large enough, cause immediate death through obstruction of the pulmonary artery; when smaller they may obstruct the smaller branches of the pulmonary arteries and cause disturbances of the pulmonary circulation (*hemorrhagic infarction*). The embolism may, however, be without effect if the collateral circulation is adequate, as is usually the case in the normal lung. The production of a hemorrhagic infarct of the lung is therefore dependent upon the size of the embolus and the condition of the pulmonary circulation. If the emboli are infective, metastatic abscesses and gangrenous processes are set up at the point of lodgment. The occurrence of multiple infected emboli gives rise to the picture of pyæmia. The larger infected emboli arising from venous thrombi find lodgment in the pulmonary circulation, but the bacteria arising from such thrombi may pass through the lungs and give rise to pyæmic abscesses in the spleen, kidneys, heart, etc. Fortunately, pyæmia is not to-day such a common condition as it was a generation ago. Thrombophlebitis of the uterine veins after abortion or childbirth is the most common source of pulmonary emboli. The diagnosis, prognosis, and treatment is the same as that discussed under phlebitis. (See also *Thrombosis.*)

PHLEBOLITHS.—As the result of the calcification of venous thrombi there arise the so-called *vein stones* or *phleboliths.* They usually lie free in saccular dilatations or in varices. Through rotation the calcified mass becomes rounded and smooth. They are found most frequently in the splenic veins, in the hemorrhoidal, vesical, and pampiniform plexuses. Adherent and partly organized thrombi may undergo calcification and appear as calcified masses in the vein wall.

AIR EMBOLISM.—This subject is discussed elsewhere. It is only necessary in this connection to mention general facts. Aspiration of air into the veins occurs particularly in the case of wounds of the veins of the neck and upper extremities, but may take place also through the veins of the head, uterus, and stomach. Small amounts entering the venous blood are absorbed, but in the case of the aspiration of larger amounts, the air collects in the right ventricle and pulmonary artery, forming a foamy mass which the contractions of the ventricle are unable to drive onward, and death ensues from stoppage of the circulation. Opinions differ as to the amount of air which must be aspirated in order to bring about a fatal termination. It is probable that the amount varies; the fatal termination depending in part at least upon other factors.

Phlebosclerosis.—Sclerosis of the veins is a common process, but does not occur to the same extent or with the same frequency as arteriosclerosis. It may involve the entire venous system, or be confined to certain veins or even to portions of these. We may therefore distinguish a *diffuse*, *local*, and *nodal* phlebosclerosis. The changes are rarely so marked as to be distinguishable with the naked eye as is the case in the arteries. Microscopically the process is characterized by a subendothelial formation of connective tissue, which assumes a hyaline character, but undergoes fatty degeneration and calcification much more rarely than is the case in the arteries. In extreme cases a partial or complete obstruction of the vessel lumen may result. These cases are usually secondary to a chronic obliterating phlebitis. Many writers speak of a *primary* and a *secondary phlebosclerosis*, but such a classification is hardly practical, as it is not possible to differentiate between a sclerosis following a phlebitis and one arising primarily.

In the great majority of cases phlebosclerosis is the result of a previous phlebitis, either acute or chronic. In a certain proportion of cases, however, the hyaline thickening of the vein wall may be of a compensatory nature, the new formation of connective tissue and elastic fibres in the intima and media serving to compensate for a weakening of the vessel through loss of its elasticity. Such a weakening of the wall may be congenital, or acquired as the result of a chronic venous stasis following cardiac and pulmonary affections, chronic intoxications, cachectic conditions, etc. Statistics show that the veins of the lower extremities most frequently show a condition of sclerosis, those of the upper extremities next, the venæ cavæ following next in order. The portal, mesenteric, and splenic veins occasionally present a marked degree of sclerosis, which is sometimes associated with extensive calcification and fatty change. The changes may be so marked as to be plainly visible to the naked eye; the smaller branches of these veins may appear like sclerotic arteries. The condition is probably secondary to an old thrombopylephlebitis, but may be caused by an increase of portal pressure due to hepatic disease or portal stenosis. Chronic intoxication may also play a causal rôle. Such sclerosis of these vessels occurs in splenic anæmia and hepatic cirrhosis. Phlebosclerosis usually bears no relation to arteriosclerosis; the latter may exist in an extreme degree without the occurrence of changes in the veins. On the other hand, extensive phlebosclerosis may be seen involving a large portion of the venous system without corresponding changes in the arteries. Phlebosclerosis presents no recognizable clinical symptoms by which it can be diagnosed with certainty. In the case of the superficial veins the condition may be revealed by the presence of thicker and more rigid vessels. In such cases it is necessary to determine whether these appearances are transitory (phlebitis) or are permanent.

Stenosis and Obstruction of Veins.—The lumen of veins may be narrowed or wholly obstructed by compression from without, by diseased conditions of the vein wall, by anomalies of the vein contents, or by combinations of these factors. On account of the thinness and relatively slight elasticity of the walls of veins, particularly of the large veins, the lumen is easily influenced by pressure from without. Such pressure may be due to tumors, aneurisms, abscesses, inflammatory infiltrations, tuberculous processes, gummata, actinomycotic nodules, etc. The contraction of scar tissue in the neighborhood of a vein may likewise affect its lumen. In exudative phlebitis the thickening of the wall due to the inflammatory infiltration may be so great as partially or completely to obstruct the vessel. Sclerosis, calcification, and the thickening of the wall due to chronic phlebitis, may also lead to stenosis or to obliteration of the lumen. Thrombosis is the most common cause of venous stenosis and obstruction. Parietal thrombi lead to stenosis; obturating thrombi to complete obliteration of the lumen. As the result of the organization of thrombi the lumen of veins may be partly obstructed by diffuse or local thickenings of the wall, by connective-tissue bridges, etc. Phleboliths also cause a more or less complete obstruction of that portion of the vein in which they are found. The invasion of the lumen by sarcoma or carcinoma may also lead to the blocking of a vein by tumor masses growing within the vessel. Combinations of these different factors may also occur.

As the result of such obstruction or stenosis the region tributary to the affected vein becomes hyperæmic or cyanotic if the collateral circulation is not perfectly established. If the obstructed vein is a chief vein and the collateral anastomoses are poorly developed, œdema and effusions into the body cavities result. Hypertrophies, chronic inflammations, hemorrhages, and thrombosis also occur in the area of stagnation. The lowered nutrition and diminished resistance of the tissues in such an area predisposes to the occurrence of gangrene.

Stenosis of the superior vena cava may be caused by aneurisms, tumors of the mediastinum, lungs, thyroid, thymus, cervical glands, tuberculosis and actinomycosis of the bronchial glands, gummata, and scars of old tuberculous, syphilitic, and actinomycotic processes. The condition is revealed by the intense cyanosis and œdema of the head and upper extremities, and by the ectasia of the superficial veins. The innominate, vena azygos, inferior vena cava, common iliac, and femoral veins may also become stenosed or obstructed. In all these cases the diagnosis is dependent upon the location of œdema, cyanosis, hemorrhage, and other symptoms due to venous stagnation. The prognosis is more unfavorable in the case of obstruction of the superior vena cava than of the inferior. Cerebral symptoms soon appear in the former case, and dangerous effusions into the pleural and pericardial sacs may occur. In general the prognosis depends upon the nature of the accompanying condition, the rapidity with which the obstruction takes place, and the possibility of the formation of a collateral circulation. The working capacity of the heart is also an important factor. The treatment must be directed to the causal factor as well as to the condition itself. Tumors, aneurism, etc., must be treated according to the indications. In all cases the strength of the heart must be maintained. Venesection may give temporary relief from cerebral symptoms in obstruction of the superior cava. The treatment in the case of obstruction of the inferior cava is more favorable; rest, proper position of the extremities, bandaging, etc., may add much to the patient's comfort. In the case of portal vein obstruction Talma's operation may be attempted. Through new blood-vessels formed in the adhesions set up between the diaphragm, abdominal wall and the liver, spleen, and omentum, the portal stagnation may be relieved to such an extent that ascites is no longer produced.

Phlebectasias and Varices.—Diffuse dilatations of the veins are known as phlebectasias; local or partial dilatations as varices. Phlebectasias are due to a thinning of the vein wall caused by stretching; inflammatory changes in the wall follow secondarily. Varices are due to primary changes in the wall, usually of the nature of a phlebitis which results in a local weakening of the wall. Phlebectasias are cylindrical, serpentine, or cirsoid; varices are saccular, nodular, or bell-shaped. The different forms may pass into each other. The nodular varices may reach the size of a hen's egg. The walls of ectatic veins are at first thin and atrophic, but after a time there develops a productive phlebitis which leads to a connective-tissue hyperplasia and sclerotic changes with atrophy of the muscle and elastic fibres. Occasionally the latter become increased. The vasa vasorum are dilated and show greatly thickened walls. The lumen of the vein may finally become partly or wholly obliterated. In the walls of old phlebectasias there is not infrequently a deposit of lime salts. Large amounts of blood pigment may also be found in the wall as the result of hemorrhages. Thrombosis is of common occurrence in the saccular varices; through the calcification of the thrombi there arise phleboliths. The pressure of varicose portions of a vein when lying close together may lead to a pressure atrophy and confluence of the neighboring parts (*varix anastomoticus*). In this way a tumor-like formation composed of communicating cavernous blood spaces may be formed. In the true varix an increase in the length of the affected veins may sometimes occur. The saccular dilatations offer conditions favorable to thrombosis, and the impregnation of the thrombi with lime salts results in the formation of phleboliths.

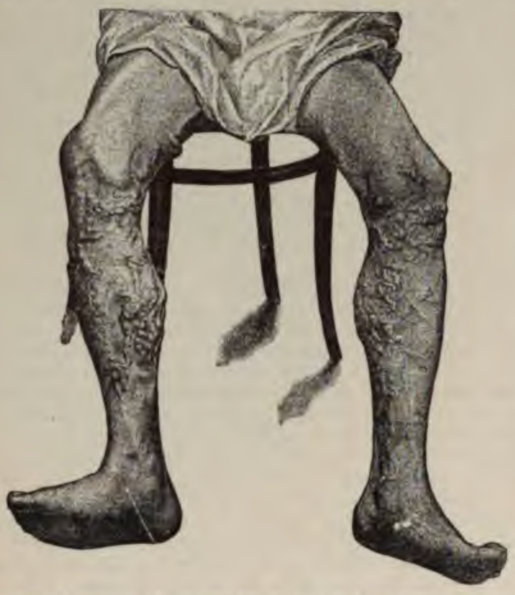

FIG. 5013.—Varices of Veins of Legs in a Man Aged Fifty-four Years, Otherwise Healthy. (After Schrötter.)

The chief etiological factor in the case of both phlebectasias and varices is to be found in a general or local disturbance of the circulation leading to an increase of venous pressure and hindering the return flow of the venous blood. A general venous stasis may be caused by cardiac weakness, valvular lesions, diseases of the lungs leading to an obstruction of the pulmonary circulation, loss of the aid to the venous circulation through the lessening of the negative pressure in the thorax, effects of gravity, etc. A local venous stasis may result from the pressure of an aneurism, tumor, gravid uterus, enlarged lymph glands, or from the obstruction of the vein by a ligature, thrombosis, obliterating phlebitis, intravascular growth of tumor cells, constricting bands of scar tissue, tight belts, garters, bandages, etc.; or through inherent weakness of the vein wall (congenital varix), excessive muscular activity, loss of tension in the tissues surrounding the vein, influence of gravity, etc. Stasis in the portal vein is usually secondary to diseases of the liver. The overloaded rectum in cases of chronic constipation may likewise cause an obstruction to the venous flow in its neighborhood. The influence of gravity is shown particularly in the case of varices of the lower extremities. In individuals who habitually stand upright without adequate muscular movements of the lower limbs, especially in long-limbed individuals, varices of the veins of the leg are of very common occurrence. The saphena magna and its branches are most frequently affected. The aid given to the venous circulation by the intermittent pressure exerted upon the veins by the contractions of the muscles is in such cases but slight; through the influence of gravity the veins become dilated, their valves become relatively insufficient, and the vein walls, unable to support the long column of blood in the vena cava, become stretched. Veins which have been dilated for some time do not regain their old calibre. The valves retain their original size, though an increase in the tissues of the walls is necessary to the enlargement of the lumen. Heredity is a factor of some importance in the etiology of phlebectasias and varices. In just what lies the weakness of the vessel wall is not yet known. The state of the tension of the surrounding tissues is also an important factor.

Phlebectasias are most common in the veins of the hemorrhoidal plexus, the spermatic veins, pampiniform and pudendal plexuses, the utero-vaginal and vesical veins, the tributaries of the portal vein, the veins of the lower extremities, etc. Dilatations are of less frequent occurrence in the veins of the œsophagus, pharynx, meninges, brain, and uterus wall. They are of rare occurrence in the veins of the upper extremities. *Hemorrhoids* are the most frequent form of phlebectasias. The knots and convolutions of dilated veins may lie above the anus (internal hemorrhoids) or project from it (external hemorrhoids). Aside from the general etiological factors mentioned above, hemorrhoids may be caused by catarrhal inflammations of the mucosa of the rectum due to constipation. The extension of the inflammation to the vein walls leads to a dilatation of the lumen and a thinning of the wall. The collateral anastomoses of the hemorrhoidal veins make them subject to the influence of stasis in either the portal system or that of the vena cava. Hepatic cirrhosis is therefore associated with more or less extensive formation of hemorrhoids. The dilatations of the œsophageal veins in cases of portal stasis are also styled hemorrhoids (*œsophageal hemorrhoids*). The dilatations of the veins along the spermatic cord are known as varicocele; those of the veins of the abdominal wall in the neighborhood of the umbilicus in the collateral anastomosis of portal stasis are designated the "*caput Medusæ.*" In the development of such a collateral circulation the veins of the œsophagus, the hypogastric, spermatic, inferior epigastric, internal mammary, and intercostal veins, the veins of the kidney capsule, the azygos veins, and the small branches in the suspensory ligament of the liver may become ectatic.

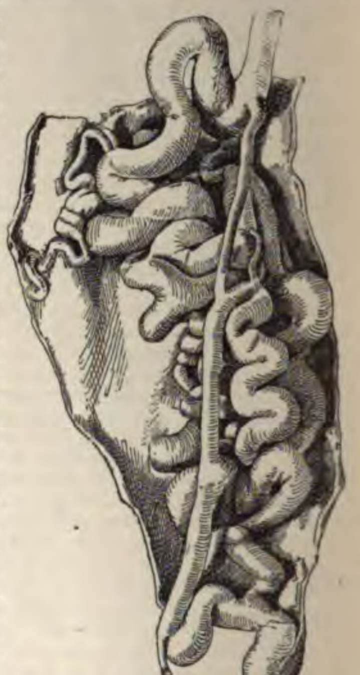

FIG. 5014.—Varices from Leg. (After Ziegler.)

The sequelæ of varix formation are of great importance. Rupture of the dilated veins is of common occurrence. This occurs most often in the case of hemorrhoids. Fatal hemorrhage may follow, or as the result of repeated small hemorrhages the most severe types of anæmia may be produced. Varices of the œsophagus, stomach, and spleen may give rise to fatal hemorrhage or to severe anæmia. Death may follow the rupture of a varix in the brain or meninges. Next to rupture and hemorrhage thrombosis is the most important result of venous dilatation. Embolism from such thrombi is most common in the case of hemorrhoids (after operation) and in the veins of the lower extremities. Thrombophlebitis and lymphangitis are not infrequent complications of varices, and may result fatally. Further, as the result of phlebectasias and the stagnation of the venous flow, the tissues of the region tributary to the affected veins present a condition of chronic œdema. In the case of the skin there may be an increased secretion of sweat; in mucous membranes a condition of chronic catarrh results. Hemorrhage by diapedesis from the smaller capillaries is of frequent occurrence. The skin over varices often shows a marked atrophy, pigmentation, desquamation, or a condition of chronic eczema (eczema varicosum). As a result of the chronic venous congestion and chronic œdema the skin is often the seat of a chronic inflammation which leads to a fibroid thickening of the dermis and subcutaneous tissues. Over the legs these thickenings may form irregular folds or nodules (elephantiasis phlebectatica). Ichthyotic thickenings of the stratum corneum may also be produced, the epidermis presenting the appearances of warty excrescences. The neighboring periosteum may likewise be involved in the inflammatory process and a new formation of bone may take place (periostitis ossificans). As the result of slight injuries or wounds torpid ulcers very often form (*ulcera cruris*, *varicose ulcers*). These run a very chronic course, and may involve a very large part of the skin of the leg. Abscesses of the skin are frequently associated with these. Thrombophlebitis, pyæmia, and amyloid disease may follow such ulcerations.

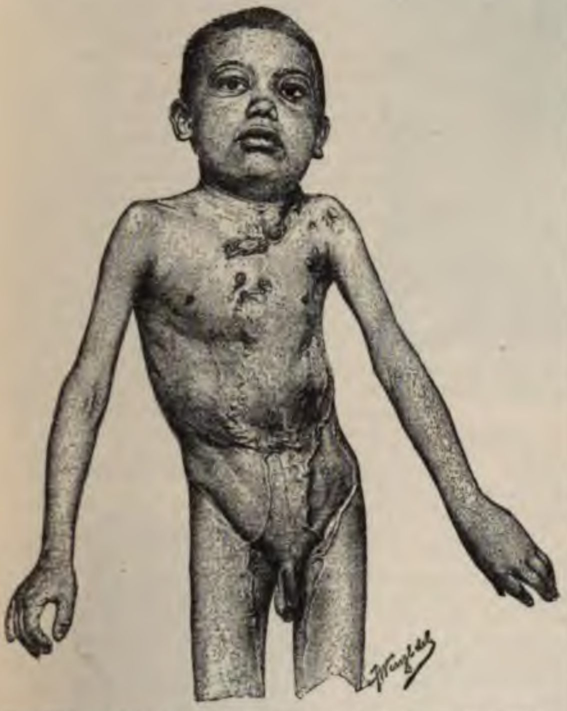

FIG. 5015.—Phlebectasia of Superficial Veins in Case of Obstruction of Venæ Cævæ due to Actinomycosis of Mediastinum. (After Schrötter.)

The diagnosis of varices offers no difficulties. The prognosis is dependent upon the extent of the varices, their etiology, and the occurrence of such complications as thrombophlebitis, embolism, hemorrhage, chronic ulcerations, amyloid disease, etc. The treatment of varices is chiefly palliative: elastic stockings, bandages, etc., ligatures, cauterization, electropuncture, excision, injections of ergotin, chloral, etc. The injection methods are at present but little used, and are in themselves dangerous. Trendelenburg's double ligature is the operation most frequently carried out. (See *Anus and Rectum. (Surgical.)*; *Varicose Veins*; and *Sexual Organs, Male, Diseases of.*)

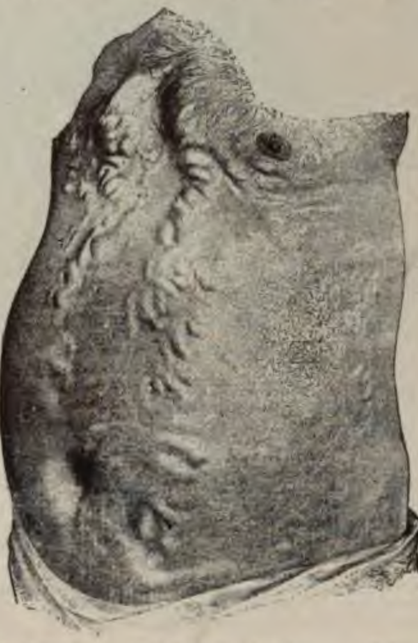

FIG. 5016.—Formation of Collateral Anastomoses Between the Superior and Inferior Epigastric Veins in Obstruction of Inferior Vena Cava. (After Schrötter.)

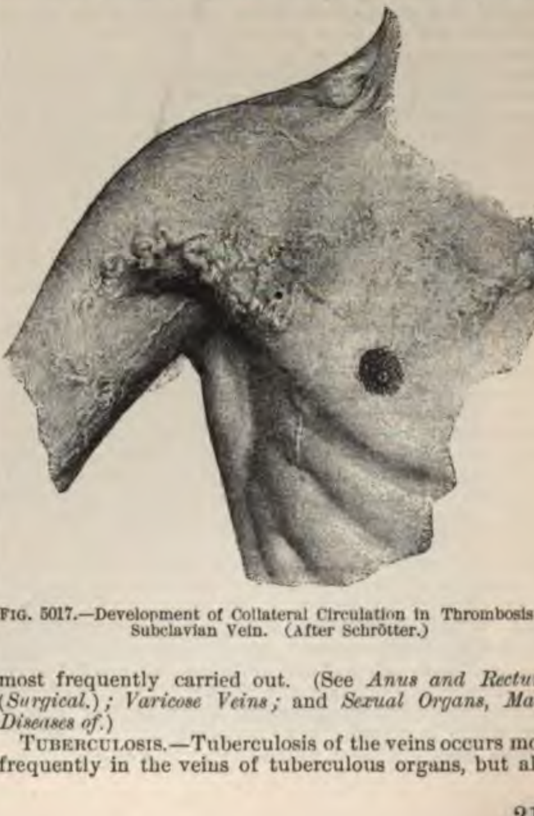

FIG. 5017.—Development of Collateral Circulation in Thrombosis of Subclavian Vein. (After Schrötter.)

TUBERCULOSIS.—Tuberculosis of the veins occurs most frequently in the veins of tuberculous organs, but also not rarely in the larger veins in the neighborhood of tuberculous lymph glands, etc. In the latter case the infection of the vein wall takes place through direct extension or through the lymphatics. In rare cases primary tuberculosis of the intima of veins may take place through the presence of tubercle bacilli in the circulation. Involvement of the veins from neighboring tuberculous processes is much more frequent in the case of the veins than of the arteries, and is one of the most common modes of dissemination of disease throughout the body. Tuberculosis of the veins presents no individual clinical picture, the symptoms being covered up by those of the primary infection. In miliary tuberculosis of hæmatogenous origin the veins throughout the body show numerous miliary tubercles in their walls, both in the intima and in the media, appearing as small gray or yellow nodules projecting into the lumen of the vessel. The earliest stages of these may appear as small collections of leucocytes or as agglutination thrombi resting upon the intima. Epithelioid proliferation of the cells of the intima occurs later, and finally typical tubercles are formed. In the case of extension from neighboring tuberculous foci the veins come to present the picture of a caseating tuberculous phlebitis.

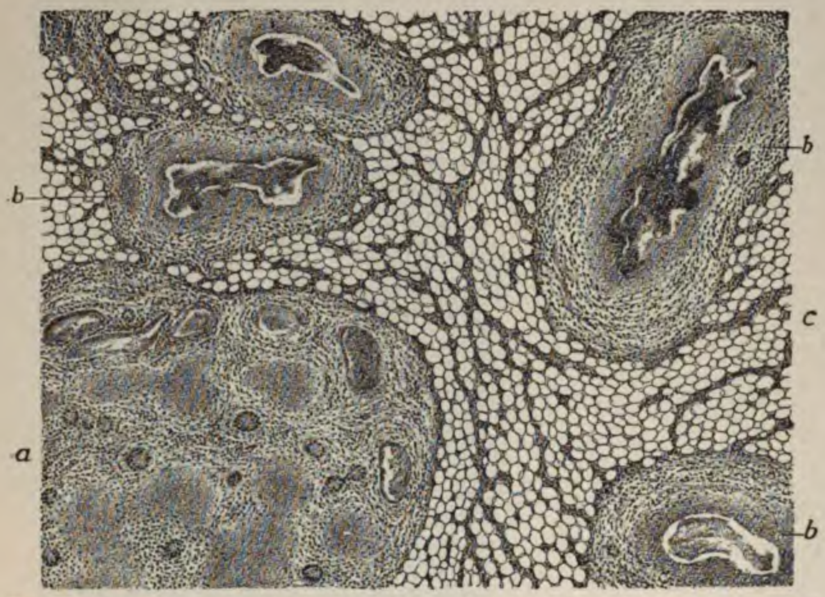

FIG. 5018.—*a*, Tuberculous lymph gland with giant cells and caseous foci—large blood-vessels at the periphery; *b*, veins whose walls are thickened by tuberculous granulation tissue, the inner layers of which show caseation; *c*, fat tissue. × 28. (Ziegler.)

SYPHILIS.—The most frequent changes in the veins ascribed to syphilis are of the nature of an obliterating endophlebitis or a chronic periphlebitis. The small veins of the meninges, brain, liver, and other internal organs are most often affected. In the neighborhood of the affected veins there is usually found a gumma or focus of induration. In the great veins, and particularly in the subcutaneous veins, symptoms of an acute phlebitis occur frequently in the early stages of syphilis, as shown by swelling, redness, and tenderness corresponding to the course of the affected vessel. In the later stages gummatous infiltrations of the vein walls and the neighboring tissues also take place. The proliferation and formation of granulation tissue may begin in the intima, media, or adventitia. Thrombosis may be associated with any of these processes. Sclerotic changes, calcification, and fatty change may follow. The portal vein may show marked changes of this character. Chiari has described a proliferating endophlebitis of the hepatic veins which he regarded as of syphilitic origin. Similar changes have also been found in the veins of the intestinal wall and mesentery associated with multiple strictures of syphilitic nature. In congenital syphilis the veins of the umbilical cord may show a thickening of the intima, due to a cellular proliferation or new formation of connective tissue. A periphlebitis syphilitica neonatorum has also been described. With the exception of the typical gummata which occur but rarely in the vein walls, the venous changes ascribed to syphilis present no distinctive characteristics, and the syphilitic origin in the majority of cases can be regarded as only probable.

ACTINOMYCOSIS.—The veins in the neighborhood of actinomycotic foci are frequently involved in the process, the resulting changes being of the nature of a chronic purulent phlebitis. Rupture of the focus through the intima may lead to a metastasis of the infection.

LEPROSY.—In lepra nodosa and anæsthetica the veins are frequently affected, presenting nodular thickenings. Microscopically the media and adventitia are infiltrated with round cells, the intima is thickened and hyaline, and the vasa vasorum are thickened. Bacilli are found in all three layers. The process is therefore to be regarded as a bacillary invasion phlebitis.

PARASITES. — Echinococcus cysts of the liver not infrequently break into the hepatic vein and give rise to metastases in the right heart and lungs. The cysticercus, filaria sanguinis hominis, and distoma hæmatobium are also found in the veins.

FOREIGN BODIES.—Under very rare conditions foreign bodies which have entered the veins may be found attached to the wall of the vessel. One case is reported of the finding of a small pistol bullet in the internal jugular.

NEW GROWTHS. — Hæmangiomata, angiosarcomata, and endotheliomata may be primary in veins, particularly the smallest veins. Primary myomata of veins have also been described. Many of the cases reported as primary tumors

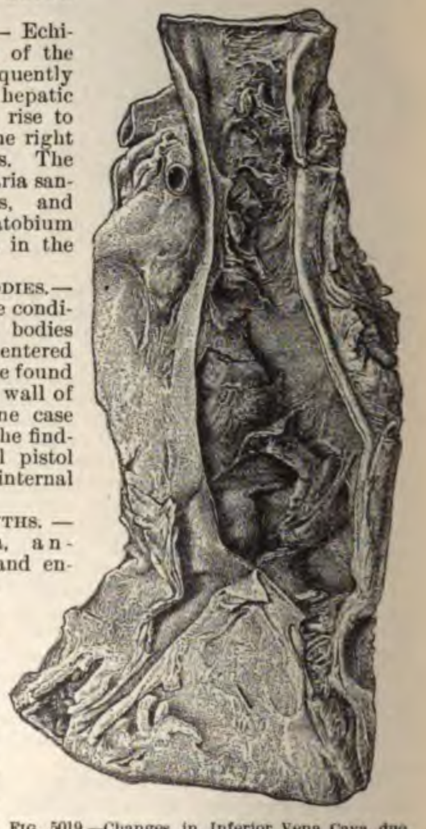

FIG. 5019.—Changes in Inferior Vena Cava due to Syphilis. (After Schrötter.)

of veins are of doubtful nature, it being very probable that the vein walls were secondarily involved. In so far as the metastasis of tumors is concerned, the veins play a much more important part than the arteries. The secondary involvement of veins by primary carcinoma and sarcoma of other organs and tissues is of very common occurrence. In the extension of the tumor into the vessel wall rupture of the tumor cells into the lumen is prevented for a long time by the endothelium, which is apparently very resistant to the advancing tumor cells. Large nodules may project into the lumen of the vein, but on microscopical examination the endothelium will be found intact over the growth. Carcinomata break through the walls of large veins more rarely than do sarcomata, because of the plastic influence which the carcinoma cells exert upon the connective-tissue cells of the vessel wall. As the carcinoma cells approach the vein wall the cells of the latter undergo proliferation, and a layer of new tissue is formed between the vein and the tumor. In the case of sarcoma there is but little plastic influence exerted upon the vessel wall, the cells of the tumor being genetically related to those of the vein wall.

In the case of primary malignant tumors of the adrenals, kidneys, testis, etc., large tumor masses not infrequently grow into the veins and may extend into the vena cava. Portions of these may break loose and lodge in the heart or pulmonary arteries. Free tumor emboli may occasionally be found in the right ventricle. Secondary carcinomata of the liver frequently break into the hepatic veins and give rise to metastases in the lungs. In the case of tricuspid insufficiency or violent spasmodic coughing a retrograde transportation of tumor cells may take place (retrograde metastasis). In very vascular tumors the veins are often markedly ectatic.

VENTILATION. See *Air,* and *House Sanitation.*

VENTNOR, ISLE OF WIGHT.—The Isle of Wight possesses certain favorable climatic features, both on account of its geographical position off the south coast of England, and also on account of its peculiar geological formation. It is at Ventnor, however, on the south side of the island, that the conditions are the most favorable for a winter resort, and Ventnor rivals Bournemouth in its reputation for the climatic treatment of pulmonary tuberculosis, both resorts having a royal national hospital or sanatorium for cases of consumption.

In general, the climate of the Isle of Wight is a marine, moist, mild one, cool in summer and mild in winter, with the prevailing winds from the southwest, *i.e.*, from the ocean. At every season of the year one can obtain here a mild tonic sea air.

In the southern portion of the island a great range of chalk downs stretches from east to west, and in the southeastern portion these downs form high, precipitous cliffs constituting the coast line, broken here and there by "chines" or deep indentations. Between the sea and these high cliffs is a narrow strip of coast-land, called the "Undercliff," consisting of irregular terraces of chalk and sandstone, the results of landslips from the cliffs above. This undercliff is from 100 to 150 feet above sea level, and extends for a distance of about six or seven miles. The aspect of the undercliff is, in general, due south. In the rear, to the north, rise the cliffs, the precipitous face of the downs, which are from 400 to 800 feet high, thus affording complete protection from the northerly winds.

Upon the undercliff, and upon a series of rocky terraces formed by the landslides, Ventnor is built, a town of about 6,000 inhabitants, stretching from the beach up the cliff to a height of nearly 500 feet; consequently the streets are very steep, and among the picturesque features of the place are this precipitous steepness and the arrangement of the streets one above another. Indeed, there are but few level stretches, and those are down by the sea.

The soil consists of soft sandstone and chalk, and is fairly absorbent and dry, but it forms readily, in dry weather, a light irritating dust. The vegetation of the undercliff is exceedingly luxuriant and varied, a proof of the mildness of the climate and the protected situation. Spring opens early, and many plants and shrubs blossom

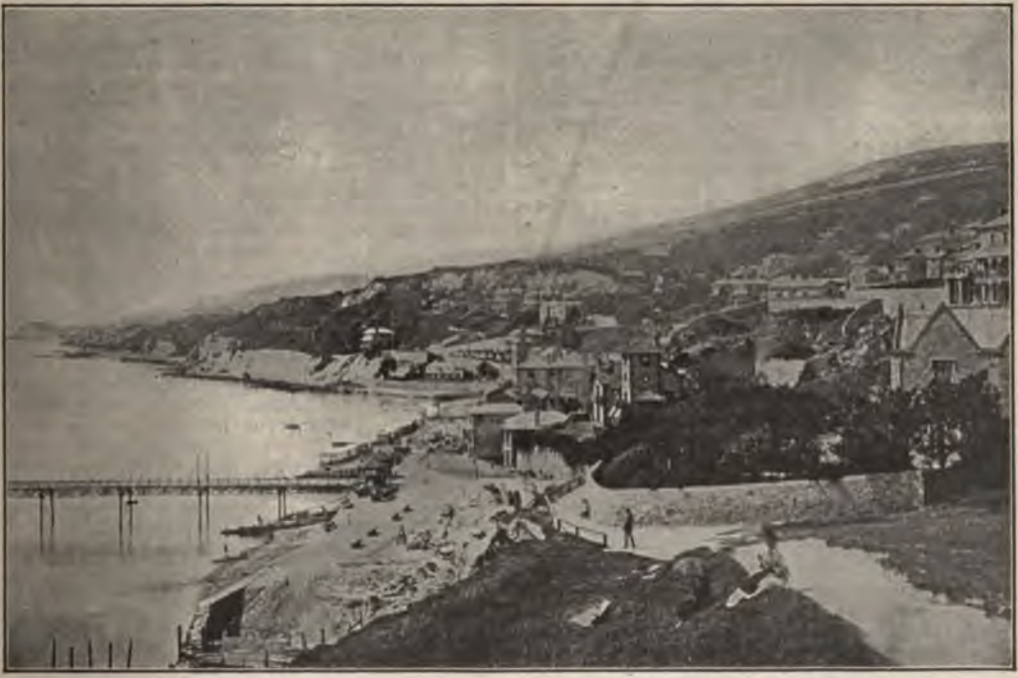

FIG. 5020.—View of Ventnor, Looking Westward.

throughout the winter. "Next to its picturesque situation, the most striking feature of Ventnor is the sea—a great brilliant mirror, reflecting, in fine weather, the light and heat of the sun against the cliff and town" (J. Mitchell Bruce, M.D., "Climates and Baths of Great Britain," 1895). There is a sandy beach affording good bathing, and there are also an esplanade and a pier. Ventnor is well drained by an efficient sewerage system, and is supplied with pure water, though hard from the influence of the chalk. The town is healthy, the death rate being 17.6.

The accompanying chart indicates the various climatic characteristics. In the first place, one observes the great equability of the temperature, not only in the yearly but in the daily range, and the absence of extremes of heat or cold.

Climate of Ventnor, Isle of Wight. Lat. 50° 45′ N., Long. 1° 20′ W.

	Jan.	Feb.	March.	May.	July.	Sept.	Nov.	Year.
Temperature (Degrees Fahr.).—								
Average or normal...	41.6°	41.9°	43.1°	53.3°	61.2°	59.1°	47.8°	50.8°
Mean of warmest.....	45.7	46.1	48.6	59.6	67.0	64.6	51.9	56.1
Mean of coldest......	37.4	37.7	37.6	47.1	55.3	53.7	43.7	45.5
Mean daily range....	8.3	8.4	11.0	12.5	11.7	10.9	8.2	10.6
Humidity.—								
Av. mean relative....	88%	86%	81%	77%	79%	80%	85%	81%
Precipitation.—								
Average in inches....	2.60	2.0	1.78	1.83	2.41	2.58	3.48	28.13
Weather.—								
Amount of sunshine in hours............	53.0	76.0	126	200	199	175	51	1638
Mean cloud 9 A.M	6.8	6.6	5.9	5.5	6.1	5.8	6.7	6.1
Days rain fell	16.0	13.0	13	12	14	13	18	164

	Winter.	Spring.	Summer.	Autumn.
Wind (Prevailing Direction).—				
Westerly and southwesterly. (Number of days)............	48	57	73	44
Easterly and southeasterly. (Number of days)............	42	35	15	47

The relative humidity is high, as would be expected on the seashore. The rainfall indicates a fairly wet climate, the autumn and winter being the wettest seasons. The winds are strong, and southwesterly gales are prevalent. As the prevailing wind comes from the southwest, it blows mild in winter and cool in summer. Easterly winds are, however, not infrequent, particularly in the late winter and early spring, and are "severe and trying." For England the amount of sunshine is large.

From what has been said above it will be seen that Ventnor possesses many qualities of a valuable health resort. Its situation, its well-drained soil, the mildness of its climate, the influence of the ocean, its excellent sanitary condition, and the opportunities for outdoor exercise, all combine to make it such. The existence of a large consumptive hospital here indicates the usefulness of this resort in the treatment of this disease, and the results which have been obtained are fairly favorable. The place is also recommended for convalescents from acute diseases and operations, for weakly scrofulous children, for persons with laryngeal and bronchial affections, hepatic and renal diseases, for the delicate and aged, for those suffering from atonic and nervous dyspepsia, and for those debilitated from any cause. Those suffering from heart disease will find little opportunity for exercise suited to them on account of the steepness of the streets.

Finally, Ventnor, which has been called "the English Madeira," is a most fascinating seaside resort in summer for the healthy, as the writer can testify to from personal experience. Besides the charm of Ventnor itself, with its wealth of vegetation and the beauty of its ocean view, there are innumerable excursions replete with interest all over the island; the roads are excellent, and the means of conveyance good and cheap. Ventnor is easily and quickly reached from London by way of Portsmouth, thence by a short steamer journey across the Solent, and again by rail from Ryde. The accommodations are of great variety and excellent.

Edward O. Otis.

VERATRINE.—(*Veratrina*, U. S., B. P.; *Veratrinum* P. G.) A mixture of alkaloids obtained from the seed of *Asagræa officinalis* (Sch. et Ch.) Lindley (fam. *Liliaceæ*).

The bulbous perennial named above, native of Mexico and Central America, was long considered a species of *Veratrum*, whence the alkaloids derived their name. The seeds, which are official in some pharmacopœias, and were formerly so in ours, are called *sabadilla* or, more correctly, *cevadilla* seeds, and are narrowly fusiform, with a flattened membranous top about 1 cm. or less ($\frac{1}{4}$ in.) in length; dark, shining, brown, wrinkled. When powdered, the dust excites violent sneezing. Taste bitter and acrid.

The seeds contain upward of four per cent. of alkaloid, isolated and named *veratrine* by Meissner in 1818, under the supposition that it was a pure alkaloid. It is now known to consist chiefly of two alkaloids, for one of which the name veratrine has been retained, the other being called *veratroidine*. Several others are supposed to be present, but have not been studied.

The mixed alkaloid is thus described by the Pharmacopœia.

A white or grayish-white, amorphous or semi-crystalline powder, odorless, but causing intense irritation and sneezing when even a minute quantity reaches the nasal mucous membrane; having an acrid taste, and leaving a sensation of tingling and numbness on the tongue; permanent in the air.

Very slightly soluble in cold or hot water; soluble in 3 parts of alcohol at 15° C. (59° F.), and very soluble in boiling alcohol; also soluble in 6 parts of ether, and in 2 parts of chloroform.

When heated to 175° C. (347° F.) veratrine melts, forming a light brown liquid. Upon ignition it is consumed, leaving no residue.

An alcoholic solution of veratrine has an alkaline reaction upon litmus paper.

With nitric acid, veratrine forms a yellow solution.

On triturating veratrine with concentrated sulphuric acid, in a glass mortar, the yellow or orange-red solution exhibits, by reflected light, a greenish fluorescence, which becomes more intense upon the addition of more acid, while the liquid is deep red by transmitted light.

On heating a small portion of veratrine with a few cubic centimetres of hydrochloric acid, the liquid will acquire a deep red color.

The isolated and purified veratrine proper ($C_{32}H_{49}NO_9 + H_2O$) occurs in white crystals, melting at 205° C. and soluble in alcohol and ether. Veratridine is an isomer of veratrine, but is not crystalline.

Veratrine is a most poisonous substance, producing violent vomiting and catharsis, followed by intense cardiac depression and acute gastro-enteritis. In ointments, unless very much diluted, it is also irritating, and not free from the danger of being absorbed. In minute doses it is occasionally given (0.0015 to 0.003 = gr. $\frac{1}{40}$ ad gr. $\frac{1}{20}$) for chronic rheumatism, neuralgia, etc., but is becoming obsolete. Externally, as liniment, ointment, or oleate, it is more frequently, yet still rarely, in this country, used for the same purposes. Most of all, however, it is employed in the above forms for pediculosis, both in man and in animals, for which purpose it is very efficient; yet it is not so safe, and no more certain, than washing the affected surface with kerosene, or a weak ($\frac{1}{2000}$) solution of corrosive sublimate.

Administration.—The Pharmacopœia authorizes two convenient preparations: the oleate (*Oleatum Veratrinæ*), which is a two-per-cent. solution in oleic acid, and an ointment (*Unguentum Veratrinæ*) consisting of 4 parts of veratrine, 90 of benzoinated lard, and 6 of olive oil.

Henry H. Rusby.

VERATROL, dimethyl-pyrocatechin, $C_6H_4(OCH_3)_2$, is a clear mobile liquid soluble in alcohol, ether, and the fatty oils. It closely resembles guaiacol (methyl-pyrocatechin), but is more irritating, so that its use is chiefly confined to external application. It has been applied with good results in intercostal neuralgia and epididymitis. Diluted with olive oil it is recommended as an abdominal application in tuberculous peritonitis.

W. A. Bastedo.

VERATRUM. See *Hellebore.*

VERONAL, diethyl-malonyl-urea, $C.(C_2H_5)_2.CO.(CONH)_2$, is a white crystalline powder of faintly bitterish taste, and soluble in 145 parts of cold water and 12 of boiling water.

The hypnotic action of various compounds, such as amylene hydrate and trional, is largely due to the presence of ethyl, so Fischer and von Mering, by the introduction of ethyl groups into various substances, have sought to produce a series of new hypnotics. Of this series the most valuable addition to our sleep-producing armamentarium is veronal. As a pure hypnotic this drug resembles trional, but seems to have greater power. Berent found that even when given in the day-time to walking patients it induced drowsiness and sometimes sleep. Würth treated eighty-four cases of insanity with twenty-one hundred doses averaging 0.5 gm. (gr. viij.) three times a day, and found the drug distinctly sedative in motor and maniacal excitement. Rosenfeld was successful in inducing sleep in hysterical and other nervous patients after bromides, chloral, trional, and warm baths had failed. Tolerance is not readily established, and after the first few nights the dose may be reduced by half. Most clinicians advise not to exceed 1 gm. (gr. xv.) at a dose, but in chronic alcoholism, delirium tremens, dementia, and acute febrile diseases, more has been found necessary. Berent used as much as 3.5 gm. (gr. liij.) without unpleasant after-effects other than heaviness and vertigo. Yet there are numerous reports of heaviness, drowsiness, headache, dizziness, and staggering gait after doses exceeding 1 gm. (gr. xv.). The last-named writer considered 1 gm. (gr. xv.) of veronal the equal of 0.015 gm. (gr. $\frac{1}{4}$) of morphine as a pure hypnotic. Where there is localized pain the drug has no effect. No noteworthy influence is exerted on digestion, respiration, the heart, or the kidneys. A few cases of skin eruption after prolonged use are reported.

Veronal, then, is a sedative to the nervous system, producing after one-half to two hours a sleep resembling the natural. Patients are easily aroused, but soon fall asleep again; when aroused they are in full possession of their faculties. The dose is 0.5–1 gm. (gr. viij.–xv.) in hot milk or in capsule. Roberts Bartholow recommends the combination of gr. x. of veronal with gr. v. of trional.

W. A. Bastedo.

VERMONT MINERAL SPRINGS.—Windham County, Vermont.

POST-OFFICE.—Newfane. Numerous summer hotels in vicinity.

ACCESS.—Viâ Brattleboro and Whitehall Railroad to Newfane; thence two and one-half miles northeast to springs.

These springs are located in the town of Brookline, fifteen miles north of Brattleboro. The situation is on Putney Heights, half a mile east of the West River and seven hundred feet above the surface. The scenery in the vicinity is very pleasing. The situation of the springs commands a view of parts of three States, and includes many points of great beauty and attractiveness. The carriage drives are numerous and very pleasant. Visitors will find excellent accommodations in several summer hotels in the vicinity. The springs are two in number, but only one of them has been improved. This spring issues from a small crevice in an enormous ledge of rock. The water is always cold, but never freezes as it flows from the spring. The discharge is about thirty-two gallons per hour. The company controlling the spring owns a large tract of land surrounding it, and is thus able to protect the water very thoroughly from surface pollution. It has been recently analyzed by Prof. S. P. Sharples, State Assayer of Massachusetts, with the following result:

One United States gallon contains (solids): Iron sulphate, gr. 1.01; calcium sulphate, gr. 0.64; magnesium sulphate, gr. 0.41; sodium sulphate, gr. 0.93; sodium chloride, gr. 0.05; silica, gr. 0.76. Total, 3.80 grains.

This cannot be termed a powerful mineral water, yet it contains iron in sufficient amount to give it useful properties as a ferruginous tonic. Abundant clinical experience goes to show that it has valuable reconstructive properties. It has been found useful in cases of anæmia and debility, enfeebled digestion, and anorexia, and in functional disorders of the kidneys. Locally it is recommended for insect bites, erysipelas, conjunctivitis, etc. The water is shipped in pint- and quart-bottle cases.

James K. Crook.

VERRUCA.—Verrucæ or warts are cutaneous excrescences which consist essentially of circumscribed hypertrophies of the papillary and epidermal layers of the skin. Their clinical characters are rather diverse. Thus, warts are congenital or acquired; they may appear upon any part of the body at any time of life; they are transitory or persistent, single or multiple; though usually small, they may attain a very considerable volume; in shape they may be rounded, flat, or acuminate, sessile, pedunculated, or filiform; their surface may be smooth, rugous, fissured, cauliflower-like; they are soft or corneous, moist or dry; in color they may present the normal hue of the skin or varying degrees of pigmentation.

The present classification of verruca is not satisfactory owing to the fact that our knowledge of essentially differentiating factors is insufficient. Based upon characters which are largely descriptive, a number of varieties are mentioned by authorities as: *verruca acuminata, acquisita, congenita, filiformis, glabra, perstans, caduca, senilis, digitata, dorsi, manus et pedis, vulgaris*, etc. Although these do not suggest a scientific division, a few of the terms enumerated may be used with advantage in the general consideration of the subject.

Verruca Vulgaris.—This is the type most commonly seen; hence the name. The lesions are hemp-seed- to split-pea-sized, single or multiple, discrete or in groups, rounded or slightly flattened, with a rugous surface which presents to the eye the appearance of numbers of closely set papillæ of variable prominence; these are capped with horny epithelium. The color ranges from skin-pink to a dirty grayish-black. The hands, fingers, and exposed parts are the favorite sites, and young people are far more commonly affected than adults.

Verruca Plana.—This variety is seen typically in the young (verruca plana juvenilis) as small, flat, slightly elevated lesions, of round or polygonal outline, and soft, smooth surface. They may be discrete or several may be merged to form more or less irregular plaques. The general appearance is not unlike that of lichen planus, though the color is more yellow than purple. The forehead, temples, cheeks, chin, and hands are the usual locations.

Verruca Senilis.—This form has been designated by some, erroneously, "verruca plana of the aged." It is sometimes seen upon the backs of individuals advanced in years. The lesions are somewhat irregular in outline, of low elevation, papillomatous, pigmented brown, and often covered with a slightly greasy scale. Verrucæ of this type have been called *seborrhœic warts*, and are prone to undergo cancerous degeneration. Similar verrucæ have been observed upon the hands of workers with the *x*-ray; in these also cancerous changes have been recorded.

Verruca Acuminata.—This type (venereal wart) occurs upon the genitalia and adjacent parts of individuals of both sexes; rarely it is seen elsewhere. Usually an irritant is present in the form of a venereal discharge. The lesions appear as papillary growths, discrete or grouped to form a cauliflower-like mass. Depending somewhat upon pressure effects they are flat and sessile, or elongated and slender. Their usual location—about the corona glandis in the male, and the labia, introitus vaginæ, and anal region in the female—favors the retention of moisture and the maceration of the lesions; the surface, therefore, is usually bright red, and covered with a secretion which is often very offensive; the practical absence of a cornified layer predisposes to slight hemorrhage, so that this secretion is frequently blood-tinged. These warts may appear in situations which are not moist, in which case there is no secretion, and the horny layer covering them becomes much thickened. Verrucæ acuminatæ are sometimes seen during the later months of pregnancy in women innocent of venereal history; they usually disappear after confinement.

Etiology.—The active causes of acquired verrucæ are not definitely known. It is certain that warts are the result of the local action of irritants, but the essential elements in these irritating agents are not known; nor are the predisposing factors, which render one skin more susceptible than another, fully understood. A microbic origin is surmised for verruca vulgaris and verruca acuminata; the former is undoubtedly mildly contagious, certainly for adjacent skin, and probably for the skin of another; while the latter is well known to be auto-inoculable. Verruca plana is said by Jadassohn to produce its kind and therefore has a specific cause; this is confirmed by an eminent dermatologist who, in a personal communication to the writer, reports having observed an epidemic of verruca plana sweep through a family. The exciting cause of verruca senilis is not known, though the progressive degeneration in the skin undoubtedly serves as a predisposing factor. Of the lesions seen upon the hands of *x*-ray operators the cause is obvious.

Pathology.—Anatomically, verrucæ consist essentially of an increased connective-tissue growth as a basis, to which is added an hypertrophy of the papillæ and the rete mucosæ. These changes are accompanied with an increase in the vascular supply. Often the hypertrophy of the papillæ is more apparent than real, the result of the actual increase in the size of the rete pegs. In most verrucæ the horny layer is hypertrophied, though the keratin transformation is not always complete. In verruca acuminata the horny layer is usually very thin, while the papillæ and rete are greatly increased. In the senile wart columns of epithelioid cells are found within the papillary layer; and throughout all layers (excepting the corneous) a peculiar infiltration of fat is present.

Diagnosis.—While the various forms of verruca are generally recognized without difficulty, it is well to keep in mind certain differentiations. *Lichen planus* has been confused with verruca plana; the former is less often seen upon the face, has a more empurpled color, is scaling and infiltrated, and itches, at times intensely. *Molluscum contagiosum* compared with verruca vulgaris is recognized by its minute punctum and its depressed centre. The lesions of *xanthoma* are distinctly yellow and would scarcely be mistaken for verruca. A distinction is also to be made between verruca acuminata of the sessile type and *syphilitic condyloma*; the latter is the papule of syphilis in moist locations, and as such is rarely papillomatous. *Verruca necrogenica* and *tuberculosis verrucosa cutis* may be recognized by their clinical course and by the histological examination of excised portions of the lesions.

Treatment.—The internal treatment of verruca is of doubtful efficacy. Crocker thinks favorably of the use of magnesium sulphate in small doses, and of dilute nitrohydrochloric acid. Arsenic, so frequently used in skin diseases, is rightly credited with good results in certain varieties, especially verruca plana.

The local treatment contemplates the removal of the lesions by curettage, electrolysis, cauterization, or by the application of substances designed to soften or to stimulate the skin. In many instances the use of the curette is most satisfactory; the scraping does not cause severe pain and the bleeding is usually slight; it is often advantageous to cauterize the oozing base with the silver nitrate crayon. In verrucæ which are very vascular the curette must be used with caution.

The method of removal by electrolysis is especially adapted to pedunculated forms: the base is transfixed with a needle connected with the positive pole of a battery, and a current of one to two milliampères is passed for about one minute; this is repeated several times, the needle being inserted at different angles through the base. The obliteration of the vascular supply thus induced causes the wart to shrivel and eventually to fall.

Of caustics glacial acetic acid and the silver nitrate crayon are the best; the use of chromic acid, acid nitrate of mercury, or potassium hydroxide is not without danger owing to their powerful caustic action. For softening the horny epithelium preliminary to curetting salicylic acid may be used; it may be applied in a solution with alcohol and ether, or in a collodion mixture. The strength should be about ten per cent., and the application should be confined to the lesion proper.

Verruca plana may be favorably influenced by applications which produce desquamation. For this the following may be used with advantage, in full strength or slightly reduced with water: ℞ Calcis vivæ, 15.00; sulphur. sublimat., 30.00; aquæ, 300.00. M. Boil down to 180 c.c. and filter. Sig.: Vleminck's solution.

Verruca senilis yields readily to radiotherapy; comparatively few exposures are required, and the results are most excellent.

Prognosis.—Verrucæ are usually very amenable to treatment; in fact, many disappear spontaneously, which accounts for the multiplicity of vaunted remedies. Senile warts may develop into epitheliomata; these may be quickly removed by radiotherapy.

Ernest L. McEwer.

VERSION. See *Obstetric Operations.*

VERTIGO.—Definition.—A condition characterized by loss of the sense of bodily equilibrium. It is accompanied by subjective dizziness, by partial or complete loss of power to stand erect and to walk in a straight line, and in severe cases by nausea and vomiting.

The sense of equilibrium should be ranked among the special senses. It is but indirectly dependent upon sight, hearing, and touch, and it has, we now believe, a special nerve organ, which is used for this purpose and no other. Any interference with the function of this organ causes vertigo, just as any interference with the eye causes blindness, or with the ear, deafness; in any case the degree of impaired function varying with the intensity of its cause.

The sense organ of equilibrium consists of: (1) a cortical centre or area, apparently located in the cerebellum, and communicating by connecting fibres with various nuclei in the medulla and pons; (2) a nerve trunk, which forms the inner root of the eighth cranial nerve (auditory), passes with it into the internal auditory meatus, and is distributed, under the name of vestibular branch, to the vestibule; (3) a peripheral end organ, consisting of the semicircular canals, the utricle and saccule. These structures contain the peripheral terminations of the nerve, which, generally speaking, consist of hair cells. Briefly, these hair cells are supposed to be acted upon by currents in the endolymph, the currents being caused by changes in position of the head. The three semicircular canals correspond to the three dimensions of space. For further particulars see the article on *Audition*, in Vol. I. of this Handbook.

Symptomatic Vertigo.—In view of the extent and complicated anatomy of the organ, it is not surprising that its functions may be interfered with by many causes other than organic disease of its structure. Disease or injury of neighboring organs is of course particularly liable to cause such interference, and hence vertigo is a common symptom of ear disease. Equally, of course, is vertigo found in various diseases of the brain and spinal cord.

Anything which causes changes in the blood supply of the organ (anæmia, hyperæmia) may inhibit its normal action. Poisoning by certain drugs, or by bacterial toxins, or by auto-intoxications, such as constipation or gout, will do the same.

Of distant troubles causing vertigo, the most frequent are the various disturbances of digestion. In these cases the vertigo is usually slight and transient, and is relieved by measures which cure the indigestion. An acquaintance of the writer, a physician about forty years of age, has frequent attacks of vertigo whenever there is an accumulation of gas in his stomach or intestines. As his digestion is not strong, these attacks are troublesome. In his case the vertigo is severe, and he has even fallen to the floor under its influence. Getting rid of the gas, by mouth or rectum, gives him instant relief. It is probable that his trouble is due to disturbance of the circulation, consequent upon pressure of the distended bowel from below through the diaphragm, interfering with the heart's action. The prompt relief obtained by expulsion of the gas goes to disprove the presence of toxins.

Constipation vertigo, in its slighter forms, is common enough. It often occurs in conjunction with headache. The only effective treatment is the administration of a brisk cathartic.

Gouty vertigo is allied to constipation vertigo, and the distinction between the two conditions is not always clear. Vertigo is seldom seen in typical cases of acute gout. It comes more often in the irregular forms, with migraine, catarrh of the respiratory and digestive mucous membranes, and pain and stiffness in various joints and muscles. It is often severe, and may be the only symptom which calls the patient's attention to his condition. It is caused by uric acid and other waste products of half-burned albumin, which accumulate in the system and act as poisons, probably directly through the tissues. The diagnosis rests upon the presence of other symptoms of gout, upon the condition of the urine, and upon the absence of signs of disease of the internal ear.

Various disturbances of the circulatory system may cause vertigo. The trouble may lie in the blood, the heart, or the vessels. Of the blood diseases, pernicious anæmia is probably the one most frequently attended by vertigo, but it is also seen occasionally in chlorosis. It is probably caused by cerebral anæmia. It is not usually severe or important. The diagnosis depends upon other signs of anæmia, and the treatment is the treatment of the general disease. Certain cases of leukæmia and Hodgkin's disease exhibit vertigo as a symptom. It may be very severe, in which case it is accompanied by signs of severe general cerebral disturbance, and is due to leukæmic lymphadenomata in the skull (Friedreich).

Cardiac vertigo is seen in many forms of heart disease. It is a common and early symptom of fatty degeneration of the heart. It usually comes on in attacks, which vary in severity over a wide range. The vertigo may be very slight, attended with nausea or slight faintness, or it may be more severe, attended with actual syncope, followed by a period of unconsciousness, and resulting in paralysis, loss of memory or intellectual power, or even death. This form of vertigo is caused by cerebral anæmia, and the diagnosis rests upon the presence of other signs of fatty heart, plus the absence of signs of ear trouble. The exact diagnosis of fatty heart is always difficult and may be impossible, but the undoubted evidence of cardiac incompetency, the absence of signs of valvular trouble, and the typical nature of the vertiginous attack, will usually give a clew.

Vertigo also occurs in other forms of heart disease, especially in disease of the aortic valves, either stenosis or insufficiency. Here the giddiness is slight and more or less constant, being much the same in either condition of the valves. The cause is disturbed brain circulation, and the diagnosis is made by examining the heart.

In aortitis and disease of the coronary arteries vertigo is often noted, especially in connection with attacks of angina. There is nothing characteristic about this form, and it is usually overshadowed by the pain, dyspnœa, sense of impending death, etc., which belong to the attack. In general arteriosclerosis vertigo is sometimes seen, due probably to changes in the cerebral vessels. This variety belongs among the encephalic vertigos.

In certain general systemic infections vertigo is often seen. Notable among these are influenza, typhus and typhoid fever, malaria, and plague. Vertigo in influenza is seen often; it may be severe, but usually does not last many days. Licéaga ("Twentieth Century Practice of Medicine," vol. xv., p. 286) declares that it is "constant and precocious, and appears whenever the patient attempts to sit, to stand, or even to raise his head." In typhoid fever vertigo is seen during the incubation period and at the beginning of convalescence. It occurs probably in about ten per cent. of the cases. At the outset of an attack of *bubonic plague* vertigo is said to be common. All these forms are caused by the toxin of the disease acting upon the brain or its circulation. They are not accompanied by deafness. They are in many cases merely a symptom of exhaustion, and they do not remain permanently after recovery from the disease.

The vertigo which follows the more severe forms of malarial fever, however, is different. It comes on after the disease has lasted for some time, is attended with deafness and tinnitus, and seems due to inflammation in the internal ear. It is rare. It belongs to the pernicious tropical forms, and there is ground for doubting if it be not due to the quinine rather than to the malaria. Ferreri reports two cases.

Certain drugs in toxic doses cause vertigo. Prominent among these are alcohol, aniline and its derivatives, quinine and salicylic acid. Alcohol probably acts by paralyzing the cortical areas in the cerebellum. Aniline acts in the same way. Quinine and salicylic acid, on the other hand, probably act directly upon the internal ear, since poisoning by either of them causes deafness and tinnitus as well as vertigo. Such cases rarely present difficulties of diagnosis.

Vertigo is also seen in certain diseases and disturbances of the central nervous system, both functional and organic. Seasickness comes under this head, being apparently caused by overexertion of the sense organ of equilibrium. The motion of the ship sends the endolymph flowing rapidly through the semicircular canals, agitating the hair cells violently, and thus interfering with their function. All symptoms of seasickness, it is well known, may be produced by rapid rotation of the body, and the fact that measures directed to the nervous system are the only ones that have been found effective in combating this malady, lends support to this view.

Neurasthenic vertigo is not uncommon. The attacks are short and not very severe, but often occasion much alarm. The diagnosis rests upon other symptoms present, and treatment is directed to the neurasthenia.

Epileptic vertigo is seen oftenest in attacks of *petit mal*. It is paroxysmal and brief. The patient feels dizzy, and perhaps falls to the ground, but recovers at once, and the vertigo disappears as the fit passes (Church).

Of the organic degenerative lesions of the general nervous system, vertigo is found often in tabes dorsalis. This vertigo is not to be confounded with the regular and constant ataxia. The two are quite distinct, and ordinarily, however extreme the ataxia, the patient does not suffer from subjective vertigo. When this occurs it is paroxysmal, and may be accompanied by vomiting and great prostration. In multiple spinal sclerosis (Church) vertigo often occurs. Here it is sometimes due to destruction of the central organ or the nerve trunk, and may present the type of Ménière's disease. These vertigos are to be diagnosticated and treated in connection with the underlying disease which causes them.

Of encephalic diseases any lesion interfering with any part of the sense organ of equilibrium may cause vertigo. It is most common in tumors or abscesses of the cerebellum and pons, in hemorrhage, or more rarely in basilar meningitis. It is constant and severe, often accompanied by nausea and vomiting, but except in connection with other symptoms it is not reliable for diagnostic purposes (Starr).

Vertigo also occurs in many cerebral diseases, such as endarteritis, general paresis, cerebral hemorrhage, cerebral syphilis. If the lesion be cerebral the vertigo is usually slight and transient.

Certain diseases of the eyes cause vertigo, especially ocular palsies. This is sometimes reflex and sometimes, probably, suggestive, the result of the double image. These cases can be relieved by blindfolding one eye, or by rectifying the muscular anomaly when possible.

Suggestive vertigo is seen often in persons who for the first time look down from a great height. It is purely psychic, and not a true vertigo at all.

Aural Vertigo.—This may occur as the result of any diseased condition affecting any part of the ear, from the auricle to the encephalic opening of the internal auditory meatus. It is specially common in labyrinthine disease. There is a type of otitis interna which gives rise to a definite and characteristic variety of vertigo, known as Ménière's disease. Anatomically it consists usually of a hemorrhage into the labyrinth, which may be caused by violence, such as a blow upon the head, or certain operative precedures upon the tympanum, such as mobilization of the stapes (Dench). Politzer says with reason that it is not the hemorrhage, as such, that causes the symptoms, but the effect of the extravasated blood upon certain structures of the membranous labyrinth. Therefore it is possible that there should be a considerable extravasate in the labyrinth without causing vertigo, or, on the other hand, a very small amount might produce it, according to whether or not the ampullar nerves are interfered with.

The true, typical, apoplectic form of this trouble is rare. According to Politzer, Frankl-Hochwart has been able to collect only twenty-seven cases in all the literature. It begins with giddiness, of such degree that the patient falls to the ground. He also suffers from intense nausea, vomiting, marked deafness, and sometimes a subjective noise in the ear like a loud report (Starr), or loud and distressing tinnitus (Politzer). The loss of hearing is usually bilateral. It may or may not be complete, but it is always severe. The course of the disease is to a slow and incomplete recovery. The nausea and vomiting first subside, and then, in the course of ten days or two weeks, the giddiness improves and the patient slowly regains his equilibrium. The deafness, however, persists in very nearly its first intensity, and the gait is apt to be more or less unsteady for months or years. Treatment must be on general principles—cold and local depletion at the outset, with rest in bed, catharsis, and nerve sedatives as required, morphine if necessary. After convalescence is established, a general supporting and building-up treatment is indicated. Politzer recommends potassium iodide, gr. xv. a day for three or four weeks, and also pilocarpine, gr. $\frac{1}{10}$–$\frac{1}{8}$ a day.

The diagnosis of true labyrinthine vertigo rests upon: 1, Its intensity—it is always severe; 2, the accompanying deafness and tinnitus; and 3, the absence of signs of (*a*) cerebral disease, or (*b*) middle-ear trouble. In Ménière's disease the symptoms are usually bilateral; in traumatic cases they may be unilateral. A very interesting case of this sort is reported by Starr. A fireman fractured the base of his skull and tore the left auditory nerve. His chief symptoms were complete deafness on the left side and constant and agonizing sense of rotation of his body on its longitudinal axis, so that if left alone in bed he would roll over and over in the opposite direction to overcome this feeling. He died on the fifth day after his accident.

Other forms of aural vertigo are less severe and less typical. The vertigo that occurs as the result of trouble in the external auditory canal (cerumen, furuncle) is slight and transient. Occasionally chronic aural catarrh will cause a certain degree of vertigo, which may be quite severe. And in chronic suppurative otitis, with cholesteatoma, vertigo may occur at any time as the result of erosion of the external semicircular canal. The writer has seen two such cases, one of which was operated upon by Dr. Whiting, of this city, with complete relief. Vertigo occurring in these cases, at the end of a long period of suppuration, is a dangerous complication, and calls for prompt surgical interference.

It is the firm conviction of the writer that in every case of vertigo, whatever be the history and circumstances, the condition of the ears should be carefully and thoroughly investigated. *Donald M. Barstow.*

VESICO-VAGINAL FISTULA. See *Vagina, Diseases of.*

VETERINARY SCIENCE IN ITS RELATION TO PUBLIC HEALTH.—Veterinary science includes in its domain a complete knowledge of the domesticated animals. It is not limited, as many suppose, to their anatomy, physiology, pathology, and therapeutics, but, in addition to these subjects, it covers zootechnics, or the economical production of animals, veterinary hygiene, or the maintenance of animals under healthful conditions, veterinary sanitary science, or the control of contagious diseases, the exclusion of exotic contagion and the inspection of animal food products. It may be said, therefore, that it is the province of veterinary science, (1) to aid in producing a supply of animal food of the best quality and in the greatest abundance; (2) to protect the sources of this food supply so far as possible from the ravages of communicable diseases; (3) to prevent the use of animal food products contaminated by disease; (4) to guard mankind from the plagues and parasites of animals which may be transmitted to the human subject; (5) to make scientific investigations of animal diseases which will advance our knowledge of these diseases and of general pathology. All of these lines of work operate directly to improve the public health.

The Animal Food Supply.—An abundant supply of wholesome food is necessary for the preservation of the public health; and as the food supply deteriorates in quality or diminishes in quantity the conditions of life become more difficult. Want, distress, and misery result. Following the impoverishment of the body come disease and an augmented mortality. Famine and pestilence are words which the long and bitter experience of the human race has associated together. The scarcity and bad quality of food is felt first and most severely where the population is most dense, and where a large part of the people, at best, have a serious struggle for existence. It follows, of course, that as a country develops and becomes more densely populated, as cities multiply and contain a greater number of people who even in times of abundance must eat inferior food, the effect of deteriorations of the food supply becomes more evident. A nation with an abundant supply of good food is already well on the way to prosperity and healthfulness.

Animal food forms a most important part of the general food supply. The stock of animals maintained in the United States at this time for the production of human food is approximately 17,105,227 milch cows, 44,659,206 other cattle, 63,964,876 sheep, 46,922,624 swine, and 250,681,593 fowls of various kinds. The raising, marketing, and slaughtering of these animals, and the production of the milk, butter, and cheese involve many problems which the veterinarian can solve, or at least should help to solve. And just as the increasing density of the human population brings new problems to the health officer and sanitarian, so an increase in the number of animals and the change from natural to artificial conditions bring new problems to the veterinarian. When animals are allowed to roam over large tracts of land, seldom or never stabled, and not pressed for the largest attainable product, when traffic between different sections of the country is at a minimum, the animals are found in the most vigorous and healthful condition. On the other hand, when animals are crowded together, stabled, fed to their highest capacity, and become a subject of traffic, disease and parasites multiply; questions of ventilation, of general sanitary methods, of proper feeding, of protection from contagion and parasites arise and become more and more urgent.

The quantity of animal food consumed in the United States cannot be very accurately estimated. Under the federal meat inspection service there were slaughtered in the year ending June 30th, 1902, 6,115,805 bovine animals, 7,434,478 sheep, and 25,277,107 hogs. In addition, many of the same kinds of animals were slaughtered for local consumption or in establishments where no inspection has been instituted. There is no systematic inspection of poultry at the time of slaughter, but the production of an abundant supply of poultry and eggs must depend somewhat upon the preservation of fowls from contagious diseases, and the knowledge through which this is to be accomplished must come from veterinary sanitary science.

The quantity of milk in its natural condition consumed in the United States is about 21,751,258,560 pounds, of condensed milk 172,647,355 pounds, of butter 1,465,299,727 pounds, of cheese 278,538,146 pounds.

These figures show the enormous extent to which animal products enter into the food supply of the country, and they indicate the importance of establishing safeguards which will make it reasonably certain that such products are wholesome and will not prove a source of disease to the consumers. Dairy cows should be inspected from time to time to determine that they are free from disease, and especially that they are free from diseases communicable to man. Dark, unventilated, damp, and filthy stables should be abolished, and it should be insisted that animals be kept under hygienic conditions. Milk is too often sold from cows suffering from tuberculosis, actinomycosis, metritis, mastitis, and other diseases which may seriously affect its quality.

It is equally important that animals should be inspected at the time of slaughter. A certain proportion of diseased animals will be found even among those which superficially appear the most healthy. It is a common practice to ship to market animals which no longer thrive on the farm; and while in many cases the owner does not know what ails them, it often happens, as with hogs affected with cholera, that they are shipped to market because they are known to be infected, and that the losses among them will be heavy if they are retained upon the farm. In addition to the animals diseased when they leave the farm, there are many which become bruised, wounded, crushed, and otherwise badly injured in transit. Some of these when they reach the abattoirs are suffering from abscesses, septic infection, abortion, and various other pathological conditions the result of injuries. These conditions can, of course, be recognized and graded as to their seriousness only by the trained veterinarian.

The Protection of Animals from Infectious Diseases.—Probably the most important line of work for preserving the food supply both in quantity and quality is that which controls, eradicates, and excludes the contagious and infectious diseases of animals. This is particularly necessary at the present time, when transportation routes and means of communication between all parts of the world have multiplied, when facilities for shipping animals and animal products have been greatly increased, and the time required to bring these from the most distant part of the world has been enormously diminished. We have reached a degree of development in these matters when it may be said that the time of transit is no longer a protection against the importation of contagion from the most distant countries.

As the veterinarian examines the condition of animals in other countries he finds that Asia, the Philippines, and Africa are overrun with rinderpest, that most deadly of all cattle diseases. He finds the contagious pleuropneumonia of cattle in Asia, Australia, Africa, and in several countries in Europe. He finds epizootic aphtha, or foot-and-mouth disease in Europe, Asia, and South America. He finds surra in India and in the Philippines. He finds Texas fever in most warm countries of the world, including South Africa, Australia, South and Central America, the West Indies, Mexico, and the southern parts of the United States. He finds sheeppox, scabies, anthrax, hog cholera, and various other destructive diseases widely disseminated throughout the world. The country must look to him to exclude such diseases, which would not only diminish the food supply, but which would increase the proportion of diseased animals coming to the abattoirs.

The United States, fortunately, has been free from some of the worst of these plagues, but distance is no longer the barrier that it has been in the past, and active measures are now required against them. Europe has again and again suffered the most terrible losses from invasions of this character. And at this writing, foot-and-mouth disease has been prevalent in most of the countries of continental Europe for more than fifteen years. Considering the large number of live animals of various kinds which annually enter the United States from abroad, including domesticated animals, menagerie animals, and those for zoological parks, pets, etc., also, the enormous quantities of wool, hides, and hair imported, it is plain that there are many channels through which contagion may be carried.

Within the last year there has occurred, in the New England States, an outbreak of foot-and-mouth disease which started near the docks of Boston, undoubtedly from imported contagion, and which has been stamped out only by the most prompt and rigid measures. With this disease in South America threatening us from the south; with rinderpest in our Philippine possessions; with foot-and-mouth disease and pleuropneumonia still existing in Europe, it is plain that nothing less than constant vigilance can preserve our flocks and herds from these plagues.

The measures adopted in the United States for excluding exotic contagion consist of an inspection of all susceptible animals, the quarantine of ruminants and swine which come from infected countries, and the disinfection of the hides of neat cattle. The period of quarantine varies from fifteen to ninety days, the animals being held in the regularly established quarantine stations of the Government. Cattle imported for breeding purposes must be tested with tuberculin to guard against tuberculosis. An inspector from the United States is now stationed in Great Britain to make such tests before the animals are purchased, as it has been found that a very large percentage of some of the principal British breeds are tuberculous. On the other hand, animals from the Channel Islands have been found free from tuberculosis and are no longer tested.

The measures for controlling contagion within the United States consist of an inspection at the principal stockyards, and at other convenient points for supervising the interstate traffic. This inspection is maintained by the Federal Government and has for its object at present the control of Texas fever of cattle, scabies of sheep and cattle, and hog cholera. In addition, many of the individual States and municipalities maintain a service for the repression of glanders, tuberculosis, rabies, Texas fever, scabies, and other diseases of the domesticated animals.

The Protection of Mankind from the Communicable Diseases and Parasites of Animals.—That there are certain diseases of animals which are communicable to man has long been known. There are also parasites of animals which likewise may be communicated and which produce results more or less serious according to the species of parasite which is involved. Among the most common of these diseases and parasites are: (1) Glanders, a disease of the genus *Equus*, generally fatal when contracted by man; (2) anthrax, a disease of horses, cattle, sheep, and swine, appearing in man either as malignant pustule or as internal anthrax, and often fatal; (3) tuberculosis, a disease common in cattle and swine, but also occurring in horses, sheep, goats, dogs, poultry, cage birds, and menagerie animals; (4) rabies, a disease of the genus *Canis*, communicable to all warm-blooded animals and to man; (5) epizootic aphtha, commonly known as foot-and-mouth disease, a very infectious malady of cattle, sometimes communicated to the consumers of the milk of diseased cattle; (6) *Cysticercus bovis*, found in cattle, is the larval form of the tapeworm of man known as *Tænia saginata*; (7) *Cysticercus cellulosæ*, found in swine, is the larval form of the tapeworm of man known as *Tænia solium*; (8) the *Trichina spiralis*, a common parasite of swine, may develop in man and sometimes produces fatal results; (9) the *Echinococcus* found in the lungs, liver, and other organs of the meat-producing animals is the cystic phase of the *Tænia echinococcus* of the dog.

It is evident that the most satisfactory way of protecting man from this source of danger is to eradicate these diseases and parasites so far as possible from the domesticated animals. Hence all veterinary sanitary work having this object in view has a direct bearing upon the public health. As complete eradication cannot be accomplished for many years and in some cases not at all, there must be constant efforts for repression and control. People must be made familiar with the dangers; too close association with animals should be avoided; the inspection of meat and of dairy cows should be universal; swine flesh should be well cooked; hides, wool, and hair, often infected with the anthrax bacillus, should be handled with suitable precautions; biological products used for the prevention or cure of human diseases should be surrounded with every safeguard to avoid contamination.

Investigation of Animal Disease as to its Influence on Human Pathology.—The investigation of the diseases of animals, and experiments conducted upon animals, have done much to advance the knowledge of pathology and therapeutics. The use of cowpox virus to vaccinate against smallpox has been of inestimable value for the control of this scourge of the human race. The existence of glanders and rabies in man has been proved by the successful inoculation of susceptible animals from suspected cases of these diseases in the human subject. The study of silkworm disease and anthrax in animals established the germ theory of contagion.

Investigations of the fowl-cholera microbe first proved that a virulent virus might be artificially attenuated to such a degree that it might be used as a vaccine to prevent disease. Experiments with the toxin developed by the bacillus of hog cholera showed that immunity might be developed by the use of such toxins. This conclusion revolutionized the prevailing ideas of immunity, and led to the researches which gave us the knowledge now possessed relative to toxins, antitoxins, and the nature of immunity. The study of Texas fever in cattle showed that the protozoan organism causing the disease was dependent upon the cattle tick (*Boophilus annulatus*) for one stage of its existence and for its conveyance from animal to animal. Later investigations brought out the fact that certain diseases of man, such as malaria and yellow fever, likewise required two distinct organisms for their production. The study of tuberculosis in animals directed attention to the communicability of the disease, and comparative inoculations of animals have demonstrated that the bacilli from certain human cases were identical with bovine bacilli. Doubts as to the transmission of tuberculosis from animals to man have thus been removed.

These instances are referred to as illustrations of the close relation between human and veterinary pathology, and of the influence of the latter upon the development of the former. It has been well said that human and veterinary medicine are not merely sister professions, but they are sister branches of the one great profession of medicine. The closer the relations existing between these two branches of the medical profession, and the more each utilizes the knowledge of the other that may be applicable to its work, the more successful will be our efforts for the amelioration of suffering, the prolongation of life, and the uplifting of humanity.

The limits of this article are such that it is not advisable to attempt a complete description of the several diseases of animals liable to be communicated to man or injuriously to affect his food supply. There are, however, important questions connected with these diseases which should receive consideration, and if the author in confining himself to such subjects as he deems essential, has produced an article that appears incomplete, it should be remembered that many topics which might have been introduced here are discussed elsewhere in this HANDBOOK by other writers.

TUBERCULOSIS OF ANIMALS.

General Characters.—The disease caused by the *Bacillus tuberculosis* affects a wide range of animal life, and is especially seen outside of the human subject, in the various species of the monkey tribe, in most kinds of menagerie animals, including mammals, birds, and reptiles; in all the domesticated animals, but more particularly in cattle, swine, and poultry; in cage birds; and in frogs and fishes. Taken from such widely different sources the bacilli are found to differ considerably both morphologically and biologically. For example, the temperature limits within which the mammalian bacillus may grow are approximately 86° to 105.8° F.; the avian bacillus, however, may multiply in temperatures all the way from 77° to 113° F.; while the reptilian and piscine bacilli have been observed to multiply in those from 50° to 98.6° F. Notwithstanding these biological differences the mammalian bacillus has been so modified that it has acquired the piscine and reptilian characteristics; and the avian has been made to take on the mammalian characteristics. The modifications which have been noticed by various investigators relative to the length, breadth, smooth or beaded form, and appearance of the colonies on various media, are not entirely constant in the bacilli obtained from the same species of animals and change very materially on different culture media. While these characters may aid in determining the source of a given bacillus they are not absolutely certain in their indications.

The avian type of tuberculosis is not readily communicated to any mammalian species and probably is very slightly if at all dangerous to man. Parrots and small birds, however, contract mammalian tuberculosis, and this is sometimes very virulent for mammals, and is believed to be dangerous for the persons who are closely associated with them. There is considerable difference between the bacilli that are generally obtained from the human subject and those derived from bovine animals. This relates both to the morphology and to the virulence. We, therefore, often speak of the human and bovine types of bacilli. Swine are most frequently found affected with the bovine type. The constancy of these types is doubtful, but in certain instances a given strain of bacilli has been known to retain its characteristics for a long time (one or more years) after being transferred to a different species of animals.

Bovine animals are the ones most frequently found tuberculous, and they are probably in most cases the source of the disease in the other domesticated species. Bovine tuberculosis has therefore attracted more attention than that of other animals and is most interesting to the sanitarian. Many points relative to this disease have been in doubt, but the investigations of recent years have added much to our knowledge of it, and we are now in a position to speak positively in regard to the principal questions at issue.

Distribution and Prevalence.—Bovine tuberculosis is a disease widely distributed and of great frequency in certain countries. Slaughter-house statistics of Prussia show 16.6 per cent. of the cattle and 2.41 per cent. of the swine to be tuberculous; in Saxony the percentage is 29.13 with cattle and 3.10 with swine; in the city of Leipsic there were found 36.4 per cent. with cattle and 2.17 per cent. with swine. Of 20,850 bovine animals in Belgium tested with tuberculin in 1896 48.88 per cent. reacted. Of 25,439 tested in Denmark from 1893 to 1895 49.3 per cent. reacted, and of 67,263 tested from 1896 to 1898 32.8 per cent. reacted.

The condition of Great Britain in this respect is particularly interesting because most of the animals imported for improving the stock of the United States are of British origin. The returns from testing British cattle with tuberculin, supplied by the Royal Veterinary College, as stated in March, 1900, showed that among 15,392 animals tested, 4,105, or 26 per cent., reacted. Of 300 head killed near Edinburgh for pleuropneumonia, 120, or 40 per cent., were tuberculous. Of 4,160 killed in England for the same reason, 20 per cent. were tuberculous. Of 398 bovine animals taken haphazard in the city of Manchester, 120, or 30 per cent., were tuberculous. The testing of the Queen's herd at Windsor showed that 36 out of 40, or 90 per cent., were tuberculous. The British Dairy Farmers' Association made investigations in 1899 with a view to some more definite understanding as to the possible extent to which tuberculosis exists in dairy cattle. Nine herds were selected for testing, and these contained 461 cows and 12 bulls. Of these animals 188, or 40.8 per cent., reacted.

During the years 1901 and 1902 a veterinary inspector has been stationed in Great Britain by the Bureau of Animal Industry, whose duty it is to test animals which are to be exported to the United States. In 1901 there were tested 720 animals, of which 74, or 10.28 per cent., reacted. In 1902 the animals tested reached the number of 935, of which 156, or 16.68 per cent., reacted. Curiously enough but one reaction was obtained, and that of a doubtful character, among 377 cattle from the islands of Jersey and Guernsey, but 99 cattle of the Jersey and Guernsey breeds which had been in the herds of Great Britain gave 34.3 per cent. of reactions. Some breeds appear to be much more seriously infected than others. Thus, of 42 British Jerseys 54.76 per cent. reacted; of 362 Aberdeen-Angus 28.73 per cent. reacted; of 33 Ayrshires 24.24 per cent. reacted; of 228 Shorthorns 23.25 per cent. reacted; of 36 Galloways 16.67 per cent. reacted; while of 428 Herefords but 3.97 per cent. reacted.

It is especially unfortunate that tuberculosis has developed to this extent in the principal British breeds and is allowed to continue its propagation. These breeds are the best in the world, and are sought for to improve the native cattle of various parts of the world. They are particularly in demand in the United States, and as might be expected they have carried tuberculosis wherever they have gone. From Australia, Argentina, and Canada we have similar accounts of the importation of British cattle and the spread of bovine tuberculosis. The United States Government has endeavored to exclude tuberculous cattle by requiring a tuberculin test. For British cattle this is made by a United States inspector located in Great Britain, and for Canadian cattle it is made by the officials of the Dominion Government.

State.	Number tested.	Number tuberculous.	Per cent tuberculous.

The percentage of the cattle in the United States affected with tuberculosis has not been accurately determined, and most of the herd tests have been made where there was reason to suspect the existence of the disease. The statistics of such tests show a higher percentage of reacting animals than would the average of all the cattle in the respective States. From a recent review by Drs. Russell and Hastings, of the Wisconsin Agricultural Experiment Station, of the tests of cattle which have been made in the United States, the preceding summary is presented.

The beef cattle coming to our markets are still quite free from tuberculosis. Of 5,559,969 cattle slaughtered during the year 1902, but 8,096, or 0.14 per cent., were sufficiently affected to cause the condemnation of carcasses or of parts of carcasses. Of 25,277,107 swine inspected at slaughter in the same year, 19,627, or 0.077 per cent., were so affected as to cause condemnation of either a part or the whole carcass. This is approximately one-half the proportion found in beef cattle. The inspection statistics show that the percentage of condemnations with both cattle and swine is increasing from year to year.

With hogs tuberculosis is a disease generally contracted from the ingestion of infected food, and hence, as the disease is allowed to spread among cattle, it will become more frequent with the hogs that follow the cattle in the pastures or that eat the skim milk, buttermilk, and other waste products of the dairies. The disease is more acute with swine and has a greater tendency to generalization than with cattle, and consequently there is more danger of the meat containing the bacilli.

Tuberculosis is not pre-eminently a disease of poor, neglected, underfed scrub cattle, as some have supposed, but on the contrary its ravages have been seen more particularly among the better class of cattle. This is accounted for by its introduction and spread through imported, pure-bred stock which entered and infected many of the best herds in the country. From these herds of improved stock it has extended to the dairy herds and common cattle.

A brief list of infected herds which have been carefully studied is inserted to show the extent to which the disease develops and the difficulty of building up a herd of good cattle under the best conditions and keeping it free from this disease:

Herd of	Number in herd.	Number tuberculous.	Per cent. tuberculous.
Soldiers' Home, Washington, D. C	63	53	84
Massachusetts Agricultural College	32	25	78

* So badly diseased that entire herd was slaughtered in 1886.

Diagnosis of Tuberculosis in Animals.—*The Tuberculin Test.*—The diagnosis of tuberculosis in animals by an ordinary clinical examination during life is in most cases difficult and often impossible. When cough, marasmus, enlarged glands, and râles are found in cows it is not difficult to reach a conclusion, but such cases are exceptional. Many cows, which show no symptoms of disease during life, are found on post-mortem examination to be seriously affected. This is even more likely to be true of breeding animals of the beef types. In hogs this disease is rarely recognized during the life of the animal.

The discovery of tuberculin and of its power to produce a rise of temperature in tuberculous individuals has been of the greatest value to the veterinarian in diagnosing the tuberculosis of animals; indeed, it may be said that the use of this agent is essential to the control and eradication of this plague. There is a consensus of opinion that every animal which reacts is tuberculous; but it must be understood that every rise of temperature is not necessarily a reaction. There may be other causes acting to increase the temperature during the same period that an increase would be expected from the tuberculin. It requires some skill to decide correctly as to what constitutes a reaction. The principal points considered are: (1) the initial temperature should not be abnormally high—not over 102.5° F.; (2) to constitute a reaction the rise should be not less than 2° F.; (3) the temperature should go above 104° F.; (4) the rise and fall of the temperature should be gradual so that when charted it shows the tuberculin curve.

Some animals which have tuberculosis do not react to tuberculin. These are generally in such an advanced stage of the disease that a diagnosis by other means may be made, or they are cases in which the disease has been arrested and the lesions are calcified or encysted. A tuberculous animal, which has already received one or more doses of tuberculin, may fail to react for this reason, particularly if the drug has been administered within two or three months. Some cattle owners use tuberculin in this manner to prevent cows reacting on an official test, and it is alleged that breeders in Great Britain have administered antipyretics to accomplish the same purpose.

Tuberculin may be used for diagnosing tuberculosis in all species of animals, and is especially valuable for the selection of experimental animals which are free from this disease.

In making the tuberculin test the temperature of the animal to be tested is first taken at intervals of two or three hours for a sufficient length of time to establish the normal temperature of the individual under the ordinary conditions of life. The proper dose of tuberculin is then injected under the skin with a hypodermic syringe. This injection is usually made late in the evening and the temperature is taken every two hours the following day, beginning early in the morning and continuing until late in the evening if a complete record is desired. From a study of a large number of such records it appears that in general the rise of temperature begins from five and one-half to six hours after the tuberculin is injected, reaches its greatest height from the sixteenth to the twentieth hour, and then gradually declines, becoming normal again by the twenty-eighth hour.

It has been charged that tuberculin is injurious to the animals upon which it is used, causing shrinkage of the milk, abortion, and aggravation of this disease. The evidence brought forward is not sufficient to sustain these assertions. Those who have had most experience in testing cattle are of the opinion that tuberculin is harmless in the dose used for this purpose. Abortion is common with dairy cows and would occur sometimes after the tuberculin tests as a mere coincidence. The milk secretion of cows may also be reduced by the excitement incident to taking the temperature, particularly if this is done by persons who are strange to them. It is possible that in some cases tuberculosis is aggravated by the tuberculin test, but in general no effect of this nature is observed with cattle. It may be concluded, therefore, that tuberculin, as used for testing cattle, has no appreciable effect upon the general health of the animals, and that it may be used without hesitation whenever it is desirable to know whether any animals in a herd are affected with tuberculosis.

Hereditary or Congenital Tuberculosis.—Tuberculosis is generally contracted by contagion from animal to animal, but a small proportion of calves are affected before birth. There are few statistics which indicate accurately the proportion of cases in which the disease is thus transmitted. Siedamgrotzky has compiled statistics from the slaughter-house returns in Saxony, from which the following data are taken:

SLAUGHTER-HOUSE STATISTICS OF SAXONY.

Year.	PER CENT. TUBERCULOUS.	
	Calves.	Adult cattle.
1895	0.24	27.48
1896	.21	26.72
1897	.26	29.13

This table indicates that in a country where about twenty-seven per cent. of the adult cattle are found to be tuberculous, approximately 0.25 per cent. of the calves are tuberculous. If we admit that fifty per cent. of the cows have the disease, we should arrive at the conclusion that one-half of one per cent. of the calves from tuberculous mothers are affected at the age of slaughter. It would be difficult to say what proportion of these contracted the disease from the mother's milk after birth, but probably the greater part of such cases are congenital. The small proportion of calves from tuberculous mothers which suffer from hereditary tuberculosis has made it desirable in certain cases to allow breeding from valuable cows which have the disease. If the calves are taken from the mothers after feeding once or twice upon the mother's milk and are afterward fed with milk of sound cows, experience shows that not over one or two per cent. at most are afterward found to have the disease.

Tuberculosis of the Udder.—Only a small proportion of the cows which react to tuberculin have lesions of tuberculosis in the mammary glands. Siedamgrotzky's summary of the slaughter-house statistics of Saxony from 1888 to 1897 covers 70,156 tuberculous cows, of which 1,040, or 1.4 per cent., had tuberculosis of the udder. The same authority states that Röckl found 1.62 per cent. of udder lesions among tuberculous cows in Germany. It would seem, therefore, that we might assume that in round numbers 1.5 per cent. of cows reacting to tuberculin may be expected to have lesions in the mammary glands. This subject is of considerable importance, because it has been assumed by some writers that the milk of tuberculous cows was dangerous only when the udder was directly involved; and evidently the milk must be more dangerous when there are such local lesions than when the tubercles are confined to other parts of the body.

Proportion of Reacting Cows in which the Milk is Virulent.—It has often been held that the milk of tuberculous cows is free from infective qualities until the mammary glands become affected. Numerous experiments have been made with the milk from reacting cows, some of which have given negative results, but in others it has been shown that from ten to sixty-six per cent. of the reacting cows gave virulent milk even when no lesions of the udder could be detected. In a recent investigation made by the pathological division of the Bureau of Animal Industry with fifty-six reacting cows it was found that twelve of these, or 21.4 per cent., at one time or another during the experiment gave milk which contained virulent tubercle bacilli. Taking all the researches on this subject, it is clear that the proportion of reacting cows giving infective milk is very much larger than the percentage of udder tuberculosis in tuberculous animals. The bacilli must, therefore, find their way to the mammary glands from the other organs of the body where the lesions are developing, and, passing through the capillary walls, gain access to the milk ducts.

Transmission of Bovine Tuberculosis to Man.—There has been much discussion over the question of the transmission of animal tuberculosis to man. Previous to the discovery of the tubercle bacillus there was much doubt as to whether the tuberculosis of cattle and human tuberculosis were identical. But when it was shown that each was produced by the *Bacillus tuberculosis*, there was a general disposition to accept the identity of the disease in the two cases and admit that it was communicable in either direction. Experimenters found, however, that the tubercle bacilli, as observed in different species of animals, varied considerably in their biological characters, and that it was difficult to transfer them, by inoculation, from some species of animals to others. It was shown that inoculations of cattle with the sputum of tuberculous persons generally failed to produce serious results, while similar inoculations with tuberculous material from bovine animals were generally fatal. There was a disposition on the part of some authorities to conclude that there might be a difference between the tuberculosis of man and that of cattle, and that it was doubtful if the disease could be transferred either from the human subject to cattle or from cattle to man. These suppositions culminated in the address of Koch at the British Congress on Tuberculosis held in London in 1901.

In this memorable address Koch held, from the results of his experiments, that human tuberculosis could not be communicated to cattle, and that if bovine tuberculosis was communicated to man this was only to an insignificant extent, the cases occurring from this source not being greater, in his opinion, than those from hereditary tuberculosis.

Numerous experiments have since been made to determine this point, and it has been found that tubercle bacilli from human subjects vary greatly in their virulence and power to cause disease in cattle. A number of investigators have succeeded in isolating bacilli from human material which were as virulent for cattle as were the bacilli obtained from the bovine subject.

A German commission was appointed to investigate this question, and the results of its experiments have recently been made known by Kossel. This commission has been more successful in producing tuberculosis in cattle with bacilli from human sources than was Koch in his experiments upon which his London paper was based. Altogether, cultures from 39 cases of tuberculosis in man were tested according to the principles laid down by Koch. He concluded that human tuberculosis was not communicable to cattle, and that therefore if cattle were inoculated subcutaneously with cultures of bacilli from human subjects and a progressive and fatal disease was produced, this would demonstrate that the person had been infected with bovine bacilli. Of the 39 cultures tested, 19, or a little less than 50 per cent., did not produce the slightest symptoms in cattle. Nine cattle exhibited, in the prescapular glands, after the lapse of four months, foci which were mostly encysted, and which in any case showed no inclination to develop. In 7 of the cases more marked disease of the prescapular glands occurred, but there was no considerable extension of the process to the adjoining glands. Four of the cultures, all of which were from children, caused generalized disease in the cattle upon which they were inoculated. These cultures were so virulent for cattle that they were considered as having been originally bovine bacilli. As there were 16 cultures of tubercle bacilli from children tested, and 4 of these had the virulence for cattle of the bovine bacillus, it is evident that 25 per cent. of the cases of tuberculosis in children investigated by this commission were due to bovine infection, according to the test proposed by Koch. On the other hand, no bacilli were found among the 23 cultures obtained from adults which were virulent for cattle. The experiments made by this commission and by other investigators apparently settle the question of the transmission of bovine tuberculosis to children, and indicate that this occurs with considerable frequency, and that measures should be taken to guard against it.

Rabies.—Rabies is a contagious disease of dogs in which the saliva is virulent, and the contagion is communicated from animal to animal by biting. The human species, and nearly all species of animals, are susceptible to this disease and contract it when inoculated. The disease is not communicated otherwise than by direct inoculation.

This disease appears to have been known from the earliest historical times, and has been referred to with such detail as to manner of transmission and symptoms that there can be no doubt as to the identity of the disease with that which is now known under this name. There have been numerous cases recorded in which the disease spread among wolves, and these animals became so savage that they attacked human beings and caused many cases of rabies in man. Notwithstanding the length of time during which the disease has been described, there have been many who doubted its existence, and especially doubted its being communicated to the human subject. These people explain the deaths of persons following bites of rabid dogs by attributing them to nervous troubles produced by fear. Questions relative to the nature and identity of rabies were in much confusion until the subject was taken up by investigators and studied experimentally.

Zinke in 1804, and Count Salm-Reiferscheid in 1813, recorded successful experiments in the communication of rabies from animal to animal by inoculation. From 1836 to 1860 Renault and Rey in France made many successful inoculations, demonstrating that this was a specific disease, and that the period of incubation might vary from ten days to over one hundred days. Magendie, Earle, Hertwig, Renault, and others made successful inoculations from man to animals, proving that the human subjects were affected with this specific disease, and that the contagion could be reinoculated into animals, such as dogs and rabbits, and reproduce the disease in them. In Magendie's case the dog which was inoculated from the human subject was allowed to bite two other dogs, which in turn became rabid after forty days. It was consequently demonstrated that rabies is communicable to man as well as to animals, and that the saliva becomes virulent with man as it does with the lower animals. The value of rabbits for making the biological tests of rabies was pointed out by Galtier in 1879, and by Pasteur a few years later. The investigations of Pasteur (1881) showed the constant virulence of the brain and medulla, and that these organs, being protected from saprophytic germs, furnished a pure virus which might be used for biological tests. He also showed the value of the method of inoculating upon the surface of the brain, in which case the disease was transmitted with great certainty and the period of incubation was reduced to a minimum. This method of inoculation has been of much value to investigators in saving time and in making their results more accurate.

Notwithstanding the experimental demonstration that rabies is a specific disease and can be easily transmitted by inoculation from animal to animal or from man to animal, there are still physicians who express doubts as to the existence of the disease. Those who oppose the enforcement of measures for reducing or eradicating the disease in dogs support their position by quoting the sceptical opinions of such physicians, and are often able to counteract the efforts of sanitarians to lessen the evil. It has been alleged that disease with the symptoms of rabies could be produced in animals by inoculating them in the surface of the brain with various inert substances, and the conclusion was drawn from this that the disease produced when inoculating from brain to brain of supposedly rabid animals was a non-specific disorder of the nervous system. This rather far-fetched conclusion never had much foundation in fact, and has been completely disproved. It is impossible to produce a disease having the period of incubation and symptoms of rabies by inoculating with inert substances, and the disease which is produced in that manner is not communicable from animal to animal, neither is such disease accompanied by virulent saliva, nor can it be reproduced in dogs and cattle by inoculating subcutaneously with the saliva or with portions of the medulla, as can be readily done with rabies. The scientific demonstration of the existence of rabies as a specific disease is as complete as has been made in the case of any other disease, and it is decidedly unfortunate that so many physicians have failed to inform themselves of the details of these investigations. The general public look to physicians for reliable information on such questions, and when the opinions which they receive are uncertain or even erroneous, great harm is done in preventing the adoption and enforcement of proper sanitary measures.

Symptoms of Rabies.—The symptoms of rabies are such as we should expect to arise from a serious disease of the central organs of the nervous system. There are, first, irritation; second, paralysis and death. The rabies virus appears to have little effect upon the system until it reaches the brain and spinal cord, where it multiplies, causes irritation, and finally interrupts the functions.

Rabies in dogs is generally classified in two forms: First, furious rabies; second, dumb rabies. In the former the animal is irritable, aggressive, and bites nearly every object which comes in its way. In the latter, the muscles of its jaw are paralyzed almost from the first appearance of symptoms, and being unable to bite, it remains more quiet and tranquil. As a matter of fact there is no essential difference in these two forms of disease. The cases of dumb rabies are those in which the paralysis comes on early in the disease; but in all cases it appears sooner or later. The saliva from a case of dumb rabies is just as dangerous and virulent as that from a case of furious rabies. A dog does not necessarily bite everything which it comes in contact with, even when it has rabies and its jaws are not paralyzed. It may be aggressive and furious all of the time or only a part of the time, or not at all. There is no disease in which the symptoms vary more than in rabies of the dog, and it is consequently impossible in any description of moderate length to give an idea of the different forms under which it may appear.

Fleming has well said that it is a great and dangerous error to suppose that the disease commences with signs of raging madness, and that the earliest phase of the malady is ushered in with fury and destruction. The symptoms appear very gradually, and at first there is only the slightest evidence of brain disease. The animal's habits and behavior are changed. It may be more restless and affectionate than usual, seeking to be near its master or mistress, fawning or licking the hands and face, and apparently seeking for sympathy or assistance. Such caresses are, however, extremely dangerous, for it has been shown that the dog's saliva is virulent for a day or two before the appearance of any symptoms, and its tongue, moist with virulent saliva, coming in contact with a part where the skin is thin, abraded, or wounded, may fatally infect the person for whom the demonstrations of affection are made. The instances in which hydrophobia has developed from such inoculations are very numerous, and every one should be warned against this kiss of affection from a dog in the first stages of this disease, which carries with it not only death, but sufferings which are dreaded more than death itself.

In most cases dogs first become dull, gloomy, morose, taciturn, and seek solitude and isolation in quiet, sheltered places or under pieces of furniture. But even in this retirement they do not remain quiet. They are uneasy and agitated; they lie down and assume the attitude of repose, but in a few minutes are up again walking hither and thither, as has been said, "seeking rest but finding none." Sometimes this restlessness may disappear for a time and the animal becomes more lively and affectionate than usual. Often it sinks into a sullen gloominess from which even its master's voice arouses it but temporarily. It becomes more and more desperate in its efforts to prepare a comfortable bed, pawing or scattering the straw, or, if in a house, scratching, tumbling, and tearing cushions, rugs, curtains, carpets, and everything of that kind within its reach.

At this period dogs may have aberrations of the senses, of the sight, hearing, and feeling, which cause hallucinations and lead them to think that they are being annoyed by something, or that some animal or person is endeavoring to injure them. They crouch ready to spring upon an imaginary enemy, then rush forward and snap at the air; or they throw themselves howling and furious against a wall as though they heard sounds beyond it.

While at first the affected dog may not be disposed to bite, it becomes more dangerous as its hallucinations and delirium increase. The voice of the master or of an acquaintance may dispel the aberrations temporarily and lead to friendly demonstrations, but an unexpected movement or touch may bring on another access and lead to a quick and unexpected bite. The disturbance of the sensations leads to chills and itching. If the place where the bite occurred is accessible, the dog licks the scar and later bites and tears the tissues. This tearing of the flesh is not always confined to the site of the inoculation, but certain regions of the body appear to lose their sensitiveness, and at the same time to convey to the brain the sensation of itching. The animal in this case bites into its own flesh with apparent pleasure and satisfaction.

Such animals may take food until the disease is considerably advanced, if it is something which can be swallowed without mastication; otherwise it is dropped after remaining a short time in the mouth. Difficulty of swallowing is an early symptom, and frequently leads the unsuspecting owner to conclude that the animal has a bone in its throat. A dog which appears to have a bone in its throat is for this reason one of the most dangerous animals in existence. The supposed bone may be there, but on the other hand the symptoms which lead to this supposition may be due to partial paralysis caused by rabies, and the owner may be inoculated with the virulent saliva while thrusting his finger or hand in the dog's mouth to dislodge a bone which has no existence.

It is commonly believed that mad dogs have fear of water and are unable to drink, but this is incorrect. They differ in this respect entirely from the human patient. They have no fear or dread of water, but swim streams and continue to drink until paralysis has progressed so far that they are no longer able to swallow.

When the furious symptoms come on, a dog is inclined to leave his home and go upon a long chase, with no apparent object in view other than to be travelling onward. He trots at a rapid pace, eye haggard, tail depressed, indifferent to his surroundings. He flies at and bites dogs, other animals, and persons whom he meets, but usually does not apparently search for them or even notice them if they remain quiet. Dogs in this condition may travel many miles and finally drop from exhaustion and die. Often after an absence of a day or two they return to their homes, exhausted, emaciated, covered with dust, and presenting a forlorn and dejected appearance. Those who have pity for such an animal and try to make it clean and comfortable are in great danger of being bitten, for the disease has advanced to a point where delirium or aberration of mind is most marked, and where a treacherous bite is most common.

If the animal, instead of being allowed to escape, is kept confined, the paroxysms of fury are seen to appear intermittently, or, in the absence of provocation, they may be entirely wanting. When excited, it howls, rushes upon objects that are thrust toward it, or throws itself upon the bars of its cage and bites with great fury.

As death approaches, the animal becomes exhausted and scarcely able to stand; the eyes are dull and sunken, and the expression is that of suffering and despair. Paralysis appears in the jaws or in the posterior extremities, and extends rapidly to other parts of the body. The animal, being unable to stand, lies extended upon its side; the respiration becomes more and more difficult; there are spasmodic contractions of certain groups of muscles, complete prostration, and death. The ordinary course of the disease is four or five days. It may be as short as two or as long as ten days.

In a typical form of dumb rabies the disease comes on with restlessness, depression, a tendency to lick objects, and paralysis of the muscles which close the jaws. As a consequence of the paralysis, the lower jaw drops, the animal is unable to close the mouth, the tongue hangs out, and an abundance of saliva escapes. This condition has led to the erroneous conclusion that mad dogs always froth at the mouth. Later, the mucous membrane of the mouth becomes dry, discolored, and covered with dust.

nimal remains quiet, does not respond to provoca- and appears to understand its helplessness. As y has said, the animal cannot bite and does not to bite. The course of the disease in this form is death usually occurring in from two to four days. form of rabies is very common, and many persons it as "drop jaw" who do not suspect its true na-

iod of Incubation.—The incubation of rabies in per- or animals which have been bitten is extremely le. Peuch has compiled a table of one hundred rty-four cases of rabies in the dog, in which the f inoculation and the appearance of the first symp- were definitely ascertained. This table is repro- from the "Nouveau Dictionnaire de Médecine, irurgie et d'Hygiène Vetérinaire," and the writer ded a column of percentages.

plain, therefore, that when a dog has been bitten ot be safely allowed to roam at large after it has solated but a few weeks. For absolute safety, log bitten by a rabid animal should be destroyed, quarantine less than a year can be regarded as afe.

Effect of Seasons upon the Development of Rabies.— pearance of rabies is not confined to the hot months mer, as is often supposed, nor to any other one of the year. The writer has compiled a table of f rabies in dogs by months, which were recorded l authority. This table covers 14,066 cases. The number of cases occurred in June, in which month ere 1,467. The smallest number of cases in any nth occurred in November, when there were 933. mber of cases in the other months varied between o extremes. This shows clearly that there is no of the year which is exempt.

Prevalence of Rabies.—Rabies is a common disease s in the United States. It has occurred contin- in the District of Columbia from 1895 to 1903, as by the investigations of the Bureau of Animal y. Reports have also been received of its exist- many parts of the United States, and particularly ities of New York, Philadelphia, Rochester, Buf- icago, Kansas City, Baltimore, and New Orleans. ave also been many reports of farm animals simi- fected in all parts of the country, but particularly ina, West Virginia, Pennsylvania, Ohio, Indiana, ebraska, Kansas, and Minnesota. These various indicate that the disease is disseminated over the ountry, and that the losses of farm animals from onsiderable. It would also appear that a much number of persons are annually bitten than be supposed from any pathological data which en published.

oms of Rabies.—The symptoms of rabies in the ges of the disease are not sufficiently definite to positive diagnosis to be made, but there is a general rule which has been laid down by all who have had much experience with the disease, and that is that every dog whose habits and disposition appear to be suddenly changed should be considered suspicious and should be isolated. The development of rabies is so rapid that in the course of three or four days all doubts should be removed. If a person has been bitten by a suspected dog, the animal should be placed in a secure enclosure and held until a positive diagnosis can be made. This is extremely important, as it gives the infected person an opportunity to take the Pasteur treatment at a time when there is the best prospect of success. If a suspected dog has bitten some person and is afterward killed, the head and a part of the neck should be removed for subsequent investigation. A histological examination of the plexiform ganglion permits of an almost certain diagnosis being made. The presence of foreign bodies in the stomach is confirmatory evidence of rabies. To make the diagnosis absolutely positive, rabbits should be inoculated by the subdural method. As this latter method requires from two to three weeks for results to be obtained, the value of the diagnosis from examination of the plexiform ganglion becomes apparent. The writer's attention has been brought to one case in which the person bitten presented the first symptoms of rabies on the same day that the disease was diagnosed with the inoculated rabbits. If the diagnosis had been made by the rapid method, there would probably have been time for successful preventive treatment.

The Prevention of Rabies.—As rabies occurs in nature only from the bite of a rabid animal, it is sufficient to prevent such biting to guard against the appearance of the disease. While all kinds of animals may bite when suffering from rabies, it is almost always a dog which is responsible for causing the disease in man, and it is believed that cats generally contract the disease from being bitten by dogs. Efforts for prevention are therefore directed to the canine species.

The measure generally adopted is the destruction of worthless, ownerless, and vagrant dogs, but this measure cannot do more than reduce the disease without preventing it entirely. The most efficient measure for preventing the spread of rabies is to cause the dogs to be muzzled or led with a leash whenever they are allowed to appear upon the streets or in public places. This measure, if rigidly enforced, will soon diminish the prevalence of the disease, and, if enforced for a sufficient time, will eradicate it entirely. The success of Germany, Holland, Great Britain, and other countries with this disease by rigid muzzling has been remarkable, and demonstrates that the same plan can be relied upon wherever it is properly carried out. Vigorous objections are made to muzzling by the owners of dogs, on the ground that muzzles are inconvenient and irritate the animals. A properly fitted muzzle, however, is not uncomfortable, nor does it interfere seriously with the dog, except to prevent his biting. The objections to muzzling regulations when rabies exists in a community are therefore unreasonable, and should neither be urged by good citizens nor encouraged by sanitary officers. If persons insist upon keeping animals which are subject to a disease which may be communicated to human beings and cause such terrible sufferings with absolute certainty of early death as follows infection with rabies, they should be willing to adopt any measures that are necessary for the protection of the community.

ANTHRAX.—Anthrax, a disease known by the French and in some parts of this country as charbon, is a disease which affects most species of warm-blooded animals, and is widely distributed, apparently occurring in all parts of the world. It is most frequent in alluvial valleys which are subject to inundations. In the United States it is most common in the southern portion of the Mississippi valley. It has been reported from many other localities, however, in the Northern States as well as in the Southern, and on the Pacific coast as well as on the Atlantic seaboard.

Anthrax is caused by the *Bacillus anthracis*, an organism which appears to be able to multiply in nature outside of the animal body under certain favorable conditions. It is a bacillus which forms spores, and in that condition it is killed only with difficulty by heat and disinfectants, and is able to retain its vitality for years in the soil. It is consequently one of the most persistent forms of contagion, and pastures once infected may be said to be permanently dangerous.

The disease is seen most frequently in cattle and sheep, animals which are very susceptible to it; but it also occurs in horses and mules and in rare instances in swine. It may begin as a local swelling on some portion of the surface of the body, or the infection may enter the body in such a manner that internal anthrax, or anthrax fever, results. In the case of external anthrax, a small, warm, and painful swelling develops—usually on the shoulder, the neck, the throat, or about the head, under the belly, or at some other point—which rapidly enlarges and very soon becomes of considerable size. If incised, a small quantity of colored serum escapes, and fibrinous clots form, having the appearance of yellow gelatinous masses. General symptoms soon appear, and the disease rapidly progresses to a fatal termination, or in some cases there is improvement and the animal recovers in the course of one or two weeks. With anthrax that has no external tumors there are only the symptoms of intense fever with rapid loss of strength, and death in the course of two or three days. Very often the disease is so violent in its manifestations that the animals die within ten or twelve hours. Sometimes they die very suddenly without presenting any marked symptoms.

Post-mortem Appearances.—The carcasses decompose rapidly, the abdomen being distended with gas a few minutes after death. The subcutaneous blood-vessels are distended with blood, and the connective tissue and muscles are stained with hemorrhages of various sizes. Blood and reddish serum escape into the connective tissue and into the cavities of the body. A fibrinous exudate colored with blood is often found in the connective tissue, in the abdominal cavity, and sometimes in the lumen of the intestines. The glands are enlarged, softened, and deeply colored. Ecchymoses on the serous surfaces are common. The liver is generally congested and friable and often of a yellowish color. The spleen is remarkable for its size, being five or six times as large as usual, and is softened, more or less broken down, and engorged with blood.

Diagnosis.—The points by which a diagnosis is made in anthrax are, the existence of the animals in an area known to be infected with anthrax, the rapid development of the disease and the violence of the symptoms, the dark color of the tissues after death, the gelatinous exudates, ecchymoses, and especially the enlarged, engorged, and broken-down condition of the spleen. A microscopic examination of the blood after the death of the animal shows the presence of the Bacillus anthracis. In case of doubt the inoculation of a rabbit or a guinea-pig may be resorted to. The death of these animals in from twelve to forty-eight hours with the Bacillus anthracis in the blood enables a positive diagnosis to be made.

Anthrax and the Public Health.—Anthrax is a disease very easily communicated to man, and is frequently fatal in its effects. It has often been known as malignant pustule, or wool-sorters' disease. While anthrax is not communicated except by direct inoculation, the contagion is so active that such inoculation readily occurs. Men who handle the carcasses of the dead animals, especially if they try to save the skins or the wool, are particularly exposed to inoculation. Flies which have fed upon the blood of the dead animals may carry a sufficient quantity upon their proboscides to inoculate persons whom they afterward bite. Infected wool, hair, and hides are, however, the principal sources of the contagion with man.

To prevent the communication of the disease from animals to the human subject vigorous efforts should be made to stamp out the disease on its first appearance. The carcasses of animals which die should be burned or deeply buried, being covered with quicklime. If the infection is from a circumscribed area, all animals should be removed from this to healthy pastures. Great care should be taken in moving the carcasses to the places where they are to be buried. All blood which has escaped from the body should be carefully removed, and the ground upon which the body has lain should be disinfected by burning. In working with wool and hair precautions should be taken to avoid so far as possible the inhalation of dust, and if suspicious swellings develop upon workmen who handle animal products they should receive prompt medical treatment.

Animals affected with anthrax generally present such evident symptoms of disease and die in such a short time that the carcasses very seldom go upon the market for food. However, there have been cases in which meat affected with anthrax has been sold and consumed, and in some cases it has caused many fatalities. The inspectors of meat should be on their guard and should carefully investigate all carcasses in which there are any appearances resembling those seen in this disease.

Prevention of Anthrax in Animals.—In some cases it is possible to prevent anthrax by keeping animals away from the infected pastures and by draining and cultivating such lands. In most cases the extension of the disease may be arrested by the prompt and proper disposal of the carcasses of the animals which die. In sections where the lands are extensively infected, vaccination with a properly prepared vaccine has been practised with considerable success.

GLANDERS.—Glanders is a contagious disease of the genus *Equus*, and is readily communicable to man. It is caused by the *Bacillus mallei*, and is characterized by the formation of nodules or tubercles, which degenerate into ulcers from which there is a characteristic discharge. It is a disease which, as seen in the horse, is generally chronic, with not very apparent symptoms and little fever.

Small nodules, from the size of a shot to that of a small pea, form in the mucous membranes of the respiratory tract. These may be seen just inside the wings of the nostrils or on the septum, and are easily detected. They are at first red and hard, but soon soften, become yellow, and break, giving rise to a small ulcer the size of the tubercle. This ulcer has a grayish bottom and ragged edges, and there is given off from it a viscous, oily discharge which is very characteristic of the disease. Glanders tubercles may also develop in the lungs and other internal organs.

Sometimes nodules appear on the under surface of the skin, which soften, discharge their contents, and are transformed into an irregular ulcer with ragged, overhanging edges. These often lead to irritation of the neighboring lymphatic vessels, which become swollen and indurated and appear as hard ridges which are hot and sensitive to the touch. These ulcers are seen most frequently on the lips and neck, the lower part of the shoulders, and the inside of the thighs, but they may occur on any part of the body. This form of glanders is called farcy. Farcy is sometimes looked upon as a milder disease than glanders, but it should be remembered that both are caused by the same contagion, and that the only difference is the organ in which the lesions are localized. The internal lesions characteristic of glanders, and the farcy ulcers, are often seen in the same animal.

In acute glanders there is a rapid development of tubercles in the respiratory tract, which rapidly degenerate into ulcers. There is an abundant discharge from the nostrils, with considerable fever and a cough which varies according to the location and character of the eruption. Swellings form over the surface of the body, rapidly followed by farcy buttons which break and form ulcers. Acute glanders is often fatal within a comparatively short time, although in some cases the symptoms subside and the disease takes on a chronic form. Chronic glanders may continue for months or even years. In most cases it results in death sooner or later, but occasionally animals improve and apparently recover. In these

-called recovered cases, however, the internal lesions nally remain and the animals continue to spread the ntagion.

Diagnosis.—The clinical diagnosis of glanders is based on the existence of the nodules and ulcers in the nos- ls, upon the character of the discharge, and the exist- ce of an enlarged, nodular gland beneath the jaw. In ses of doubt, guinea-pigs are inoculated, and these ani- ls develop a specific orchitis which enables a diagnosis be made.

In recent years the toxin produced by the culture of *Bacillus mallei*, which is known as mallein, has been ed as a test on the same principle that the tuberculin t is applied for the diagnosis of tuberculosis. It is in- ted subcutaneously, and if the horse is affected with nders there is an elevation of the animal's temperature d also a large, sensitive swelling at the point of inocu- ion. Mallein has been found very useful in picking t those animals in an infected stable in which the dis- e has not progressed far enough to show characteristic nptoms, and those in which the lesions are internal and which the general health of the animal is not affected.

Treatment.—For practical purposes glanders may be nsidered an incurable disease. The measures to be pted for its eradication are the prompt destruction of diseased animals as soon as a positive diagnosis can made, and the thorough disinfection of the stables in ich they have been kept and of all the articles, such harness, buckets, curry combs, and brushes, which e come in contact with them. Glanders is a common l widely disseminated disease, and more energetic asures than have heretofore been enforced are needed its suppression.

landers and the Public Health.—Glanders is communi- le to man by direct inoculation or by particles of the charge from a glandered horse coming in contact with mucous membranes of the eye, nose, or mouth. ally it is the persons who care for the glandered ses that become affected. Sometimes, however, per- s who are passing a diseased horse at the time when norts or coughs may become infected by the virulent cus lodging upon their mucous membranes or on the where there is an abraded surface. Cases are also wn in which a wife has taken the disease from her hus- d, and in which persons who have acted as nurses have tracted the disease from a patient. In man it is a hsome disease and one which usually ends in death. disease can be guarded against only by reducing the nber of glandered horses, and, in case of the disease nan, by taking suitable precautions to prevent the nsfer of the contagion to those who care for the pa- t

APEWORMS OF ANIMALS IN RELATION TO THE PUBLIC LTH.—The larval stages of several tapeworms are nd in the organs of the meat-producing animals. *icercus bovis* occurs in cattle, and when eaten by man s rise to the common tapeworm found in this coun- known as *Tænia saginata*. This tapeworm is not a dangerous parasite. It may bring about digestive ubles, and it is occasionally very difficult to expel, but rule we may say that the parasite is only of tempo- importance, its effects passing off when the worm is elled.

he *Cysticercus cellulosæ*, or larval form of *Tænia so-*, occurs in pork. When the infested pork is eaten adult parasite develops in man. Physicians should inguish between the two tapeworms mentioned, be- e *Tænia solium* is a very much more dangerous para- than *Tænia saginata*. If a patient soils his hands the microscopic eggs during defecation, or if he has rse peristalsis of the intestines strong enough to y one or more segments of the tapeworm into his nach, he may be infected with the larval stage of *ia solium*. In this case the embryos escape from the nents to the stomach and wander to various parts of body, more especially to the muscles, the eyes, and brain. If one or more of the larvæ develop in the eye the brain, more or less serious conditions may result, according to the part which is affected. The physician, in treating patients affected with the *Tænia solium*, is also exposed to some danger of infection with the eggs, and such infection would produce the larval stage.

The existence of these two parasites in American cattle and hogs makes it proper to suggest that the practising physician has a duty to perform in seeing that all tapeworms passed by his patients are totally destroyed, unless they are preserved for scientific investigation. It too often happens that the patient is not properly instructed in this matter, and passes the worm in some place where the eggs are scattered so that they afterward infect animals. It has been observed that the meat inspection in Germany has resulted in decreasing the frequency of tapeworm disease in man, and also the infection with the larval stage of *Tænia solium*. We have no exact statistics on this subject in the United States, but it would appear that the meat-inspection system must necessarily contribute somewhat to the decrease of these parasites.

Another parasite of this kind is the echinococcus, which causes the hydatid disease. It is a bladder worm which may be found in almost any part of the body of the meat-producing animals, and especially in the lungs and liver of cattle, sheep, and swine. This parasite is not directly transmissible to man by eating an organ affected with the bladder worm, but if the hydatid is fed to a dog each separate head of the cyst—and there may be thousands in a single cyst—develops into a tapeworm, the *Tænia echinococcus*. This is probably the smallest tapeworm known, having very few segments, and only the last segment is gravid with eggs. The dog scatters the eggs of this tapeworm broadcast, and the domesticated animals become infected with it. Mankind may also become infected by too close intimacy with dogs. In Iceland, where men and dogs live during the long months of winter in the same huts and without any idea of sanitary precautions, it is said that one person out of forty-three is infected with the echinococcus disease. In some parts of Germany the disease is also very frequent. Post-mortem statistics have been given, showing that at Rostock 2.43 per cent. of the cadavers were affected; at Breslau, 1.47 per cent.; at Berlin, 0.76 per cent. The disease can be controlled only by careful meat inspection and the destruction of all hydatids that are found. To prevent the multiplication of this parasite dogs should be prevented from feeding upon the offal of slaughter-houses.

Daniel E. Salmon.

VEVEY, SWITZERLAND.—Vevey, situated on the northeastern shore of Lake Geneva, four miles west from Montreux, has an admirable position and a mild climate, but is less favorably situated than the latter resort in respect to protection from the north and northeast winds, and has a more changeable temperature. Its altitude is 1,250 feet above sea level. It is a town of about 8,000 inhabitants, and is renowned for its lovely views of lake and mountain, its charming walks and excursions, and its cleanliness. Some one has called it Dutch in cleanliness, French in gayety and love of pleasure, and Swiss in its sentiment. Together with the other towns in this protected region, it has been called the "Nice of Switzerland."

It is recommended as a favorable place for the "after-cure" to those who have been taking the waters at Aix-les-Bains, Vichy, Carlsbad, and other spas. It is also a good place for a residence before and after the Riviera season. Autumn is considered the best season, at which time one can take the grape cure, for a description of which the reader is referred to the article *Meran*, in Volume V. of this HANDBOOK. In the summer the milk cure and lake baths are used.

The water supply comes from the mountains, and is said to be unexcelled. The mortality is very low.

In winter the mean temperature never goes below 32.5° F., and in summer rarely above 86° F. The average mean monthly temperature is as follows: January, 32.5° F.; February, 35° F.; March, 40.6° F.; April, 44.9° F.; May, 49.6° F.; June, 57.2° F.; July, 58.8° F.; August, 58.9° F.; September, 54.2° F.; October, 49° F.; November, 39.3° F.; December, 33.4° F. The yearly average is 46° F. The average number of rainy days for the year is sixty, and of snowy days, seven. Fog is rare. The "Bise" or cold north wind is often felt here and produces trying changes of temperature.

On account of the changeable temperature this resort is not to be recommended for pulmonary tuberculosis, but is favorable for convalescents, for persons suffering from general debility or from some nervous affection, for certain cases of digestive disturbances, and for those who for any reason are "run down." Higher latitudes can easily be reached by means of a funicular railway, and one can go from Vevey to the castle of Chillon by electric railway. Within easy distance of Vevey are very many walks and excursions through vineyards, parks, and gardens, affording extended and fine views. One also can make excursions on the lake, and there are boats for rowing. The accommodations are excellent, abundant, and not expensive; pensions abound. There are good physicians, and an English church.

Vevey is easily reached in about twenty-two hours from London, either by rail or by boat from Geneva, or from other points on the lake.

Lausanne, ten or fifteen miles farther west, possesses a climate somewhat similar to that of Vevey. It is cold in winter but sunny, and is exposed to the northerly and southwesterly winds. The town is hilly, and is 1,700 feet above sea-level. The especial features of this place are the inexpensive living and the excellent schools.

FIG. 5021.—View of Vevey as seen from the Eastern End of the Lake of Geneva.

Of all these resorts on the northern shore of Lake Geneva, Montreux possesses the best climate and has the most protection from the north winds. *Vide Montreux* in Volume V. of this HANDBOOK.

In the Rhone Valley, to the eastward, are several resorts of value, such as Aigle-Les-Bains, a hydrotherapeutic establishment; Champrey; Sierre; and particularly Bex, beautifully situated in the midst of the mountains and possessing a mild climate. Spring and autumn are the best seasons. Here one can take the grape cure, and also employ the saline springs which are used in the form of baths and douches, excellent facilities for which are afforded at the Grand Hôtel des Salines. (See *Bex* in Vol. I.

Edward O. Otis.

VIBURNUM OPULUS.—*Cramp Bark.* "The bark of *Viburnum Opulus* L. (fam. *Caprifoliaceæ*)," U. S. P. This is a large shrub growing in the northern parts of Europe, Asia, and America. It produces red fruits and in one of its cultivated forms is the snowball tree of our gardens. The bark is thus described in the Pharmacopœia:

"In flattish or curved bands, or occasionally in quills, sometimes 30 cm. long, and from 1 to 1.5 mm. thick; outer surface ash-gray, marked with scattered, somewhat transversely elongated warts of a brownish color, due to abrasion, and more or less marked with blackish dots, and chiefly in a longitudinal direction with black, irregular lines or thin ridges; underneath, the easily removed corky layer of a pale brownish or somewhat reddish-brown color; the inner surface dingy white or brownish; fracture tough, the tissue separating in layers; inodorous; taste somewhat astringent and bitter."

It is identical in composition and properties with the next, but is rather more frequently used for abdominal cramps. The dose is 4–8 c.c. (fl. ʒ i.–ij.), and it is commonly given in the form of the official fluid extract.

H. H. Rusby.

VIBURNUM PRUNIFOLIUM.—*Black Haw.* "The bark of *Viburnum prunifolium* L. (fam. *Caprifoliaceæ*)," U. S. P. This species is a shrub or small tree growing from Connecticut to Illinois and southward, with oval, obtuse or slightly pointed, finely serrated leaves, and sessile cymes of small white flowers. The stem-bark is in thin pieces or quills, glossy externally, of a purplish-brown color, with scattered warts and minute black dots; when collected from old wood it is grayish-brown; the inner surface of the stem-bark is smooth and varies in color from white to a pale rust-brown; fracture, short; odor, peculiar, somewhat like that of valerian; taste astringent and bitter. The root bark, which is very superior, is in small, chip-like, curved pieces, of a deep rust-brown and much more bitter.

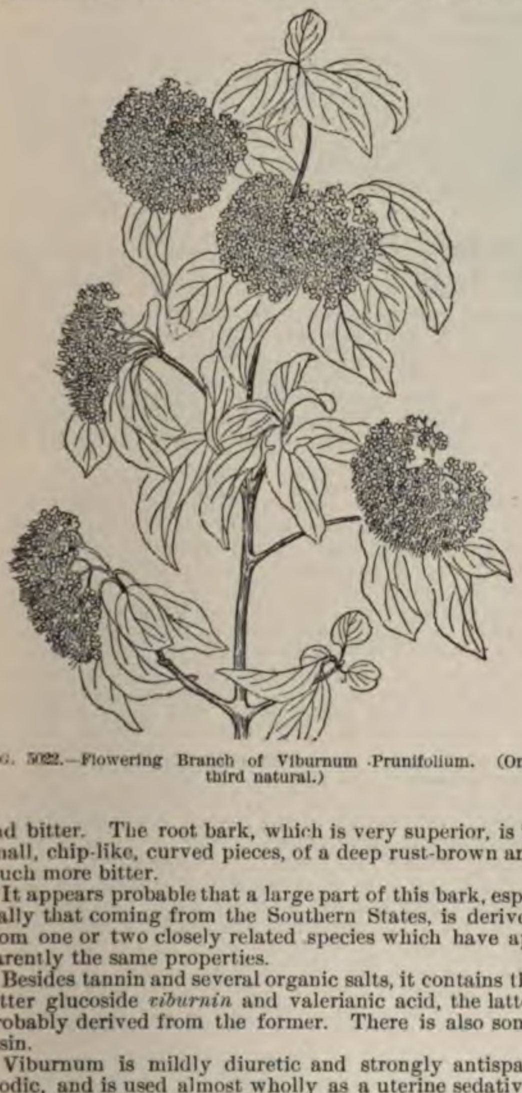

FIG. 5022.—Flowering Branch of Viburnum Prunifolium. (One-third natural.)

It appears probable that a large part of this bark, especially that coming from the Southern States, is derived from one or two closely related species which have apparently the same properties.

Besides tannin and several organic salts, it contains the bitter glucoside *viburnin* and valerianic acid, the latter probably derived from the former. There is also some resin.

Viburnum is mildly diuretic and strongly antispasmodic, and is used almost wholly as a uterine sedative. This use is chiefly in the prevention of threatened miscarriage, for which it is one of the most generally useful drugs, but it also extends to other spasmodic and painful uterine conditions. The dose is 1–4 c.c. (fl. ʒ ¼–i.), and the official fluid extract is commonly employed.

H. H. Rusby.

VICHY, FRANCE.—This far-famed resort, the most frequented in France if not in all Europe, is situated in the great central plain, on the right bank of the Allier River, at an elevation of about 750 feet above sea-level. It is easily reached from Paris, lying almost due south at a distance of about 230 miles. It has a permanent population of 12,000, augmented by from 50,000 to 60,000 visitors. In the season, which extends from May to October, it becomes a sort of second Paris in the character of its amusements and attractions. The climate is mild and much like that of Paris; during July and the first part August, however, the weather is often very hot. In the city there is a park with central garden containing the largest bath establishment in France; there is also a casino with a fine theatre, reading-rooms, etc. Indeed, every effort is made to render the resort most attractive to the visitor, as well as hygienically wholesome.

The waters are those known as thermal alkaline, different springs differing from one another chiefly in the temperature, which varies from 57° to 113° F., and in the amount of free carbonic acid gas. Some contain a very little iron. There are fourteen regular springs which constitute the principal group of the Vichy waters, and others in the neighborhood. The most important and best known of the Vichy waters are the Grande Grille, Célestins, Hôpital, Puits-Chomel, Lucas, Mesdames, Parc, Lardy, Puits-Carré, and Larband.

The following is the composition of the three first named of these springs according to Cyr in Jaccoud's "Noveau Dictionaire de Médecine et de Chirurgie Pratiques," given in grams per litre:

Solids.	Grande Grille.	Célestins.	Hôpital.
Sodium bicarbonate	4.883	5.103	5.029
Potassium bicarbonate	.352	.315	.440
Magnesium bicarbonate	.303	.328	.200
Strontium bicarbonate	.003	.005	.005
Calcium bicarbonate	.434	.462	.570
Ferrous bicarbonate	.004	.004	.004
Manganous bicarbonate	Trace.	Trace.	Trace.
Sodium sulphate	.291	.291	.291
Sodium phosphate	.130	.091	.046
Sodium arsenate	.002	.002	.002
Sodium borate	Trace.	Trace.	Trace.
Sodium chloride	.534	.534	.518
Silica	.070	.060	.050
Total solids	7.006	7.195	7.155
Temperature (Fahrenheit)	107.6°	57°	86°

The waters are used both for drinking and for baths. There are several large bathing establishments equipped with every hydrotherapeutic appliance: vapor baths, thermal mineral-water baths, douches, inhalations, douche massage, and carbonic-acid baths and douches. The water is clear, and the taste of the Grande Grille is not disagreeable. The waters are generally taken in small doses, 100–400 gm.—varying according to the individual and his malady—before meals. The waters of the different springs are not drunk indiscriminately, but each according to the malady: thus, for example, the Grande Grille is for hepatic troubles; the Célestins, for gout; and so on. It is well for the patient to consult one of the local physicians as to the kind of waters he should take and the method to be pursued in their use; and one is at no loss to find a medical adviser here, for there are said to be about a hundred.

The affections for which these waters are most frequently recommended are various dyspeptic conditions—the indigestion of chronic alcoholism, chronic catarrhal gastritis or enteritis in which there are no very acute symptoms; hepatic conditions—gall stones. "In the latter affection, the physicians at Vichy claim for the waters an absolutely curative power, asserting that they not only prevent the formation of gall stones, but even relieve the pain of an acute attack, restore the appetite, and cause the jaundice to disappear." Even when surgical interference is considered necessary, it is advised to try the waters before an operation, if one can delay without danger, and, if an operation has been performed, to follow it by a course of the waters. In gout, rheumatism, uric-acid diathesis and diabetes, these waters have been found to be beneficial. In certain pelvic disorders of women they are also said to be of value. At least one-half of all the patients who frequent this spa are said to be dyspeptics.

A course of these alkaline waters is somewhat severe, and one should possess a certain amount of constitutional vigor to take them with advantage. An after-cure in Switzerland or elsewhere in a tonic climate should follow the Vichy "cure."

The accommodations are excellent, and there is an English church service.

The waters are largely exported, and can be had in almost every civilized land. Artificial Vichy, a more or less perfect counterpart of the natural water, is likewise everywhere to be had.

For an extended account of Vichy, its various bath establishments, and indications for the use of its waters, the reader is referred to "Stations Hydro-Minérales, Climatériques et Maritimes de la France," Paris, 1900.

Edward O. Otis.

VICKSBURG, MISSISSIPPI.—This city, picturesquely situated on a high bluff overlooking the Mississippi River, is about equidistant from Memphis and New Orleans. It is not a health resort, but is mentioned here and a chart of its climate is given as illustrating the climate of the lower Mississippi valley. The city is the largest in the State, with a population of about fifteen thousand, and is commercially important. It is, however, best known historically from the important part which it played in the Civil War. Besides the attraction of its fine situation on the river, it is also worthy of a visit from the fact that it contains the largest national cemetery in the country—a sad and forcible reminder of the intense struggle that took place about it.

CLIMATE OF VICKSBURG, MISS., LAT. 32° 22′, LONG. 90° 53′. PERIOD OF OBSERVATION, TWELVE YEARS.

	Jan.	March.	May.	July.	Sept.	Nov.	Winter.	Year.
Temperature (Degrees Fahr.).—								
Average or normal..	48.4°	59.1°	73.4°	83.8°	79.7°	60.2°	50.4°	65.6°
Mean of warmest....	56.4	69.8	83.5	92.3	85.0	66.4		
Mean of coldest......	40.7	51.9	64.2	73.2	66.1	46 8		
Average daily range.	15.7	17 9	19.3	19.1	18.9	19.6		
Highest or maximum	80.0	85.0	95.0	100 0	98.0	84.5		
Lowest or minimum.	10.0	27.0	46.0	62.0	48.0	23.0		
Humidity.—								
Average relative.....	71.4%	64.4%	67.2%	72%	71.9%	70.8%	69.5%	69.6%
Precipitation.—								
Average in inches....	5.27	6.83	5.18	4.0	4.06	6.5	15.76	60.09
Wind.—								
Prevailing direction..	N.	S.	S.E.	S.W.	N.	S.E.	S.E.	S.E.
Average hourly velocity in miles........	5.9	6.8	5.2	4.0	3.9	6.2	6.2	5.4
Weather.—								
Av. No. clear days....	6.9	10.2	12.6	10.0	12.0	9.5	23.1	122.6
Av. No. fair days.....	9.9	10.6	11 7	14.9	11.2	11.1	30.0	142.8
Av. No. clear and fair days...............	16.8	20.8	24.3	24 9	23.2	20.6	53.1	265.4

Referring to the table, the reader will observe that the climate is quite semi-tropical—mild in winter and hot during a long summer. There is a large amount of rain quite evenly scattered throughout the year, although rather more falls in the spring. Attention is called to the small wind velocity, there being considerably greater freedom from wind in this valley station than at New Orleans at the mouth of the river, and at various other coast stations at this latitude or lower. There is a fair amount of sunshine, although the number of clear and fair days in this portion of the "sunny South" only exceeds the number in Boston, for example, by twenty-eight, and New York by fourteen.

Attention is also called to the similarity of this climate to that of the region represented by Little Rock, Ark. In the latter there are the same freedom from wind, about the same rainfall, and almost identically the same number of clear and fair days. The yearly temperature is also quite similar, though somewhat lower. It may be added that the climate of this region, represented by Vicksburg, is regarded as a healthful one.

Edward O. Otis.

VICTORIA, AUSTRALIA.—It is hardly to be supposed that an invalid from any part of Europe, or of the United States, or of Canada, would seek residence in so remote a country as Australia, and yet it will be of interest to give a brief summary of the climate of this portion of that country, containing, as it does, the most populous city of Australia, Melbourne; for the traveller or the merchant may have occasion to visit this portion of the world, if the invalid does not, and it may be of service to him to know something of the climatic conditions he is to encounter.

Victoria exhibits, in its physical features, the three divisions or regions common to the whole island continent: a littoral region of sixty or more miles in breadth; a mountain range approximately parallel to the coast, or from one to five thousand feet in elevation; and beyond these mountains lies the great inland basin, the home and origin of the hot winds. Of the peculiarities of the climate of the great inland basin or plains, perhaps sufficient mention has been made under the article *Australia* in Volume I. of the HANDBOOK, and it will be sufficient to repeat here that the climate of these vast plains is characterized by heat and dryness. The summers are hot, the thermometer frequently rising to 110° F., but the dryness of the air makes the heat more endurable. The other seasons of the year are "delightful." "In winter there is a little morning frost, but the midday is always warm. Autumn and spring present an almost ideal perfection of climate" (Lindsay). This is the great sheep-grazing country, the home of the "squatter."

The highland or mountain region exhibits the characteristic climatic features of altitudes: the range runs across the whole breadth of the colony, is well wooded, and the higher portions are often covered with snow. The existence of this mountain range is the one topographical feature of the country, says Richards, demanding attention on the part of any one desiring to understand the chief cause for such local modifications as exist in the general climate of the colony.

Of the coast region the climate of Melbourne can be taken as fairly representative, as well as representing in

a general way the climate of the whole colony, and a study of the chart of Melbourne, herewith given, will serve to demonstrate the leading climatic characteristics.

In the first place it is to be borne in mind that Australia is south of the equator, and, hence, the seasons are reversed from those in north latitude; their summer is our winter, and so on for the other seasons. Whereas the mean summer temperature is the same as that of middle Europe, it will be seen that it is subject to great variability. The hot winds blowing from the desert of central Australia produce sudden great elevations of temperature, rapidly followed by a fall produced by a change in the direction of the wind. These hot squalls, as they may be called, produced by the hot north winds, are accompanied by dust and by a very considerable fall in the humidity; indeed, the heat and dryness are so intense that on one occasion apples were literally roasted on the trees. The highest mean temperature occurs in January, and the lowest from the middle of July to the beginning of August.

The winter is usually characterized by frequent rains and high winds. Ice and frost infrequently occur at this season, and at Melbourne the temperature seldom falls much below the freezing point.

The autumn season (March, April, and May) is considered "the most genial and beautiful portion of the year"; the temperature is moderate, the north winds grow cooler, and vegetation, which has been withered by the summer's dryness and heat, bursts forth again as soon as the moisture returns.

The spring (September, October, and November) resembles in character the autumn; the weather is usually mild and even quite warm. Sometimes there is a large rainfall in October and November; or there may be considerable diminution of rain at the beginning of October, and in November the dry and even hot northerly winds may blow and parch the vegetation.

In brief, the climate of this region is characterized by high temperature and frequent dust storms, comparatively mild winters, and agreeable climatic conditions in spring and autumn.

Sudden and extreme variability of temperature is not uncommon, especially in summer. The rainfall varies largely in different seasons—from nineteen to thirty-two inches. The percentage of cloudiness appears to be pretty high, though in general cloudless sunshine is one of the features of the Australian climate. The wind velocity is considerable, and, as has been mentioned, the hot north wind of the summer is a veritable furnace blast.

Melbourne itself, a city of about 500,000 inhabitants, including its suburbs, lies at the head of Port Philip Bay, and is spread out over a large area. There are wide streets, numerous parks, squares, and gardens, and many fine public buildings. The number of suburban towns and the great expanse of the city are a striking feature of the place. Melbourne appears to be a healthy place of residence. In rural Victoria pulmonary tuberculosis is not very frequent, but in Melbourne, as in all large centres of population the world over, this disease is prevalent. In the coast region rheumatism and cardiac affections are said to be common. Malaria does not prevail in Australia.

Edward O. Otis.

VICTORIA MINERAL SPRINGS.—Custer County, Nebraska.

Post-Office.—New Helena. Hotel built recently.

New Helena is reached by the Burlington and Missouri Railroad. The springs are seven in number, and are at a level of 2,600 feet above tide water, in a level prairie country having fine roads. It is said that an average of three hundred and fifty clear, sunny days in the year may be counted upon in this region. The accommodations for visitors are limited at present, but improvements are at this time being added. The springs were discovered in 1888, and it is stated that no two of them are exactly alike. The largest, known as the "Magnesia" Spring, is used for bottling. Each spring has a different flow, yielding from twelve hundred to three thousand gallons per hour. An analysis, made in 1888, resulted as follows (we are unable to secure the name of the analyst): One United States gallon contains (solids): Calcium carbonate, gr. 15.63; magnesium carbonate, gr. 11.27; iron carbonate, gr. 0.08; sodium sulphate, gr. 2.16; calcium sulphate, gr. 18.03; magnesium sulphate, gr. 12.06; potassium sulphate, gr. 1.46; ammonium sulphate, gr. 0.23; sodium chloride, gr. 1.26; lithia, iodine, and bromine, traces. Total, 62.18 grains.

The water has an unvarying temperature of 55° F. It is coming into considerable use as a commercial water, and in addition to table and domestic use it is recommended for stomach and kidney disorders.

James K. Crook.

VICTORY STRONTIA SPA.—Put-in-Bay Island, Ohio. This mineral well is located on the spacious grounds of the palatial Hotel Victory, sixty miles by steamer on Lake Erie from Detroit, forty miles from Toledo, and twenty-two miles from Sandusky. The well is four hundred and ninety feet deep, and is sheathed with an iron casing for about two hundred feet. The water rises to a level of twenty-five feet from the ground surface and its supply appears to be practically inexhaustible. The following analysis was made by G. A. Kirchmaier, Ph.D., chemist to the Ohio Dairy Food Commission: One United States gallon contains (solids): Strontium sulphate, gr. 33.75; calcium sulphate, gr. 65.98; magnesium carbonate, gr. 14.35; calcium carbonate, gr. 25.69; iron, gr. 0.20; sodium chloride, gr. 1.12; potassium chloride, gr. 0.91; silica, gr. 0.14; alumina, gr. 0.08. Total solids, 142.22 grains.

This analysis is chiefly noteworthy on account of the large quantity of the comparatively rare ingredient of strontium which it exhibits. The therapeutical relations of this agent have not yet been fully outlined. Some of the salts of strontium have been found to possess a useful application in chronic gouty manifestations, in muscular and in subacute articular rheumatism, and in diabetes. More recently it has been employed with apparent advantage in parenchymatous nephritis. Some observers have recommended strontium as a valuable intestinal antiseptic, and useful in flatulent dyspepsia, with fermentative changes in the alimentary tract. Aside from the possession of this ingredient the waters of the Victory Spa would appear to possess useful properties as a mild saline laxative and antacid. The fortunate location of the well so near the big summer hotel, whose name it bears, will no doubt serve to bring it to speedy notice.

James K. Crook.

VILLACABRAS SPRINGS, SPAIN.—The springs of Villacabras are situated in the province of Madrid, Spain, and are owned by a French company which exports this water under the above name. It is a natural mineral purgative water, and is said to have neither a repulsive smell nor a bitter taste, and to be painless in its action.

The analysis, made by Prof. C. F. Chandler, of New York, is as follows:

In one United States gallon there are (solids): Sulphate of soda, gr. 9,340.5765; sulphate of potash, traces; sulphate of magnesia, gr. 218.3164; sulphate of lime, gr. 119.0627; sulphates of iron and alumina, traces; chloride of sodium, gr. 50.9641; silica, gr. 2.2219. Total, 9,726.1416 grains.

As will be seen from the above, the "Glauber's salt" is the principal ingredient of this water, and the one upon which its purgative action depends. The dose is, as a laxative, from four or five tablespoonfuls; as a purgative, half a tumblerful or more. The effect of the water is said to be increased if it is diluted, and it is therefore recommended that in intervals between the doses some light liquid nourishment or plain water be taken.

Villacabras water can be recommended for those conditions which require a non-stimulating laxative or purgative, such as hepatic torpor, chronic constipation, gastro-intestinal catarrh, etc. It is also recommended for children and persons of delicate taste on account of its freedom from objectional odor and bitter taste.

Edward O. Otis.

VIOFORM, iodochloroxychinoline, is an antiseptic powder recommended by Tavel, Bischler, and others as an efficient and odorless substitute for iodoform.

W. A. Bastedo.

VIRGIN HOT SPRINGS.—Washington County, Utah.

Post-Office.—Washington. Visitors accommodated in ranches near by.

These springs are located on the Rio Virgin, four miles south of Tognerville. The nearest railroad station is at Milford, Beaver County, eighty miles distant, by private conveyance. The elevation here is 3,200 feet above the sea-level. The surrounding country is of a rugged, mountainous character. According to Mr. Thomas Judd, of St. George, Washington County, the rainfall does not exceed three and one-half inches annually. The air is mild, sweet, and balmy, even during the winter months. On February 27th, 1896, the date of Mr. Judd's letter, almond and apricot trees were in full bloom in the open air. The springs are six in number, and supply a stream large enough to run a grist mill. The temperature of the water is 130° F. No analysis has yet been made. The springs have not been much improved as yet, but are resorted to by the settlers for rheumatism, skin diseases, and other affections. It is the intention of the present owners to put the springs into proper shape as a health resort as soon as the railroad has been completed to within a reasonably accessible distance.

VISCERA, HOLLOW, AND BONY SINUSES, MEASUREMENTS OF.—The formation of a standard of measurements of the hollow viscera of the human subject is attended with the difficulty that the viscera themselves vary in size, even in the same individual at different times. A cavity or tube with soft, yielding, elastic, muscular walls, allowing expansion and contraction within wide limits, must be always changing in size with the changes in its solid, liquid, or gaseous contents. There cannot, therefore, be any fixed, determinate standard; but the size must be said to be *about* thus and so, varying not only with the conditions just stated but with the development of the individual. Any consideration of dilatations due to obstruction below, or of abnormal contractions due to disease of the part itself, is outside the scope of this article; but these variations illustrate well the degree which expansion or contraction may attain.

The basis of this article is mainly the work of previous investigators, supplemented by some of my own. In determining what should be considered hollow organs there was some difficulty, since all the vascular and mucous canals might be included. I decided to limit the article to the subjects mentioned below; and, at the suggestion of the editor, I have added the maxillary sinus. For measurements of the nose, mouth, heart, and womb and its appendages, I would refer to the special articles in this Handbook, and to monographs and text-books treating of those organs. Much valuable information is obtainable from Cruveilhier, Cloquet, Quain, Allen, Holden, Mackenzie, Todd and Bowman, and Richardson.

Measurements of diameters may be understood as including the walls of the cavity or canal, which are usually so thin as practically not materially to alter what, at the best, are variable results. In some cases, as in the investigations of Mackenzie on the œsophagus, plaster-of-Paris was run into the viscus and allowed to harden. The measurements were then taken upon the mould. Whatever material is used for filling or injection, it will, of course, be necessary to support the organ in water or other fluid, to prevent misshapement; I suspect that even then the best obtainable results would be only approximately correct.

The *pharynx* is a bag-like canal, closed above but continuous below with the œsophagus, communicating in front with the nose, fauces, and larynx, and lying at the back against the first five cervical vertebræ. Its œsophageal end is usually opposite the cricoid cartilage in front and the body of the fifth cervical vertebra behind. Its length and diameters vary according as the organ is in a state of rest, or as deglutition or speech is taking place.

It is subdivided into three portions: A nasal portion, or naso-pharynx; a buccal and guttural portion, or oro-pharynx; and the laryngo-pharynx. In the modulation of the voice the oro-pharynx is the part almost exclusively affected; in deglutition, movements of both oro- and laryngo-pharynx take place.

The length is usually stated to be from 4 to 4.5 in. (10 to 11.5 cm.) which may be increased to 5.5, or even 6.5 in. (14 to 16.5 cm.), by distention, or reduced to 2.5 in. (6.5 cm.) in the greatest possible contraction. Mackenzie gives the maximum length at about 5, and Allen at 5.5 in. (12.5 to 14 cm.). Allen gives the length of the naso-pharynx at 1.5 to 2 in. (4 to 5 cm.).

The breadth varies in different parts. The superior transverse diameter, measured between the posterior margins of the internal pterygoid plates, is, according to Mackenzie, 1.6 in. (4 cm.), to Cruveilhier, 1 in. (2.5 cm.), and to Allen, 8 lines (16 mm.). This diversity of measurements shows well the great variation in size in different subjects.

The diameter of the buccal portion, taken between the posterior extremities of the alveolar borders, is, according to Cruveilhier, about 2 in. (5 cm.), but may be reduced to 1 inch by the contraction of the constrictors.

The widest part of the laryngo-pharynx, opposite the greater cornua of the hyoid bone, measures 2 in. (5 cm.). Cruveilhier, however, measuring between the summits of the greater cornua, found but 1 in. and 2 lines (3 cm.); and between the superior cornua of the thyroid cartilage, 1 in. and 2 or 3 lines (3 cm.). [A comparison of hyoid bones from different adults has given me distances, between the summits of the greater cornua, varying from $1\frac{5}{16}$ in. (33 mm.) to $1\frac{10}{16}$ in. (41 mm.)].

The narrowest part, opposite the cricoid cartilage, is about 1 in. (2.5 cm.). Cruveilhier gives the breadth in the interval between the inferior cornua of the thyroid cartilage as about 11 or 12 lines (2.5 cm.); muscular contraction here may obliterate the cavity.

The antero-posterior diameter varies less than the vertical or transverse. It is increased when the larynx is carried upward and forward, and diminished when it is carried upward and backward; it may be said to depend generally on the length of the basilar process of the occipital bone. Mackenzie gives it as $\frac{4}{5}$ in. (20 mm.) for the naso-pharynx.

The *œsophagus* varies in length according to the stature of the individual. The canal extends from opposite the fifth cervical vertebra to the level of the tenth thoracic. In the adult male it is from 9 to 11 in. (23 to 28 cm.) in length.

The diameter varies at different levels. It is narrowest at the beginning, opposite the cricoid cartilage, and becomes narrowed also somewhat in passing through the diaphragm. Allen states that it is narrowed at the beginning of the thoracic portion, being there 1 in. (2.5 cm.) in diameter. Mouton and Mackenzie made elaborate measurements, which show, among other things, that the transverse diameter is much greater than the antero-posterior. A comparison shows the transverse diameter at the beginning of the canal to be from $\frac{4}{5}$ to 1 in. (21 to 25 mm.); 6 inches below this point, $\frac{3}{4}$ to $\frac{4}{5}$ in. (18 to 21 mm.). It then steadily increases until it reaches 1 in. (25 to 27 mm.). It is from $\frac{5}{8}$ to 1 in. (16 to 25 mm.) where the tube passes through the diaphragm, and then slightly increases.

The antero-posterior diameter at its origin is ⅜ to ⅝ in. 0 to 14 mm.); at one-third of its length below, ½ to ¾ i. (13 to 19 mm.); at a point two-thirds of the way own, ⅝ to ¾ in. (15 to 20 mm.); at the lower end, ½ to 1 . (14 to 25 mm.).

The method of examination is to fill the œsophagus ith plaster-of-Paris and measure the mould.

The *stomach* is very mobile and distensible, is subject prolonged distention, and may also contract much hen empty. It is much larger in those who eat but e, and that a full, meal a day. In certain diseased nditions, as in stricture of the pylorus, it may become ormously distended. In long-continued abstinence it comes much contracted. As the result of the action of ong acids, it is said to have contracted to the size of an dinary gall bladder.

Its length, from the cardiac cul-de-sac to the pylorus, from 9 to 12 in. (23 to 30 cm.); Todd gives it as from to 15 in. (33 to 40.5 cm.). The widest diameter is be- een 4 and 5 in. (10 to 12.5 cm.); at the pylorus it asures 2 in. (5 cm.), and for the whole organ 4 in. (10 .). The total surface is about 1¼ square foot; capac- , about 175 cub. in. or 5 pints (2.5 litres); Allen esti- tes the capacity as 62 ounces. The greatest circum- ence is 13 in. (33 cm.); the smallest, 3 in. (7.5 cm.).

The *small intestine.* It is probably impossible to meas- the length of the small intestine with anything more n an approach to accuracy, because of its convoluted pe. After the mesentery is cut away preliminary to measurements the intestine becomes lengthened im- diately on manipulation, so that the length is greater n it was before the section. The calibre, too, is very able, according to the increase and decrease of gas- s and other contents. Its length is usually stated at to 25 ft. (6 to 7.5 metres).

ts calibre gradually diminishes from the beginning to point of junction with the large intestine. Some of older anatomists, as Cruveilhier, stated incorrectly t the intestine was funnel-shaped. Sometimes, in ob- ction of the bowel, it becomes enormously dilated; at other times may be exceedingly contracted. en distended it is cylindrical; when empty it may be ptical.

he *duodenum* extends, in the shape of a horseshoe, n the pyloric end of the stomach to the left side of second lumbar vertebra, opposite the superior mesen- artery and vein. It is named from its length, which qual to the breadth of twelve fingers. Most authors the length as from 10 to 12 in. (25 to 30 cm.); Cru- hier and Richardson make it 8 or 9 in. (20 to 22.5). It may be subdivided into four portions. The . the ascending or hepatic, extends horizontally back- d and to the right, and joins the second portion near neck of the gall bladder; it is about 2 in. (5 cm.) . The second, or vertical portion, uniting at an an- with the first, descends vertically and a little toward left, as far as the third lumbar vertebra. Its length m 2 to 3 in. (5 to 7.5 cm.). The third, or lower sverse portion, directly continuous with the second, e longest and narrowest of the three; its length g from 3 to 4 in. (7.5 to 10 cm.), or, according to d, 5 in. (12.5 cm.). The fourth or second ascending ion ascends vertically by the left side of the spine, is 1 in. long, (2.5 cm.).

e calibre of the small intestine is 1¼ to 2 in. (3 to 5 . My own measurements in the adult have given 1⅛ ¼ in. (28 to 31 mm.), and in the new-born infant ¼ 6 mm.). The circumference, as measured by Cru- ier, was from 5 to 6½ in. (12.5 to 16 cm.) at the begin- of the small intestine, 4⅛ in. (10.5 cm.) at the mid- 3½ in. (nearly 9 cm.) a little above the ileo-colic e, and 4½ in. (11.5 cm.) at the valve itself.

e *large intestine*, after removal from the cadaver, readily be measured along its tapes. Its length is 4 to 6 ft. (1.2 to 1.8 metre). Distention is said to nish the length.

diameter gradually diminishes from its beginning to nd, except that there is a considerable dilatation just above the anus. In a general way, it may be stated to be from 1⅜ to 2¾ in. (3.5 to 7 cm.).

The measurements of the individual parts are as follows:

The *cæcum* is the largest part of the large intestine (it is small in the carnivora, large in the herbivora). Its length is three or four fingers' breadth, from 2 to 4 in. (5 to 10 cm.). Its diameter is about the same as the length. Cruveilhier made two measurements of its circumference, the cæcum being moderately distended; just below the ileo-colic valve it measured 11 in. and 3 lines (28.5 cm.); in another subject, 9½ in. (16.5 cm.).

The *vermiform appendix* varies greatly in length, being from 1 to 6 in. (2.5 to 15 cm.). Its diameter is usually given as that of a crow quill or goose quill—about one-third of an inch (8 mm.). It is a little wider at the cæcal junction.

The *ascending colon* is about 8 in. long (20 cm.); the transverse colon, 12 in. (30 cm.); the descending colon, 11 in. (27.5 cm.); and the sigmoid flexure, 22 in. (56 cm.). Cloquet states that the transverse colon is longer and larger than the ascending and descending portions, which are about equal to each other. The diameter of the ascending portion is less than that of the cæcum, and greater than that of the transverse colon. The circumferences of the parts, according to Cruveilhier, are as follows: The ascending colon and right half of the arch, 8 in. 9 lines (22 cm.) in one subject, 5 in. (12.5 cm.) in another; of the left half of the arch and descending colon, 6 in. (15 cm.) in one, and 5½ in. (14 cm.) in the other. The sigmoid flexure was 5¼ in. (13.5 cm.) in circumference. My own measurements give a diameter of from 1⅝ in. (40 mm.) to 2½ in. (6.5 cm.) for the ascending and transverse portions and sigmoid flexure, and ¾ inch (18 mm.) for the descending portion, which, in my experience, is generally collapsed. In the infant, at term, the diameter of the colon wàs 1 in. (2.5 cm.).

The *rectum* is from 6 to 8 in. long (15 to 20 cm.). The first portion, from opposite the sacro-iliac joint to the middle of the sacrum, is about 3 in. (7.5 cm.) long; the second portion, to the end of the coccyx, 2½ to 3 in. (6.5 to 7.5 cm.); the third portion, 1 to 1½ in. (2.5 to 4 cm.). Its diameter in the upper part is the same as that of the colon, gradually increasing downward and finally contracting suddenly. Quain says that the upper part is narrower than the sigmoid flexure. According to Cruveilhier the circumference is 3 in. (7.5 cm.); in the lower part, 4 to 5 in. (10 to 12.5 cm.).

The *gall bladder* is from 3 to 4 in. long (7.5 to 10 cm.); and its diameter, at the widest part, is from 1 to 1½ in. (2.5 to 4 cm.); in the infant, at term, ½ in. (12 mm.). Its capacity is ½ to 1½ ounce (48 c.c.); it varies very much, and in some diseases may amount to 6 ounces (192 c.c.).

The *ureter* measures 12 to 18 in. (30 to 45 cm.) in length. In diameter it is equal to a crow quill or goose quill; the most contracted portion is in the substance of the bladder.

The *urinary bladder* is of a somewhat pyramidal shape; in a fairly dilated condition it measures about 5 in. by 3 in. (12.5 by 7.5 cm.); and its capacity is about 1 pint (0.5 litre), or, according to Allen, from 6 to 13 ounces (0.2 to 0.4 litre).

The female bladder is broader transversely and more capacious than the male. This may be partly due to the fact that women are more influenced by the customs of society than are men; and it is broader, also, more often in women who have borne children. The bladder is said to be relatively larger before than after birth, and relatively smaller in children than in adults. This also may be due to habit.

The temperament, nature of diet, temperature of the air, and position of the body, all may affect the size of the bladder.

The *vagina* of the unimpregnated woman averages 4 in. (10 cm.) in length on the anterior wall and 5 to 6 in. (12.5 to 15 cm.) on the posterior wall; according to Allen, the tube is 2½ in. (6.5 cm.) long, its posterior wall bein

5 lines (12 mm.) longer than the anterior. The walls may be separated in the virgin about 1 in. (2.5 cm.).

The *larynx* is said to be one-third larger in the male adult than in the female. The average length of the vocal cords is, in the male, 7 lines or ⅝ in. (14 mm.); in the female, 5 lines (10 mm.). The measurements in a number of male subjects did not vary the twelfth of an inch. In females the cords are about one-fourth shorter than in the male. The average length of the glottis is, in the male, 11 lines (23 mm.); in the female, 8 lines (16 mm.). The transverse diameter of the glottis is, in man, 3 to 4 lines (6 to 8 mm.); in woman, 2 to 3 lines (4 to 6 mm.). Mackenzie gives the diameter as ½ in. (12 mm.); in boys it is much less.

The *trachea* extends from opposite the fifth cervical vertebra to the second or third thoracic. Its length is from 4 to 5 in. (10 to 12.5 cm.), varying with the elevation and depression of the larynx and the extension and flexion of the neck. There is a difference of from 2 to 2½ in. (5 to 7.5 cm.) between full extension and extreme contraction, the contraction being limited by the contact of the rings.

Its diameter is directly related to the capacity of the lungs, and is greater in the male than in the female; it is about the same throughout its whole extent, varying according to age and individual peculiarities and is from ¾ to 1 in. (18 to 25 mm.). In a man, aged about ninety, whose trachea I measured, it was wider in the middle (namely, 1¼ in. or 31 mm.) than above or below, where it was 1 in. (25 mm.); antero-posteriorly the upper part measured 1 in. (2.5 cm.), the lower part ¾ in. (18 mm.).

The *right bronchus* is about 1 in. long (2.5 cm.); the left, 2 in. (5 cm.). The right is much wider than the left, its diameter being nearly as great as that of the trachea itself. In one woman whose trachea I measured, the diameter was 10 lines (20 mm.); the right bronchus was 8, the left 5 lines (16 and 10 mm.).

The *maxillary sinus*, or *antrum of Highmore*, varies greatly in capacity; it is relatively small in the young and large in the old. In a number of skulls of adults I found it to vary on the two sides. From its irregular shape I made no attempt to take its diameters, but only its capacity, which I obtained by crowding raw cotton against its connecting foramina and filling the sinus with mercury. In many measurements the capacity was found to be from 10 to 12 c.c. (℥ iiss. to iij.); in a few it was as low as 8.5 c.c., and in others as high as 15 c.c. (2.7 and 3.75 drachms).

The *external auditory meatus* consists of a bony and of a cartilaginous portion. According to some authors these are nearly equal in length; others, as Allen, state that the bony portion is twice the length of the other. The entire canal is about ¾ to 1½ in. (18 to 37 mm.) in length, a little longer on the floor than on the roof, because of the oblique direction of the tympanic membrane, the anterior wall and floor extending 3 or 4 lines (6 to 8 mm.) farther inward.

The diameter varies very much. In some subjects the end of the little finger can be passed in for quite a distance; in others the canal will hardly admit a goose quill. It is not of equal diameter throughout, being narrowest about the middle, although Allen states that it is widest at the junction of the bony and cartilaginous portions. The external portion is flattened from before backward, so that the vertical diameter (nearly ½ in. or 11 mm.) is nearly double the antero-posterior (¼ in. or 6 mm.). The middle portion is more cylindrical. The internal portion is flattened from above downward, making the antero-posterior diameter (⅜ in. or 9 mm.) greater than the vertical (⅓ in. or 7 to 8 mm.).

The *tympanic cavity* communicates in front with the Eustachian tube, and behind with the mastoid cells. Its diameters are as follows: Antero-posterior, about ½ in. (12 mm.); Toynbee says, ¾ in. (18 mm.); the transverse diameter varies, in different portions, from $\frac{1}{12}$ to ½ in. (2 to 12 mm.), it is narrowest in the middle; the vertical diameter is ¼ to ½ in. (6 to 12 mm.).

The *Eustachian tube* connects the tympanum with the pharynx. It consists of an osseous and a cartilaginous portion. The osseous portion varies very much in length, according to different observers, ranging from ½ to 1 in. (12 to 25 mm.); Allen says 14 lines (about 28 mm.). The length of the cartilaginous portion is about 1 in. (25 mm.); total length of tube about 1½ in. (37 mm.); Toynbee and Cruveilhier say 2 in. (50 mm.).

The pharyngeal orifice is wide and dilatable; elliptical in shape; about ½ in. (12 mm.) in diameter. The remainder of the tube is so constricted that it barely admits an ordinary probe. Sappey gives its vertical diameters as follows: Tympanic orifice, 5 mm.; at osseo-cartilaginous junction, 3 mm.; in middle of tube, 4 to 5 mm.; at pharyngeal orifice, 6 to 8 mm. Transverse diameters: Middle of osseous portion, 3 mm.; osseo-cartilaginous junction, 1 to 2 mm.; middle of cartilaginous portion, 3 mm.; at pharyngeal orifice, 5 to 6 mm.

The *mastoid cells* vary very much in size in different individuals and at different ages, being always small in youth. In some individuals they occupy the entire interior of the bone behind the external auditory meatus for 1½ in. (37 mm.) and have a vertical diameter of 2 in. (50 mm.). They are usually subdivided, and communicate anteriorly with the tympanic cavity.

The *nasal duct*, including the lachrymal sac, is about 1 in. long (25 mm.), the sac and duct proper being nearly equal in length, namely, about ½ in. each (12 mm.). The duct proper is directed downward, backward, and a little outward; is rather ovoid in section; its diameter varies greatly and is smaller than that of the sac; it varies also on the two sides of the same individual. The upper part averages about ⅛ in. (2 to 3 mm.); the lower part is about 0.5 mm. wider. Noyes found in one case that the duct on one side was round and ⅛ in. (3 mm.) in diameter; on the other, oval, and ¼ in. (6 mm.) in diameter. The nasal terminus is somewhat dilated.

The *frontal sinuses* vary much in size in different individuals, and on the two sides of the same. They are always small in youth. The right and left are generally entirely separate, but sometimes communicate through a small opening. They are often subdivided into smaller cavities.

My own measurements of capacity gave the following results: The right, ⅓ to 1½ drachms (1⅓ to 6 c.c.): the left, ⅙ to ⅓ drachm (1⅓ to 4⅔ c.c.). As showing the difference, sometimes, between the two sides, I found in one case that the left sinus was to the right as 70 to 95. Perhaps the best idea of the size which they sometimes attain is formed from the fact that the larvæ of insects, living centipedes, musket balls, etc., have been found in these sinuses.

Daniel S. Lamb.

VISION, PHYSIOLOGY OF.—In order to read with profit a presentation of the physiology of vision one should be thoroughly conversant with the anatomy of the eye, with the general principles of refraction, and with the application of those principles to the dioptrics of the eye.

The reader is referred to the excellent articles of Dr. Baker and Dr. Gradle on the anatomy of the eye (Vol. IV., p. 63) and the dioptrics of the eye (Vol. IV., p. 83).

Vision comprises two distinct phases of activity: 1. *Optical*, in which phase the eye as an optical instrument focusses upon the retina images of objects. 2. *Sensory*, in which the sensorium is made conscious of the form and color of the image through the neuro-epithelial cells, rods and cones, and the two orders of sensory neurones.

A. Visual Optics: The Eye as an Optical Instrument.

Possessing a lens with an adjustable focal distance, a diaphragm with an adjustable aperture, a pigment lining for absorption of dispersed light, and a screen for the reception of the image, the eye must at once be recognized as a typical optical instrument. Used as it is for viewing distant objects whose image is infinitesimal compared with the object, the eye resembles a telescope. But the ustable diaphragm in front of the lens and the screen the reception of the image are points which make it e strongly resemble the photographic camera.

ll of the optical instruments consist of two distinct hanisms: (1) *A refractive apparatus* for focussing the s of light, (2) *a directive apparatus* for directing the of the instrument at the object whose image is to be ved

VISUAL REFRACTION: THE REFRACTIVE APPA- S OF THE EYE.—Before entering upon the considera- of this topic it might be interesting to note that the hanical and thermal stimuli of one's environment are e unmodified preparatory to their stimulation of the ory end-organs, and the pressures and tensions and perature act directly upon the sense organs trans- d practically unmodified through the superficial rs of the cuticle. The chemical agents, however, h serve to stimulate the sensory nerves of smell and must enter into solution before the end-organs are ulated. Furthermore, the vibrations of ponderable er must be condensed and intensified by the trans- ing apparatus of the ear before they can sufficiently ulate the end-organs of hearing.

nally, the vibrations of the imponderable, luminifer- ther can only be recognized as light by the primi- eye spots of the cœlenterates and echinoderms. re has, through the lapse of ages, evolved a visual organ which is able to recognize not only the dif- ce between light and darkness, but also to perceive orm and color of distant objects. In order to accom- this rays of light are focussed into a clearly defined e through the refractive apparatus of the eye.

Application of the Laws of Refraction to the Mam- n Eye.—See *Eye, Dioptrics of*, by Gradle, Vol. IV.

The Optic Disc or Blind Spot.—(1) *The location of ind spot* may be determined as follows (Marriotte's riment): On a white card make a black cross and a about three inches apart. Closing the left eye, hold ard vertically about ten inches from the right eye so bring the cross to the left side of the circle. Look ly at the cross with the right eye, when both the and the circle will be seen. Gradually bring the toward the eye, keeping the axis of vision fixed the cross. At a certain distance the circle will dis- ar, *i.e.*, when its image falls upon the entrance of ptic nerve. On bringing the card nearer, the cir- appears, the cross of course being visible all the

The outline of the blind spot may be determined as s: Make a cross on the centre of a sheet of white and place it on the table about 30 cm. from the s; close the left eye and look steadily at the cross the right eye. Wrap a penholder in white paper, g only the tip of the pen point projecting; dip the in ink, or dip the point of a white feather in ink, eping the head steady and the axis of vision fixed, the pen point near the cross and gradually move it right until the black becomes invisible. Mark this Carry the blackened point still further outward it becomes visible again. Mark this outer limit. two points give the outer and inner limits of the spot. Begin again, moving the pencil first in an d, then in a downward direction, in each case ng where the pencil becomes invisible. If this be n several diameters an outline of the blind spot is ed, even little prominences showing the retinal s being indicated.

The size of the optic disc may be readily determined ng the formula given below. Let x equal the long t the disc to be determined; a, equal the long axis map, as measured; d, the distance from the nodal to the sheet of white paper upon which the map of hite disc was drawn; f, equal the distance from the point to the retina: Then $x : a :: f : d$ or $x = \frac{af}{d}$.

ccommodation.—See *Eye, Dioptrics of*, by Gradle, V.

(*d*) *Imperfections of the Refractive Apparatus of the Eye.*—It will be remembered that the sole function of the eye as a refractive apparatus is to focus rays from any object, near or far, upon the retina; that when the accommodative apparatus is at rest the image of an object 6 metres or more distant is formed upon the retina in the normal eye. The distance of the image depends, then, upon the focal distance, but the principal focal distance depends in turn upon the radius of curvature, the index of refraction, and the location on the optical axis of the elements of the dioptric system. In the nature of the case the index of refraction cannot change perceptibly. In the principal imperfections of the refractive apparatus of the eye the position of the elements of the dioptric system upon the optical axis is faulty. If the screen (retina) is too far back the rays will come to a focus before reaching the retina. The subject will attempt to correct the difficulty by bringing the object near to the eye, thus increasing the conjugate focal distance until the image falls upon the retina. This bringing of the object near to the eye is a sign of a condition of the eye, which has, in consequence, been called "*near-sightedness*," or *myopia*, and it may be corrected by placing before the eyes concave or divergent lenses which enable the subject to see distant objects.

The retina may be too close to the nodal point; that is, the eyeball may be flattened in the antero-posterior diameter. In that case rays of light from a distant object would not be brought to a focus by the time they reach the retina. The subject will attempt to correct the difficulty by bringing into action the accommodative apparatus of the eye, thus bringing the focus nearer to the nodal point until it falls upon the retina and the object is clearly seen. This condition is called "*far-sightedness*" or *hypermetropia*. The oculists correct it by placing before the eyes convex or convergent lenses which enable the subject to see distant objects without the help of accommodation.

The radius of curvature of the cornea may be different in different planes. If the radius is shorter in the horizontal than in the vertical plane the rays which lie in that plane will be focussed nearer to the nodal point than will those which lie in the vertical plane. It must be evident that the eye would, under such conditions, be quite unable to focus both horizontal and vertical lines at the same time. Bringing the object nearer does not relieve the subject; using the accommodation does not help the condition. It is held by some ophthalmologists, however, that a modified accommodative act may contract the ciliary muscles in one place more than in another and thus correct or at least partially correct the condition.

The most effective way of relieving the condition without artificial means is for the subject to bring the eyelids very close together, leaving only a narrow horizontal slit. In this way all of the rays are cut out except those in one plane, and if these do not fall upon the retina when the eye is at rest, the subject may bring the object nearer to the eye or may use the accommodation. This condition of the eye is called by the oculists *astigmatism*, and it is corrected by placing before the eyes plano-convex or plano-concave cylindrical lenses which change the curvature of the refracting surface in one plane only. It is only necessary to adjust the axis of the cylinder at such an angle as to increase the curvature in the plane where it is smallest (or decrease it through the use of plano-concave cylinders in the plane where it is greatest) to put the dioptric system into approximately perfect condition.

2. VISUAL MECHANICS.—As the telescope or the camera must be provided with a directive apparatus by means of which the direction of its optical axis may be changed, so the eye is provided with an apparatus for changing the direction of the line of vision. In directing the vision from one point or object to another the axis of the eye is turned upward or downward, outward or inward, or is circumducted, in short, the axis of the eye has an absolutely universal motion within its limits.

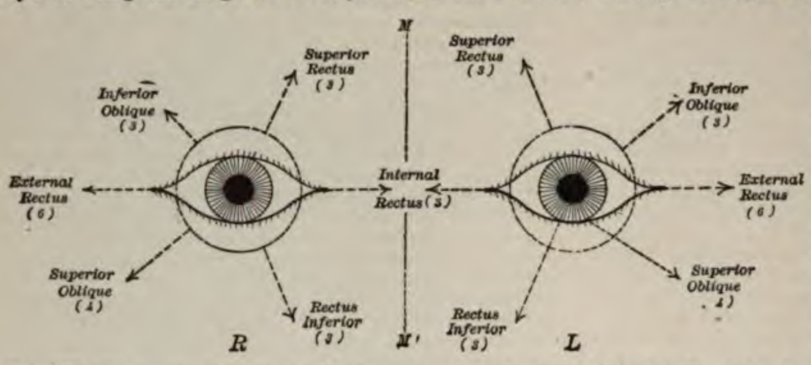

FIG. 5023.—Diagram to Illustrate the Directions toward which the Optical Axis is Directed or Inclined by the Contraction of the Individual Muscles. *MM'* is the median line; *R*, the right eye, and *L* the left one. The numbers in parenthesis (3, 4, and 6) indicate the innervation of the muscle. (After Waller.)

(*a*) *Monocular Fixation.*—The term monocular fixation is used to designate the mechanical adjustment of the eye to bring the image of the object upon the macula lutea, the most sensitive portion of the retina. If one studies the movements of one eye (the other being shaded) he will find that it readily follows the movements of an object held in front of it, however quickly or through whatever angles or directions it may be moved by the observer. The directive apparatus of the eye consists of the six muscles described in the article on anatomy, moving the eye about three different axes of rotation:

(1) A horizontal axis about which the eye rotates upward and downward; (2) a vertical axis about which the eye rotates from right to left; and (3) a longitudinal axis which coincides practically with the physiological axis or line of vision and about which the eye rotates (slightly) when the oblique muscles are in action. These three axes are rather arbitrarily located. Inasmuch as the eye is a spherical body resting in a hollow spherical socket, and inasmuch as it rotates freely in any direction about the intersection of the three assumed axes, it is somewhat simpler to take a central *point of rotation* about which the eye may rotate in any direction whatsoever under the action of one or more of its six muscles.

Waller's excellent diagram (Fig. 5023) given in the accompanying figure, will enable the student to interpret the mechanism of the directive power of the eye. Take, for example, the movement of the optical axis of the right eye outward or away from the median line in the horizontal plane. This movement is accomplished by the external rectus innervated by the sixth nerve. Again, take the movement of the axis of the eye upward in the vertical plane. It is evident that the superior rectus alone cannot accomplish this; but that that muscle must act in conjunction with the inferior oblique. In a similar manner movement vertically downward requires the combined action of the inferior rectus and the superior oblique.

In general the contraction of a single muscle causes a rotation of the eye in the direction indicated in the diagram for that muscle; while rotation in any other direction than the six which are indicated by the arrows requires the interaction of two muscles, and frequently the coördinative influence of two nerves. To circumduct the eye, sweeping its axis around a circle requires the action of all of the muscles, acting two or three at a time; an action the exactness of adjustment and the complexity of coördination of which must compel the admiration of any student of mechanics.

(*b*) *Binocular Fixation.*—This expression is used to designate the coördinated binocular movement which results in directing the physiological axes of both eyes upon the same object. If the object fixed by both eyes be a small one, its image falls upon the fovea centralis; if it be a large one, it will be disposed about that point symmetrically, as shown in Fig. 5024.

The lower part of the object being focussed upon the upper segment of the two retinæ, and the right part of the object being focussed upon the left part of the two retinæ, that is upon the median segment of the right retina and the external segment of the left retina.

It is evident that we have to deal with a complex mechanical action: (1) With double monocular fixation, and (2) with convergence of the visual axes of the eyes. If one refers to Waller's diagram he can readily tabulate the muscles involved in directing the two eyes in any particular direction. If in Fig. 5024 the object *O* move toward the right eye along the visual axis *ONF* the fixation of the right eye will not need to be readjusted. If, however, the visual axis of the left eye *ON'F* follow the movement of the object, it will have to deflect to the right, thus making a greater angle ($<F$ Om) with the median line (mm') than existed before. This increase of the *angle of convergence* is brought about by the internal rectus. If through weakness or through paralysis this muscle is unable to rotate the eye far enough to bring the points *O*, *N'*, and *F* into a straight line, then the retinal image would not fall upon the field ($a'b'c'd'$) and there would be a double visual sensation, "double vision," or *diplopia*. Failure for any other reason to produce perfect binocular fixation leads to the same derangement of vision. This is the principal, though not especially frequent imperfection of the directive or mechanical apparatus of the organ of vision, and

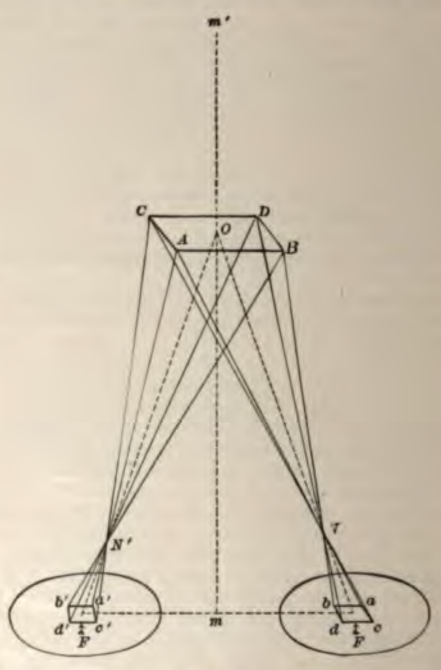

FIG. 5024.—Diagram showing the Symmetrical Correspondence of the Retinal Field. *N*, Nodal point; *F*, fovea centralis. The observer is supposed to be looking down upon the optical apparatus from above. Note that the line *C D*, which is on the lower side of the object, is the upper side of the image; and that the line *B D*, which is the right side of the object, is the left side of the image, which brings it at the inner segment of the right retina and the outer segment of the left retina.

ten corrected by oculists through the use of pris-
c lenses which bend the optical axis, bringing the
e upon the proper field of the retina.

VISUAL SENSATION. THE EYE AS THE SENSE ORGAN OF VISION.

e retina is the end-organ of vision; its function is to
ve the impression of the image focussed upon its
ce by the optical apparatus and to transmit the im-
ion to the brain. About all that can be said is that
ghts, shades, and colors of the retinal image excite,
neuro-epithelial cells, metabolic changes which are
nced more or less by the action of the light upon
igments in the associated tissues. The neuro-epi-
l cells are composed of an efferent element repre-
l by the cones or rods of the external layer of the
that is the scene of the metabolic changes referred
ve. The chemical changes start, along the afferent
nt (dendrite) toward the cell body, an impulse which
nsmitted by the efferent element (neurite) to the
eurone of the cerebral layer of the retina, thence
second neurone to the sensorium of the brain.
phases of visual sensation which seem most profi-
briefly to discuss are retinal stimulation, retinal
ility, and visual sensations.
ETINAL STIMULATION.—*A. The Stimuli.*—(*a*) *The*
of stimuli which lead to visual sensation are limited
lly to: (1) Diffuse light in its various colors, and
ages of objects. In either case the stimulus is light,
seems expedient in view of what is to follow to
ntiate between the light in general and images of
s. The retina, in common with all highly special-
ssues, responds to all stimuli with the same general
ion. If one press upon the side of the eyeball a
f light will be seen upon the opposite segment of
ina. The retina is stimulated under the finger, but
ferred to the opposite side. When a mechanical
to the head makes one "see stars" these luminaries
l sensations due to the mechanical stimulus. Elec-
may also produce the sensation of light.
t being a mode of undulatory motion, it may vary
ways: (1) In the number of vibrations per unit
2) in the amplitude of the vibrations. The first
on is comparable to the variation in the pitch of
and leads to the color scale; the second variation
parable to loudness, and is recognized in the inten-
the sensation.
he duration of the stimulus may be very short.
tric spark whose duration is less than a millionth
econd is long enough to produce a sensation
). The sensation which a stimulus calls forth is
h longer duration than the stimulus itself. This
evident when one looks at a rapidly rotating
a spoke occupies a particular position for only an
simal fraction of time, yet it calls forth a sensa-
n the position which the spoke takes during the
finitesimal unit of time another sensation is in-
but the sensation of the previous stimulus persists
two sensations blend. The result of this blend-
he images of the rotating spokes is to produce the
f a solid wheel. In a similar way if a luminous
attached to the rim of the rotating wheel the
n which it produces will not be a point of light,
nore or less elongated line of light. The faster
tion of the wheel the longer the arc of light until
he speed of the rotation may be great enough to
the line of light around the whole circumference
rcle in a solid ring of light. Carpentier says that
val of 0.027 of a second must elapse between two
f light in order that both can be seen separately.
e Irritability of the Retina.—1. *Factors Involved*
al Irritability.—(*a*) *The structure of the retina*
important relation to its irritability. The two
neuro-epithelial cells—the rods and the cones—
equally distributed over the retina. There are
in the macula lutea; this portion of the retina
s the cones only. The macula lutea is especially
sensitive to the fine lines of images focussed upon it; *i.e.*, it is the only portion of the retina from which one may receive a clearly defined image. That portion of the retina outside of the macula lutea is only faintly sensitive to form, but is very sensitive to light and responds to very slight modifications in the intensity of the stimulus.

(*b*) *The retinal pigments* bear some relation to the irritability of the retina. Melanin or fuscin is the brownish-black pigment which makes up the pigment layer of the retina. This pigment seems to form a stock from which other pigments may be replenished. *Rhodopsin*, or "*visual purple*," is found in the rods, and is therefore absent from the macula lutea. *Chromophanes* are red, green, and yellow oil globules found in the cones. The chromophanes are not found in the eyes of mammals.

(*c*) *Varying irritability of different areas* of the retina is probably due to varying distribution of the rods, cones, and pigments. The following facts are important in this connection: 1. The macula lutea is the area of clearest definition of form; it is, in fact, the only area sensitive to the fine structural details of an image. 2. The macula lutea possesses cones but no rods, and in its most sensitive area—the fovea centralis—the cones are brought into special prominence by the thinning out of all the other elements. 3. The portion of the retina most sensitive to variations of the intensity of diffused light is that portion outside of the macula. 4. The portion of the retina outside of the macula is richly studded with *rods*, and each rod possesses its supply of rhodopsin. A solution of rhodopsin bleaches in the light. The retinal image may be acutally "fixed" by treating with four-per-cent. solution of potassium alum, the retina which has just been removed immediately after thorough exposure following rest in the darkness. The "fixed" image is called an *optogram*.

These facts seem to justify the conclusion that *the cones are the structures which receive form pictures, and the pigmented rods are the structures which receive light and color impressions.*

2. *Direct and Indirect Vision.*—These terms designate respectively the central field of clear definition and the surrounding field of indistinct definition. One may get a very good idea of the difference between direct and indirect vision by holding before one eye (the other being shaded) at a distance of 30 cm. a printed page. Direct the line of vision at a small word; the surrounding words will be recognized for a distance of perhaps 2 cm. in any direction, but by studying the sensation very carefully, keeping one particular letter constantly fixed in the line of vision, that one letter is the only letter upon the page that is absolutely clearly defined. The image of that letter lies upon the centre of the fovea centralis, the two adjacent letters lie upon the slanting sides of the fovea, their definition is only slightly less distinct than that of the central letter. The form of the next adjacent words can be made out with sufficient clearness to enable the observer to say definitely what the words are, but he would be quite unable to detect any slight typographical imperfection in the words. The field of direct vision may be taken to be that which is focussed upon the macula lutea which is 1.25 mm. in diameter, subtending about five degrees of angle at the nodal point.

(*a*) *Indirect Monocular Vision.* The field of indirect vision includes all of the visual field outside of that of direct vision. The accompanying figure (Fig. 5025) shows the field of indirect vision for white light bounded by the shaded portions of the figure. Note in the centre the five-degree circle of direct vision within which the form and structural features of objects are clearly defined. Note the blind spot (*B*) at the right of the macula in the figure, and showing that the optic nerve enters the eye to the median side of the fovea located from 12.5° to 17.5° from the centre and a little above the horizontal line from the fovea. Note that the boundary of the field for the indirect vision of the white light crosses the upper vertical meridian at 55°, the median meridian at 60°, the lower vertical meridian at 70°, and the external meridian beyond 90°. The determination of the line bounding the field of vision is called *perimetry*, the record and the instrument used in getting it a *perimeter*. The field for yellow light is within that for white, the field for blue light is within that for yellow, the field for red light still farther withdrawn from the periphery, and the field for green very much smaller than that for red. Perimetry has considerable clinical importance because in certain pathological conditions the perimeters are considerably modified either by being generally contracted or by being dotted with islands of total or partial blindness.

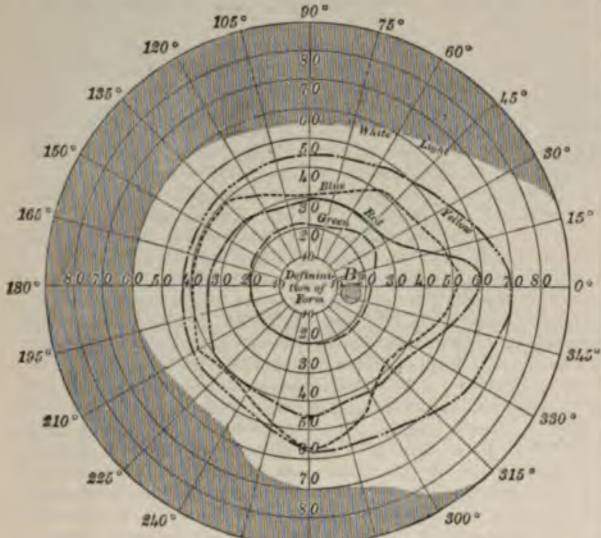

FIG. 5025.—Perimeter Chart with Tracings. (Krapart.)

(*b*) *Indirect Binocular Vision.* To determine just what the field of indirect binocular vision is one has only to find the overlapping areas of indirect monocular vision when both eyes are directed to the same point. The accompanying figure (Fig. 5025) is for the right eye. If one trace upon the same chart the field sensitive to white light in the left eye, the open external end of the field will extend off to the left and the circular median end to the right, reaching the 60° circle. The right and left perimeters will thus overlap in an almost circular area bounded right and left by the 60° circle, above by the 55° circle, and below by the 70° circle. The field thus bounded is that for binocular indirect vision for white light.

II. VISUAL SENSATIONS.—(A.) *Fundamental Sensations.*—The sensations which light induces in the sensorium may not be so easily differentiated as are those of sound, but they are closely analogous to sound. In sound we differentiate pitch, loudness, and quality, dependent respectively upon number of vibrations per unit of time, upon the amplitude of the vibrations, and upon combinations of overtones; in light we differentiate *color*, *intensity*, and *form*, dependent respectively upon number of vibrations per unit of time, upon the amplitude of the vibrations, and upon combinations of intensities (lights and shadows).

1. *Form.* The sensation of detail in structure is clearest at the fovea centralis, and decreases progressively in every direction from that point in the retina. That this specialization of form-sensation is in some way connected with the fact that of the rods and cones cones only are present in the macula, and these are brought into special prominence in the fovea, has been suggested above. But the color sensation is also induced by stimulation of the fovea, though Kühne and others show that differentiation of color is less acute at the fovea than in areas outside of it.

2. *Intensity.* Intensity depends upon the amplitude of the vibration of the medium, which last transmits the light to the eye. As in the case of intensity of sound, this may depend upon the amplitude of vibration of the sonorous or the luminiferous body, or upon the summation of the effects of several vibrating bodies. The sound produced by two sonorous bodies of the same pitch and amplitude will be more intense because of the summation of the undulations; in the same way the light produced by two candles will be more intense than that produced by one.

The sensation induced by lights of varying intensity is not commensurate with the intensity, but obeys Weber's law of sensation: "The smallest change in the magnitude of a stimulus which one can appreciate through a change in one's sensation always bears the same proportion to the whole magnitude of the stimulus" (as formulated by Foster). Applied to vision, the proportion is 1 to 100, that is, 0.1 candle power added to or subtracted from a 10 candle-power light, 1 candle added to or subtracted from a 100 candle-power light, and 10 candles in a 1,000 candle-power light can be detected, and so on.

3. *Color.* Color depends upon the number of vibrations of a luminous body, as pitch depends upon the number of vibrations of a sonorous body. The white light that comes from the sun may be readily decomposed into a number of principal colors and an innumerable number of intermediate mixtures. The principal colors have the following rate of vibration: Red, 392 trillions of vibrations per second; orange, 532 trillions; yellow, 563 trillions; green, 607 trillions; blue, 653 trillions; indigo, 676 trillions; violet, 757 trillions. These vibrations range in wave lengths from 0.00000766 mm. to about half of that length.

The colors named above are the principal or the clearly pronounced colors of the spectrum. From three of these all other colors may be produced; these three are the fundamental or *primary colors: red, green, violet.* The accompanying figure (Fig. 5026) shows graphically the relation which these colors bear to each other. Not only does a combination of all of the colors produce white, but a combination of certain of the colors in pairs produces white; these pairs are called complementary colors: (1) Red and greenish-blue; (2) yellow and indigo; (3) orange and cyan blue; (4) violet and greenish-yellow.

How the different colors can stimulate the retina has been the subject of considerable controversy.

(*a*) *The Young-Helmholtz theory* assumes that there are in the retina three different kinds of sensory elements which respond to the three different primary colors—red, green, and violet—and that "*every color of the spectrum excites all of the elements, some of them feebly, others strongly*" (Landois). The perception of color is then a resultant of the combined sensations brought to the sensorium by the three sets of elements.

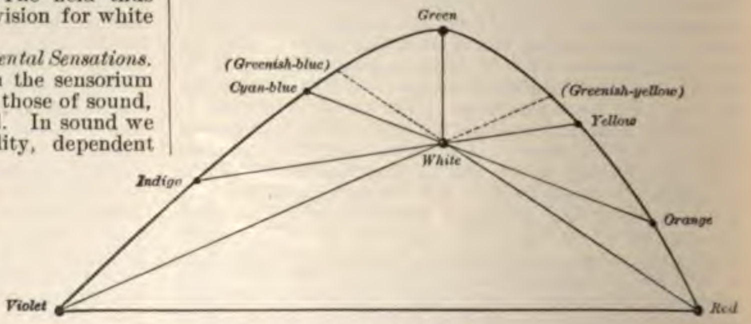

FIG. 5026.—Geometrical Color Table.

(*b*) *The Hering theory* is based upon the principles of metabolism and upon the color law of Grassman: "If two simple but non-complementary spectral colors be mixed with each other they give rise to the color sensation, which may be represented by a color lying in the spectrum between both and mixed with a certain quantity of white"; *i.e.*, every color sensation except those of the primary colors may be produced by a color of the spectrum plus white. Hering assumes: (1) That light produces metabolism in the retina; (2) that the metabolic processes are in part anabolic and in part katabolic; (3) that white, red, and yellow sensations are katabolic, *i.e.*, accompanied by disintegration and fatigue; and that black, green, and blue sensations are anabolic, *i.e.*, accompanied by integration and rest; (4) these metabolic processes are assumed to be paired—*i.e.*, white and black sensations affect the same visual substance in opposite directions. Red and green stimulate another visual substance, and yellow and blue stimulate a third. Now, according to Grassman's law of color sensation: Any color sensation, except that of a primary color, may be produced by a color of the spectrum plus white. Hering assumes that white visual substance is katabolized not only when one sees white, but incidentally in all color sensations except primary ones.

(*c*) *The Franklin theory* is not antagonistic to either of the foregoing, but rather supplementary. It is based upon the facts of comparative physiology, and assumes that the rudimentary eye distinguishes between light and dark only, and possesses neither form nor color senses; so that the fundamental point of departure is a sensation of simple light or dark (Hering's white and black sensation) produced by stimulation of a fundamental "*visual gray*," which causes an accentuation of either the white or the black in it (presumably by modifications in the metabolism set up). This theory assumes that the yellow-blue substance was next developed and the red-green last.

The adherents of either the Young-Helmholtz or the Hering theory, especially the latter, may well accept the Franklin theory as supplementary, as it accounts easily for the fact that red-green color-blindness is most common, and yellow-blue blindness rather rare, while inability to see black and white is found only in cases of congenital, total blindness. Furthermore, reference to the perimeter chart shows that white-black covers the largest area of the retina, yellow-blue an area within that, while red-green is smallest and quite near the centre.

B. Secondary Sensations.—1. *After-images.* If one fix the gaze upon a brightly illuminated figure or pattern for fifteen seconds and then direct it toward a plain surface the image of the pattern gazed at will be seen upon the plain background of the second field of vision. If the after-image has the same colors as the first it is called a *positive after-image.* Positive after-images are usually caused by strong stimuli of short duration rather than by moderate stimuli of long duration. If the after-image is in the complementary color of the original pattern it is called a *negative after-image.* If one gaze intently at a green pattern, then turn to a red field, the pattern appears deep red upon the red field. It will also appear red upon a neutral field. *Negative after-images are a sign of retinal fatigue.*

2. *Contrast.* Contrast is the accentuation of a color sensation through contiguity or succession of another color, especially a complementary color. A piece of note paper may look white upon a black background, but if it is put upon a really white background it will be seen to be far from white. In a similar manner blue or yellow accentuate each other, as do red and green. Various other combinations have this reciprocal effect. If the effect is produced by looking at the two contrasting colors at the same time, the sensation is called *simultaneous contrast*; if by looking at the contrasting colors one after another, it is called *successive contrast.*

C. Color-blindness.—Of the male population four per cent. or five per cent., and of the female population about one per cent. are unable to differentiate certain colors. Such persons are called "color-blind."

1. *Complete Color-blindness* (*Achromatopsy*). Individuals thus afflicted can distinguish lights and shades, but have no color sense whatever. According to the Hering theory, they lack both the red-green and the yellow-blue visual substance; according to the Franklin theory they represent cases of arrested development of color sense in a condition representing a very primitive condition when only the fundamental color substance is present.

2. *Yellow-blue Blindness.* In this condition the blue end of the spectrum is absolutely dark, and the yellow may be more or less *illuminated*, but void of *color.* This represents also an arrest of development; but this arrest occurs after considerable progress has been made.

3. *Red-green Blindness.* This is by far the most common form of color-blindness, and as assumed by the Franklin theory to represent the last step in the development of the color sense and, therefore the first to fail in case of an arrest of development.

4. *Acquired Color-blindness* may result from disease of the retina.

5. *Normal Color-blindness* exists in the periphery of the retina. Passing from without inward the outermost sensation is that of white (and black); the next that of yellow and blue, followed by red and green (see *Perimetry*, on page 244).

III. VISUAL PERCEPTIONS AND JUDGMENTS.—One may have a sensation of black lines upon a white surface without perceiving in the lines a letter or word. The retino-cerebral apparatus brings to the sensorium of the untutored savage the same sensations as it does to the sensorium of the scholar. The savage "senses" a written word upon a page, but does not *perceive* it; on the other hand, the scholar may "sense" the twigs upon the forest path without perceiving in their position and condition the track of an animal. Simple sensation involves nothing higher than the sensorium. There is no reason to believe that the sensorium brings to the consciousness of different individuals different sensations. Perception involves cerebration in the interpretation of sensations. Perception involves previous knowledge or memory of the same or related sensations. Effectual perception, like effectual marksmanship, depends upon the man behind the instrument.

Visual perception is the *seeing with understanding.* *Visual judgments* are based upon visual perceptions and represent conclusions reached after comparison of previous perceptions.

(*a*) *Acuteness of Vision.*—It is frequently necessary to test the acuteness of vision through a comparison of visual perceptions. An individual whose acuteness of vision is in question presents himself to the ophthalmologist for examination. If the subject is schooled in interpreting dim and distorted images, he may mislead the observer for a few moments with his acute perception, but the faulty sensation must sooner or later reveal itself. The observer will present to the subject a series of letters in unusual combinations, so that there will be no way in which he can get a clew for his judgment to work upon.

To be more concrete: The acuteness of vision is tested by reading letters of various heights at various distances. The normal eye (emmetropic eye) should see clearly at 6 metres—the oculists' infinity—letters which subtend an angle of 5′; *i.e.*, letters $1\frac{1}{8}$ cm. in height. At 12 metres the normal eye should distinguish and name letters which are $2\frac{1}{4}$ cm. in height. These letters subtend an angle of 5′—the minimum angle of clear vision. If the individual can see at 6 metres what he should see at 12 metres, he is credited with: Vision $= \frac{6}{12}$; if he can see at 6 metres what he should see at 30 metres, he is credited with: Vision $= \frac{6}{30}$. If by cultivation the visual power has been brought up above the average so that he can see at 6 metres what the average eye must bring to 3 metres to see, he will be credited with: Vision $= \frac{6}{3}$.

The acuteness of vision varies much with the habits and employment of the individual. Persons employed at fine close work acquire a microscopic vision—*i.e.*, ability to see and interpret the minutest detail of structure. Persons employed in vocations which require long-distance vision acquire telescopic eyes—*i.e.*, ability to see and interpret structure of distant objects. Sailors and rangemen possess this ability to a marked degree.

(*b*) *Visual Estimates.*—1. *Estimate of Distance.* This judgment is based upon a combination of at least two sensations or perceptions: (*a*) Sensation of the accommodation required to focus the image of the object upon the retina; (*b*) the sensation of the convergence required to direct the two visual lines at the same object in the binocular vision. These sensations are examples of muscular sense. One estimates these muscular efforts instinctively. Upon these instinctive estimates one bases his judgment of the distance of an object. But other considerations may enter in to assist in the estimate of distance. For example, a movement of the head or body causes a displacement of nearer objects in the background formed by more distinct objects; one learns by experience how much this displacement should be for given distances, and bases his judgment accordingly. The known size of an object is an important factor in the estimate of its distance. In this estimate one instinctively measures the image and compares it with the image of the same object at a short distance.

2. *Estimate of Size.* This judgment is based upon two perceptions: (1) The size of the image, and (2) the distance of the object. Various other considerations may enter in to modify the judgment.

The subject of visual illusions belongs more properly to psychology than to physiology, and will, therefore, not be discussed here. *Winfield S. Hall.*

VITAL STATISTICS.—Vital statistics constitute the science of numbers as applied to the life history of communities (Newsholme). The French term "demographie" is nearly synonymous with vital statistics. One of the highest living authorities (Körösi) defines vital statistics as the science of the physical life of human society.

The principal data with which vital statistics are concerned are the following: (1) Population; (2) marriages; (3) births; (4) sickness; (5) deaths.

The significance or value of vital statistics lies very largely in the relation of these data to each other and to the various sub-groups into which they are usually classified; namely, the sexes, ages, conjugal condition, residence, occupation, race, season of the year, and, in the case of deaths and sickness, the causes of the same.

In the following paper upon vital statistics the writer has made free use of the data which were obtainable from the New England States, and especially from the State of Massachusetts, since these States constitute almost the only group of States in the Union which have had a fairly complete system of registration during a period of several years, Maine being the last one of the New England States to adopt a system of registration, which she did in 1892.

Reference is also made to the vital statistics of other states and countries as occasion requires.

Population.—An accurate knowledge of the number of the population forms the basis of all vital statistics. For example, a comparison of the numbers of deaths in any given community with those in any other community has no significance unless the number living in each community out of which these deaths occurred is also known.

Our knowledge of the numbers of the people living in any civilized country is obtained from the census, an enumeration made at stated periods, usually at ten-year intervals. In modern times the first census was taken in Sweden in 1749. The first census of the United States was taken in 1790, and the first in England in 1801. Few census enumerations were made in any country with sufficient details as to age, sex, and race to satisfy the purposes of sanitarians and those interested in life insurance, until the latter part of the nineteenth century.

In the United States the census is taken decennially during the month of May in the years divisible by ten. It is especially desirable in a country where the population is subject to constant changes in consequence of the variable factor of migration that census enumerations should be made oftener than once in ten years. Hence a few States (Massachusetts, Rhode Island, and Michigan) take an intermediate census, which gives the advantage of a new starting-point from which to make estimates of population in intercensal years.

Various methods are adopted for estimating the population in intercensal years:

1. In a community where a strict record of emigration and immigration is kept, and a complete system of registration of births and deaths is also enforced, the population may be accurately calculated by balancing the difference between the births and deaths and the increase or decrease due to migration. This is done in the city of Berlin and in New Zealand, but is impracticable in most countries on account of the deficiency in the necessary data.

2. Other methods occasionally adopted consist of estimates based upon the number of assessed polls in a city, the number of names in a city directory, the number of children of certain ages enrolled in the schools, or the number of new inhabited houses. None of these, however, can be deemed to be reliable.

3. We may assume that the annual increase during the present decade will be one-tenth of the total increase in the last decade. By this method a city of 50,000 inhabitants in 1890, increasing to 60,000 in 1900, should have 65,000 in 1905 and 70,000 in 1910. By this method, however (that of arithmetical progression), no allowance is made for the fact that the increase increases. There is a steadily increasing number of persons each year who attain marriageable ages and become parents.

4. The method now generally adopted in most countries is that which is advised and employed by the registrar-general of England, which assumes that the same rate of increase will continue as that which prevailed in the preceding period, *i.e.*, that the population increases in geometrical progression.

The following example illustrates this principle: If the census population of a city was 50,000 in 1890 and had increased to 60,000 in 1900, what is its estimated population in 1905?

Find the rate of increase from 1890 to 1900.

If P = the population at the census of 1890, and if P^1 = the population at the census of 1900, and if R = the rate of increase; then

$P^1 = P + R^n$ in the n^{th} year.

$\text{Log } P^1 = \log P + 10 \log R.$

$\frac{1}{10}(\log P^1 - \log P) = \log R.$

$$\frac{4.7781513 - 4.6989700}{10} = .0079181 = \log R.$$

Then $P_{1905} = P_{1900} R^5$.

$\text{Log } P_{1905} = 4.7781513 + 5(.0079181) = 4.8177419$ = log of 65,727, the estimated mean population for 1905.

In the foregoing formula r may be taken as the ratio of increase, R being equivalent to $1 + r$.

By the same method the same city should have an estimated population of 72,000 in 1910, instead of 70,000 which would result from the application of the arithmetical method.

None of the foregoing methods can be depended upon to give accurate results in all cases, since irregularities affecting the different factors which control the population are always likely to occur. In one decade a town may experience a rapid growth in consequence of immigration, prosperous times, and a high birth rate, while in the next decade one or all of these factors may be decidedly changed. A quinquennial census is very desirable, especially in American States, where migration is an important though very variable factor.

Registration of Marriages, Births, and Deaths.—Unfortunately, in by far the majority of the States of the Union no complete system of registration exists, and consequently no accurate knowledge of the vital statistics of such States can be had until state legislation shall have so far advanced as to make registration compulsory.

A law was enacted in the Massachusetts colony in 1639, requiring registration of marriages, births, and deaths, but it was not until more than two centuries r (1842) that the law was so perfected as to require ection and publication of the returns by some central hority. Connecticut followed in 1848, and Rhode nd in 1853, and there are at present nine or ten States ch have sufficiently effective registration laws to ble these States to furnish accurate information rela- to the marriages, births, and deaths which occur in their limits.

nprovements have been introduced in these States in the principal cities in recent years for the purpose erfecting the returns and of substituting the new ification of Bertillon for that of Dr. Farr, which prevailed for half a century. Much improvement is desirable in the direction of certificates of death, rein indefinite and defective terms are too often used efine the causes of death. It is highly important careful instruction should be given upon this sub- in all medical colleges. (See *Death Certification.*)

ie registration of sickness and the compulsory notifi- n of infectious diseases furnish valuable information the prevalence of certain forms of illness among the le. But the former has scarcely ever been applied e general population except in Michigan, where ns from a limited number of physicians have secured mation from a State having a sparsely settled popu- 1. By a recent law in England, compulsory notifica- is also now applicable to all cases of lead, arsenic, phorus, and anthrax poisoning when contracted in shops or factories.

e infectious diseases to which compulsory notifica- pplies in England are smallpox, cholera, diphtheria, ranous croup, erysipelas, scarlet fever, typhus and id fever, and puerperal fever, and also any infec- disease "to which the act has been applied by the authority in manner provided by the act." (See *cation of Infectious Diseases.*)

registration of disease often furnishes definite in- tion which cannot be obtained from the registration aths alone, since the fatality of different diseases very much. For example, the fatality of measles ally from one to two per cent. of the cases, while f typhoid fever is from fifteen to twenty per cent. atality of any disease may also vary from year to Some diseases which seriously affect the popula- are not very fatal in certain countries, while in countries they are much more so. It is only, there- hrough the information obtained by comparing the f the registration of diseases with that of the regis- of deaths that the fatality of such diseases can be ined.

example, the number of cases of malarial fever d to the public health authorities in Italy in the s of September and October, 1902, were 58,787 and uted sixty-four per cent. of all cases of illness noti- om all causes (*i.e.*, of infectious diseases), in those s, and the deaths from the same cause were much r in proportion to the number of cases than they n more northern countries where malarial fever is evalent and less severe in type.

s and ordinances requiring similar notices of infec- iseases from attending physicians are now in force more densely settled and older States and in many f this country, and the tendency is constantly tow- provement and extension of the practice into parsely settled districts. In England a fee is usu- anted for each notice, but this is not the usual cus- America.

RIAGES.—Marriages are usually notified by the ng clergyman, magistrate, or other person legally zed to marry. They are usually stated numeri- a ratio per thousand of the total population, as iage rate, *e.g.*, 9.5 per thousand, which is also ent to nineteen per thousand (persons married), nber of persons married being twice the number marriages.

re accurate method would be to reckon the mar- te as a ratio of the number of unmarried persons of marriageable ages. The marriage rate is usually higher in the cities and towns than it is in the rural districts.

Conditions which affect the marriage rate are: (1) High or low cost of living; (2) unequal distribution of the sexes at marriageable ages; and (3) prolonged war.

During the Civil War the marriage rate of Massachusetts fell from 19.62 (persons married) per thousand population in the five years preceding the war (1855–60) to 18.66 in the war period (1861–65), and rose again to 20.96 in the five years immediately following the war.

Fecundity of Marriage.—The marriages in any year give rise to births which are recorded during the following twenty years or nearly so. The division of the sum of these births by the marriages would express the fecundity of the marriages, but it is impossible to follow each family and count the children, hence some ready method must be adopted for estimating the fecundity. In a stationary population in which the marriages do not increase from year to year, the births of any year might be divided by the marriages of the same year to obtain the desired result; but the marriages are constantly increasing, hence the births of a given year must be divided by the marriages of a previous year. This interval in Sweden is six years, and Dr. Farr assumes a similar period for England. In the twenty-eighth registration report of Michigan (1894), Dr. Wilbur assumes a mean period of five years, and states that, "for convenience, comparison of births may well be made with the marriages of the preceding five-year period, and with little sacrifice of accuracy." The mean period for the foreign-born is slightly longer than that for the native-born.

In the New England States the number of births to each marriage among those of foreign birth is nearly twice as great as among those of native birth, the average number among natives during the past half-century being about 2.2 and among the foreign born 4.4 to each marriage.

Divorces.—It is customary in some States and countries to publish the statistics of divorces in connection with other registration returns. The divorces are usually reckoned as a proportion of the marriages of the same year. Under the rule, however, that a class or group of facts is best compared with those out of which such class or group is taken, the divorces might more reasonably be compared with the marriages of an earlier period, the time being estimated from the average duration of marriages among the divorced. In New England this time is about eleven and a half years.

BIRTHS.—Births are usually reckoned as a rate per thousand of the living population. But, since the proportion of women of child-bearing ages varies much in different communities, this method is liable to error. Even if the proportion of women of child-bearing ages were equal, the comparison might not be free from error if in one population the proportion of single women were much higher than in the other.

The following example illustrates this point:

	Birth rate per 1,000 inhabitants (1883-'87).	Birth rate per 1,000 women aged 15 to 45 years (1883-'87).
Bradford, Mass	21.5	74.7
Nantucket, Mass	15.8	70.5
Percentage excess of birth rate of Bradford over that of Nantucket	36%	6%

According to the ordinary method of reckoning, Bradford had a birth rate thirty-six per cent. higher than that for Nantucket, but a statement of the birth rate "per thousand women aged fifteen to forty-five" shows an excess in Bradford of only six per cent.

Bradford was, at the time of the foregoing estimate, a rural town in which the population was subject to ordinary conditions, the population in 1885 being 3,106. Nantucket was an island community, living under extraordinary conditions, its population of nearly 10,000 in

1840 having been seriously depleted by the migration of persons of young and producing ages, so that the ratio of women aged fifteen to forty-five was considerably below the average. The years to which these figures apply are the five years 1883–87, the approximate mean population of the period being that of the census of 1885. The mean annual births for the five years (1883–87) constitute the other factor.

On the other hand, if a population with an unusually high birth rate be considered, like that of Holyoke, other conditions are found to prevail. In Holyoke, during the same five years (1883–87), the mean annual birth rate was 43.3 per thousand, or twice that of Bradford and nearly thrice that of Nantucket, while the birth rate per thousand women of child-bearing ages (147.7 per thousand) was also twice that of those towns during the same period. In this instance the high birth rate was undoubtedly due to the existence among the population of a large number of French Canadians of young and producing ages, whose fecundity is proverbial.[*]

The birth rate in most civilized countries in the past half-century has shown a gradual tendency to decline (see table on page 263). This diminution appears to have been caused in most countries by postponement of marriage to more mature years and by a larger proportion of celibacy. In France this diminution has become so serious as to reduce the birth rate in a few recent years to a lower point than the death rate, and to awaken apprehensions as to the future stability of the population.

The chief cause of the diminution of the birth rate, according to Newsholme, is "the deliberate and voluntary avoidance of child-bearing on the part of a steadily increasing number of married persons."

Stillbirths.—The term births as heretofore used implies living births. Stillbirths, in conformity to general usage, are considered in a separate category, since, as births, they add nothing to the living population, never having lived in the sense of having a separate existence. For similar reasons, as deaths they subtract nothing from the living population and are not included in the death rate.

The deaths of still-born males are usually from 25 to 50 per cent. greater in number than those of females. In the forty years 1856–95 there were registered in Massachusetts 31,656 male still-born children and 21,202 females of the same class. These all together constituted 2.96 per cent. of all births living and dead in the same period.

Sex of Living Births.—The ratio of males to females among all births, living and dead, varies in different countries within quite narrow limits, and is usually from 104 to 107 males to each 100 females.

The following figures show the relation of the sexes at birth in different countries for a ten-year period (1871–80):

BIRTHS OF MALES TO 1,000 FEMALES.

German Empire[*]	1,062	Holland	1,063
Switzerland	1,063	England[†]	1,038
Austria	1,067	Denmark	1,058
Italy	1,071	Sweden	1,060
France	1,063	Norway	1,061
Belgium	1,058	Massachusetts[‡]	1,066

[*] The figures for the German Empire are for the years 1872–80.

[†] Stillbirths not included in the figures for England, which probably accounts for its difference from the other figures.

[‡] The statistics for Massachusetts are for the forty years 1856–95.

The foregoing figures are the average results of over 50,000,000 births which occurred in the countries named. This difference in the number of each sex at birth partially disappears in the first years of life in consequence of the higher mortality of boys.

Plural Births.—Plural births occur with considerable regularity, those of twins constituting from a little less to a little more than one per cent. of all births, while triplets constitute a little more than one-one hundredth of one per cent. of all births. The following observations of births in several countries show slight differences in these ratios; they are the result of observations upon over twenty million births in the countries named:

RATIO OF PLURAL BIRTHS.

	Twins in 1,000 labors.	Triplets in 1,000 labors.
Switzerland[*]	12.2	0.12
Prussia[*]	12.2	.13
Bavaria[*]	12.4	.15

France[*]	9.8	.11
Sweden[*]	14.4	.17
Massachusetts, 1856–95	9.2	.13

[*] "Die Bewegung der Bevölkerung," Bern, 1885.

Illegitimacy.—In all countries where registration exists a certain proportion of the births are found to be illegitimate.

So far as the States of the Union are concerned, there is no very definite information to be had upon this point.

From such sources as are obtainable it does not appear probable that the percentage of illegitimacy in the United States is as great as that of other countries. The statistics of the large cities, and especially of those which contain foundling asylums and lying-in hospitals, show larger percentages than the rural districts.

The following table presents the illegitimate birth rates deduced from over thirty million births in the countries named:

ILLEGITIMACY IN DIFFERENT COUNTRIES.[*]

	Illegitimate births per 1,000 births.		Illegitimate births per 1,000 births.

France	74	Norway	85
Belgium	75	Switzerland	50
Holland	32	Massachusetts (1856–91)	13

[*] "Die Bewegung der Bevölkerung in der Schweiz," Bern.

DEATHS.—Death rates are calculated in proportion to every thousand of the living population, the unit of time being a year. This unit is employed when death rates for shorter periods (a week or month) are stated. They represent the number who would die out of each thousand of the population if the same death rate were to continue throughout the year.

The following is the best plan for obtaining the weekly death rate with accuracy:

The correct number of weeks in a year being 52.18,[*] if the population of a city is 250,000 and the number of deaths in a given week is 95, the death rate for that week is 19.8:

$$\frac{250{,}000}{52.18} = 4{,}791. \qquad \frac{1{,}000}{4{,}791} = 0.2087;$$

0.2087 is the factor by which the deaths for each week, in the case of city of 250,000 inhabitants, must be multiplied.

Therefore, 95 × 0.2087 = 19.826 or 19.8. This is the crude death rate.

Various corrections are required to insure accuracy, the most important factors being the deaths in public institutions, visitors, and the influence of age and sex, all of which vary in different communities. The inmates of a public institution, hospital, asylum, sanitarium, prison, or state almshouse in a given city, town, or district may consist almost wholly of persons belonging to other districts. All deaths of outsiders occurring in such institutions should, therefore, be subtracted, and all deaths of inhabitants occurring in outside institutions should be added in estimating the death rate. The living population, so far as it is derived from outside sources, should also be excluded, as well as the deaths of such persons, in making up an estimate of death rates, in order to make the death rate approximately correct. In many of the Rocky Mountain health resorts, as well as others of the South and West, it is also customary to exclude the deaths of visitors in making up the death rate.

---

[*] The birth rate of some of the lower counties of Eastern Canada in recent years has been as high as fifty-eight to sixty per one-thousand inhabitants.

[*] More accurately 52.17747, leap years being reckoned; but 52.18 is sufficiently accurate for practical purposes.

The Relation of the Death Rate to the Birth Rate.—While a high birth rate in a single year may be contributory to a high death rate in the same year and year following, it does not follow that a continuously high birth rate will be productive of a correspondingly high death rate. It is true that the death rate of children under five is very much higher than that of the general population, but if a high birth rate continues for several years it then increases the ratio of the total population at ages when the mortality is at its lowest point, and thus lowers the general death rate.

The Effect of Age and Sex Distribution upon the Death Rate.—Two cities, towns, or districts which are entirely alike in their climate, density of population, and sanitary conditions may have very different death rates, on account of differences in the age and sex constitution of their populations.

The population under five years of age may have a death rate of 60 per 1,000, and that of persons over sixty-five years of age may be as high as 80 or 90 per 1,000, while that of adults from twenty to sixty years of age may be only 12 per 1,000. It is therefore plain that a predominance of children under five years of age, or of persons over sixty-five, will raise the general death rate, while an excess of persons between twenty and sixty will lower it.

MASSACHUSETTS—DEATHS TO 1,000 LIVING AT EACH OF TEN GROUPS OF AGES, 1899-1901.

	All ages.	0 to 5.	5 to 10.	10 to 15.	15 to 20.	20 to 25.	25 to 35.	35 to 45.	45 to 55.	55 to 65.	All over 65.
Males	18.3	58.4	4.7	2.8	4.7	6.7	8.0	10.5	16.3	31.7	88.6
Females	16.7	48.0	4.6	2.9	4.4	5.9	7.3	9.4	14.2	26.5	82.8

ENGLAND—1881-90.

	All ages.	0 to 5.	5 to 10.	10 to 15.	15 to 20.	20 to 25.	25 to 35.	35 to 45.	45 to 55.	55 to 65.	65 to 75.	All over 75.
Males......	20.3	61.6	5.4	3.0	4.3	5.7	7.8	12.4	19.4	34.7	70.4	162.7
Females....	18.1	51.9	5.3	3.1	4.4	5.5	7.4	10.6	15.1	28.4	60.4	148.0

Again, an excess of males will tend to raise the death rate, while an excess of females lowers it, since, as shown in the accompanying tables, the death rate of females at all ages except from ten to twenty years is less than that of males. While it is proper, therefore, to compare the death rate of a given city for any year with that of a previous year, provided there were no material changes in the population in the intervening years, it is not safe to compare the general or crude death rates of one city with those of another without taking account of the differences in the ages and sex constitution of the populations of such cities. It is for this reason that the death rates of the older cities of the Atlantic coast cannot safely be compared with those of newly settled Western districts, where young adults between the ages of fifteen and forty-five are in excess of numbers.

In the following table the age and sex constitution of two cities are compared with that of the State at large, as an illustration of these differences. In the State at large the sexes in 1900 were in the ratio of 48.75 per cent. of males to 51.25 females, or 1,051 females to 1,000 males, while that of Boston was in the proportion of 1,040 females to 1,000 males, and that of Salem 1,109 females to 1,000 males.

CENSUS OF 1900. AGE DISTRIBUTION.

Ages.	MASSACHUSETTS		BOSTON.		SALEM.	
	Males.	Females.	Males.	Females.	Males.	Females.
Under 5 years...	505	501	510	512	530	520
5 to 10 years ...	457	456	437	435	506	473
10 to 15 years ...	467	411	378	377	411	427
15 to 20 years ...	411	437	356	397	405	449
20 to 25 years ...	461	534	467	565	449	519
25 to 35 years ...	921	995	1,076	1,074	842	920
35 to 45 years ...	704	708	780	744	631	710
45 to 55 years ...	470	492	462	478	448	523
55 to 65 years ...	292	334	253	289	286	377
All over 65 years	224	286	148	213	220	328
Unknown	23	11	35	14	13	13
	4,875	5,125	4,902	5,098	4,741	5,259
	10,000		10,000		10,000	

In Newton there were 1,234 females to 1,000 males, but in Gloucester the males predominated, there being only 873 females to 1,000 males in that city. These differences are determined largely by the character of the industries conducted in the different cities.

With reference to ages, there were in Massachusetts in 1900 52.45 per cent. of the population between twenty and fifty-five years of age, in Boston 56.46 at the same ages, but in Salem only 50.42 per cent.

Again, there were in Massachusetts 11.36 per cent. of persons over fifty-five years of age, in Boston 9.03 per cent., and in Salem 12.11 per cent.

In Boston the children under fifteen constituted 26.49 per cent. of the population, but in Holyoke those of the same age were 33.12 per cent. of the population.

All these differences have an effect upon the death rate according to the preponderance of persons at healthy ages.

Method of Correction for Age and Sex Distribution.—The method shown in the following table has been adopted by the registrar-general of England, and has been indorsed by other statisticians, notably by Körösi, whose method requires less calculation since he advises only four age periods for correction instead of eleven, as in the English tables. The periods recommended by Körösi are as follows: All under one year; all from one to twenty years; all from twenty to fifty years; all over fifty years. He also advises that the population of Sweden be taken as a standard of distribution, Sweden being a very healthy population. Dr. Ogle suggests the adoption of a combined standard, made from the seven principal European nations. The English tables employ the population of England and Wales as a standard, and in the following table (on page 250) the writer has referred each of the cities to the population of Massachusetts as a standard of comparison.

In the following table the *standard death rate* signifies the death rate at all ages, calculated on the hypothesis that the rates at each of the ten-age periods in each city were the same as those of the States during the three years, 1899–1901. The death rate at all ages in the State during that period having been 17.48 per 1,000.

The *factor for correction* is the figure by which the crude or recorded death rate should be multiplied, in order to correct for variations of sex and age distribution.

The *corrected death rate* is the recorded death rate multiplied by the factor for correction.

The *comparative mortality figure* represents the corrected death rate in each city, as compared with the recorded death rate in the State in 1900 taken as 1,000.

RECORDED AND CORRECTED DEATH RATES PER 1,000 PERSONS LIVING IN MASSACHUSETTS CITIES OF MORE THAN 25,000 INHABITANTS IN 1900.

Holyoke	15.55	1.124	21.96	24.68	1.354

* Correction has been made in the four cities of Worcester, Taunton, Chelsea and Boston for deaths of non-residents occurring in sixteen public and private institutions, 119 deaths in Worcester, 79 in Taunton, 90 in Chelsea, and 419 in Boston.

The figures in the last column may be read as follows: After making approximate correction for differences of age and sex distribution, the same number of living persons that gave 1,000 deaths in Massachusetts in 1900 gave 816 in Brockton, 1,184 in Boston, 1,354 in Holyoke, etc.

The first column in the table is obtained by assuming that the mean mortality in Massachusetts in 1899–1901 prevailed in each of the twenty cities in the list.

The age and sex distribution of each city at the last census (1900) being known, the mean mortality in Massachusetts (1899–1901) is applied to the population thus constituted, producing as a result the series of death rates in column 1. The differences between the cities in this column are consequently caused only by the difference in age and sex distribution. As an example of the method of obtaining these *standard death rates*, the figures for Boston may be taken (see the following table). Here the total population of Boston in 1900 was 560,892. The whole number of calculated deaths was 9,122. The standard death rate for that year was therefore $\frac{9,122 \times 1,000}{560,892} = 16.26$ per 1,000, as shown in the foregoing table.

Now the mean annual death rate of Massachusetts for the three years 1899–1901 was 17.48. This ought to be the same as the calculated death rate for Boston, which was obtained by applying the mean annual death rate of the State at the different age groups to the population of Boston at these age groups.

But this standard death rate of Boston was lower, as shown in the table, which arises from the fact that the distribution of age and sex in the Boston population is more favorable than that of the State at large (see table, page 249).

The standard death rate being lower for Boston, must be raised in order to bring it into comparison with the death rate of the State; that is, it must be increased in the proportion of 16.26 to 17.48. This fraction $\frac{17.48}{16.26} = 1.075$. This number 1.075 is the factor for correction for age and sex distribution by which the crude or recorded death rate of Boston must be multiplied in order that it may be comparable with that of the State.

By multiplying the recorded death rates in column 3 by the factors for correction, the corrected death rates are obtained as given in column 4. These are the death rates which would have been recorded in each city had its population been identical, so far as age and sex distribution are concerned, with that of the State.

Ages.	MEAN ANNUAL DEATH RATE IN MASSACHUSETTS, 1899–1901, PER 1,000 LIVING AT EACH GROUP OF AGES.		POPULATION OF BOSTON IN 1900.		CALCULATED DEATHS IN BOSTON (1900).

This principle in vital statistics is specially applicable to those towns from which, in consequence partly of local conditions, the young and vigorous portion of the population has emigrated, as in the case of Nantucket, Mass., which in 1840 had a population of 9,012; but this number had diminished to 3,142 in 1885. Of this population of 3,142, only 43.8 per cent. were between the ages of twenty and fifty-five, when the death rate is low, as compared with 52.4 per cent. at the same ages in the State at large. The percentage of the population who were over fifty-five (at which ages the death rate is high) was 29.6, as compared with only 11.4 in the State at large in the same census year. As a consequence, Nantucket in that year should be credited with a standard death rate of 27.02, a factor for age and sex correction of 0.733. The crude or recorded death rate of the town was 33.74 per thousand, the corrected death rate 24.73, and the comparative mortality figure 1,261.

According to F. L. Hoffmann, the fallacy of disregarding the effect of age distribution is shown in a recent United States Government report, wherein it is stated that "the significance of the annual *rate of death* from disease in the Philippines (17.2 per thousand) may be better appreciated by comparison with the rates in some of our well-known American cities. Mr. Root gives a table showing the annual death rates of Washington, Boston, etc., together with the mortality rate from disease of soldiers in the Philippines. Even a moment's reflection would have made it clear that a comparison of the death rate of soldiers, mostly of ages from eighteen to thirty, could not properly be made with the mortality of the general population at all ages. Even a comparison with the general death rate of cities, at ages from fifteen to forty-five, which, according to the then available census of 1890, was 10.9 per thousand, would not have been accurate, in that soldiers represent a carefully selected class of physical risks in contrast to the general population, which includes the sick and otherwise physically impaired. The only accurate method of comparison which could have been suggested to the Secretary of War by the surgeon-general of the army would have been the average mortality rate from disease of soldiers in the United States army previous to the war with Spain.

But by this method the argument advanced by Mr. Root could not have been proven, for, according to the annual reports of the surgeon-general, the mortality of soldiers from disease during the five years, 1891–95, was at the rate of 4.3 per thousand, while during 1896 the rate was 3.8, and during 1897 it was 3.1. In other words, the mortality of soldiers in the Philippines from disease was four times as great as the mortality from disease of United States soldiers under conditions of peace." (F. L. Hoffmann, in Transactions of American Statistical Association, December, 1902, p. 198.)

INFANT MORTALITY.—The mortality of infants under one year of age should not be compared with the general population, since the relative number of living infants varies much in different communities. A more correct method is to compare the deaths of infants one year old with the living infants of the same age. It has not been found practicable, however, by ordinary census methods to find the number of infants with accuracy. This is shown by the census figures of almost any State or country for the first five years of life.

For example, the figures for Massachusetts in the state census of 1885 and the United States census of 1900 were as follows:

NUMBER OF CHILDREN LIVING AT CERTAIN AGES.

Years.	State Census (1885).	U. S. Census (1900).
0–1 year	35,888	60,492
1–2 years	27,327	53,943
2–3 "	40,353	56,257
3–4 "	38,061	56,678
4–5 "	36,706	54,867

In the foregoing table the numbers of children found who were under two years of age, but over one year, were less in each census than those who were a year older as well as less than those who were a year younger. But since immigration does not largely affect the numbers at these early ages, we should naturally expect to find a diminishing series beginning with the first year of life, the deaths making the numbers for each successive year of life less and less. This error appears in the eighth census also, and in order to obtain the number of infants under one year correctly it is necessary to calculate a redistribution of these early years, or, what is preferable, to use the births as a standard.

For the purpose of greater accuracy, the deaths under one year occurring in a calendar year should be compared with the births of an earlier period, since many of the infants under one year dying in any year were born in the previous year. For this reason it is customary to employ as a standard of comparison the births occurring in a year ending with June 30th, and to compare with this number the deaths under one year occurring in the calendar year ending December 31st.

Upon this basis, the infant mortality of Massachusetts during the twenty years, 1856–75, was 150.3 per thousand births, and that of the succeeding twenty years, 1876–95, was 161.2 per thousand, the mean of the forty-year period being 156.7. The births employed in this calculation were those which occurred during the period beginning July 1st, 1855, and ending June 30th, 1895; and the deaths under one year were those which occurred in the forty calendar years, 1856–95, inclusive.

The infant mortality of the five following years, 1896–1900, was respectively 167.7, 148.1, 149.1, 148.0, and 159. The infant mortality of cities is usually greater than that of the rural districts. In Massachusetts, in the ten years 1881–90, the infant mortality of the cities was 174.9 per thousand births, and that of the rural districts was 129.5. The following table presents the infant mortality of several countries:

INFANT MORTALITY.* DEATHS UNDER ONE PER 1,000 BIRTHS.

Countries.	Years.	Infant Mortality per 1,000 Births.	Countries.	Years.	Infant Mortality per 1,000 Births.
Ireland	1884–88	94	Italy	1884–91	192
Sweden	1881–90	97	Prussia	1886–92	207
Scotland	1885–90	120	Hungary	1884–87	212
England	1885–91	144	Austria	1886–87	246
Belgium	1881–91	159	Saxony	1886–92	281
France	1885–90	165	Bavaria	1879–88	287
Holland	1885–90	179			

* From paper by Dr. Eross, in Koch's Zeitschrift f. Hygiene, vol. 19, 1896, p. 371.

An important factor in relation to infant mortality is the method of feeding. The best information upon this point comes from the city of Berlin, where, for several years, all infants have been classified with reference to the method of feeding, so that the ratio of deaths of each class could be estimated.

The results of these observations extending over a series of years were as follows. Mortality per thousand infants under one year old in Berlin:* Among those who were fed on the mother's milk only, 7.4 per 1,000; on mother's milk and cow's milk, 21.4 per 1,000; on cow's milk alone, 42.1 per 1,000; on milk substitutes, 67.7 per 1,000; on cow's milk and milk substitutes, 125.7 per 1,000. These figures are the result of observations upon 65,720 deaths of infants under one year old in Berlin.

The health commissioner of Buffalo claims a large reduction in the infant mortality of that city by the suppression of the sale of nursing-bottles having long tubes attached and by other ordinances of a similar character.

Effect of Intemperance and Poverty upon Infant Mortality.—It is hardly necessary to assert the effect of these factors in the causation of infant mortality. In every country the records show their damaging effects. Cities in which intoxicating liquors are freely sold under license laws have a higher infant mortality than those cities in which such sale is forbidden by the popular vote. In the census year 1895, the infant mortality in the seventeen cities of Massachusetts in which licenses were granted was 174 per 1,000 births, while in the cities in which no licenses were permitted the infant mortality was only 122 per 1,000. In this estimate no account was taken of those few cities in which the sentiment of the voting population was so equally balanced that a change from license to no license, or *vice versa*, took place during the year in question.

The effect of poverty is shown in Dr. Billings' census volume relating to the vital statistics of certain cities, wherein the mortality of children under five years of age in one ward of a certain city inhabited by a poor class of residents was 157.1 per 1,000 living of the same age, while a neighboring wealthy district had a mortality of only 40.4 for the same class.

Again, the average pay of shoemakers is from sixty to ninety per cent. greater than that of cotton and woollen operatives. The infant mortality of the three shoe-manufacturing cities of Lynn, Haverhill, and Brockton for the ten years 1881–90 was 146.1, while that of the cotton factory cities Fall River, Lowell, and Lawrence for the same period was 227 per 1,000 births.

Effect of High Birth Rate.—That a high birth rate is not necessarily a concomitant of high infant mortality is shown by Dr. H. May in a letter to *Public Health* (March, 1903), in which he shows that while the birth rate had fallen in each of the following large cities, the infantile mortality had risen.

---

* International Statistical Bulletin, vol. ii., No. 2, p. 14.

City.	BIRTH RATE.		Fall in birth rate. Per cent.	INFANTILE MORTALITY.	
	1876.	1901.		1876.	1901.
Salford	49.3	29.2	43.0	189	204
Manchester	39.8	29.1	27.0	180	199
Birmingham	42.8	32.1	25.0	160	187
England and Wales	36.3	28.5	20.5	146	151

Density of population has an influence upon the death rate. The death rate of rural districts is lower than that of cities, as a general rule. The urban districts of England in 1899 had a death rate of 19.2 per 1,000, while that of the rural population was only 16.3. In Massachusetts the death rates in 1890 and 1900 in the urban and rural populations were respectively 20 and 18.5 per 1,000 in the urban districts and 17.8 and 17.3 in the rural districts. It is only when the density has reached a certain degree of intensity that it begins to assert an appreciable effect. Even then it is what is implied in or is an attendant upon aggregation, rather than the aggregation itself, that is harmful. Poverty and intemperance are usually greater in densely populated districts than elsewhere, with their accompaniments of deficient food and clothing and bad housing. Hence the excess of phthisis in tenement-houses, and especially in those tenements consisting of two or three rooms only. Newsholme says that "the true density that should be considered is the number of persons to each room, not the number of persons on a given area" ("The Vital Statistics of the Peabody Buildings," Royal Statistical Society, February, 1891).

Dr. Farr had proposed an extremely mathematical rule or formula for the calculation of the death rates of populations of different density, stating at first that the mortality increases in proportion, not to the density of population, but to the sixth root of the density. This formula he afterward changed to the eighth root approximately, or, more exactly, to 0.11998.

By this formula if d and d' = density of population of two places, and m and m_1 = mortality of population,

$$\text{then } \frac{m'}{m} = \sqrt[8]{\frac{d'}{d}} \text{ and}$$

$$m' : m :: \sqrt[8]{d'} : \sqrt[8]{d}$$

In 345 English districts which had a mortality of 19.2 per 1,000, the density was 186 persons per square mile. What was the mortality in 9 of these districts which had a high density of 4,499 per square mile?

$$\frac{m'}{19.2} = \sqrt[8]{\frac{4,499}{186}} \qquad m' = 28.6$$

So closely was the ratio found to be followed in places whose sanitary conditions were fairly the same, and which differed only in density of population, that Dr. Farr proposed that in any sanitary inquiry the influence of density should first be discovered by means of the foregoing formula, and that the effect of other influences above or below this should then be investigated. But the death rate has declined in recent years, as density has increased. In England the density of population has increased from 307 per square mile in 1851 to 497 in 1891, while the death rate meanwhile has declined from 22.5 to 19.1 per 1,000 in the same time. In New England the density increased from 75.8 in 1890 to 90.2 per square mile in 1900, while the death rate decreased as follows: In 1892, 19.9; in 1893-97, 18.3; in 1898-1900, 17.3.

With Newsholme, therefore, we are led to believe "that either the relationship between density of population and mortality is accidental rather than essential, or that countervailing influences are at work."

While, therefore, this strict mathematical formula may be applicable to the densely crowded portions of large cities when compared with each other, it does not necessarily apply when the condition of one district is compared with its own condition at an earlier period when the density was much less. Nor can it be employed in comparing the populations of cities and districts in the United States, without careful correction for age and sex distribution.

In the three States of Maine, New Hampshire, and Vermont, with an average density of population of 30.2 per square mile, the death rate in the nine years 1892-1900 was 16.90; but in the three States, Massachusetts, Rhode Island, and Connecticut, with an average density of 296.5 per square mile, the death rate in the same period was 18.55 per 1,000.

To a certain degree the number of rooms occupied by a given number of people bears a definite relation to the density of population as well as to its social condition, and hence has a direct effect upon the death rate, as shown in the following table for the city of Glasgow:[*]

Size of houses.	Census population (1901).	DEATHS FROM ALL CAUSES.		INFECTIOUS DISEASES.		PHTHISIS.		RESPIRATORY DISEASES INCLUDING CROUP.	
		Deaths.	Death rate.	Deaths.	Death rate.	Deaths.	Death rate.	Deaths.	Death rate.
One room	104,128	3,405	32.7	771	7.4	247	2.4	792	7.6
Two rooms	348,731	7,418	21.3	1,576	4.5	620	1.8	1,600	4.6
Three rooms	151,754	2,081	13.7	290	1.9	178	1.2	362	2.4
Four rooms and more	136,511	1,533	11.2	139	1.0	99	.7	272	2.0
Whole city	....	....	20.6	....	3.8	....	1.8	....	4.3

The Effect of Occupation upon Mortality.—The occupation or calling in which persons are engaged has an influence upon the health and consequent length of life of those who are thus employed, some occupations being more favorable to health than others.

Various methods have been adopted for measuring the comparative healthfulness of occupations. For several years it was customary in some of the older States to give the *mean age at death* of persons engaged in different occupations and thus to compare them with each other. This method, however, is entirely fallacious. For example, the average age at death of judges in Massachusetts was 65.9 years, of clerks 36.4 years, and of students 23.7 years. These figures obviously have no value as determining the comparative length of life or healthfulness of the persons engaged in these employments.

Nor is it a strictly correct method to compare the number dying in any given occupation with the number engaged in such occupation, since the persons entering upon the duties of one occupation may do so at a much earlier or later age than those entering another occupation which may be compared with it.

According to Newsholme,[†] the only trustworthy method is to compare the mortality of those engaged in one occupation and of a given age, with the mortality of those engaged in another occupation and of a corresponding age.

The circumstances which render certain occupations injurious to the health of persons engaged in them are overcrowding and defective ventilation, extremes of heat and cold, inhalation of noxious vapors, and especially of dust, both organic and inorganic, exposure to lead and other poisons, mental anxiety, and exposure to intemperance.

---

[*] "The Death Rate in One-Apartment Houses," by A. K. Chalmers, M.D., Medical Officer of Health of Glasgow, 1903.

[†] "Vital Statistics," third edition, page 172.

Observations upon the mortality of occupations in American communities are generally untrustworthy and inaccurate; first, because of wrong methods adopted; and second, because of the shifting and unstable character of persons employed, as compared with those engaged in foreign industries.

The following table, constructed by Dr. Tatham from the registrar-general's returns of England for the years 1890–92, may be deemed accurate for English occupations. It embraces the statistics of death of 61,215 men who were engaged in the occupations named in the table.

Occupations.	AGES.				Comparative mortality figures.
	25–35 years.	35–45 years.	45–55 years.	55–65 years.	
Clergyman, priest	4.86	4.23	5.18	10.52	533
Lawyer, solicitor	5.32	10.67	17.72	34.50	821
Physician, surgeon	6.69	14.92	21.04	34.16	966
Commercial traveller	6.09	12.62	21.41	39.28	961
Farmer, grazier	4.29	7.03	11.20	23.97	563
Agricultural laborer	5.54	9.14	13.56	24.83	666
Fisherman	9.13	10.60	18.61	25.65	845
Innkeeper, bartender, etc	15.21	23.32	34.84	53.18	1,642
Innkeeper's servant	15.06	24.52	35.24	52.68	1,659
Grocer	5.40	8.62	14.34	24.92	664
General shopkeeper	8.89	14.03	19.92	32.59	973
Printer	9.10	14.40	21.56	43.39	1,096
Butcher	7.53	15.66	22.65	43.32	1,096
Corn miller	5.07	9.33	18.90	38.83	845
Hatter	6.96	15.35	24.75	43.90	1,109
Baker, confectioner	6.49	11.00	22.18	35.45	920
Tailor	6.86	13.67	21.98	37.59	989
Hairdresser	9.41	15.01	23.28	39.03	1,099
Shoemaker	7.66	11.35	19.85	35.25	920
Tanner	5.78	6.40	18.69	32.78	756
Currier	6.79	12.67	22.16	40.62	998
Tool, scissors, file, saw, needle maker	8.36	18.38	32.93	57.52	1,412
Blacksmith	5.80	10.81	20.74	39.45	914
Copper, lead, tin, zinc worker	7.43	13.98	24.55	46.02	1,123
Bricklayer, mason	6.55	13.45	22.04	40.23	1,001
Carpenter, joiner	5.78	9.36	17.19	32.15	783
Plumber, painter, glazier	7.04	14.79	25.13	45.58	1,120
Woollen operatives	6.99	11.99	20.58	43.76	996
Cotton, flax, linen operatives	7.13	13.38	25.11	55.06	1,176
Wool, silk, cotton dyer and printer	10.90	16.14	28.05	57.95	1,370
Potter, earthenware maker	8.19	19.58	42.97	75.13	1,706
Coal miner	6.29	9.63	19.42	43.79	935
Tin miner	8.06	14.32	33.20	66.09	1,409
Glass maker	11.32	17.88	32.14	60.79	904

In the foregoing table, the first four columns of figures present the death rates at four different ages of persons engaged in the specified occupations. For example, the death rate of clergymen, twenty-five to thirty-five years of age, is 4.86 per 1,000; of innkeepers of the same age, 15.21 per 1,000. The figures in the last column should be read as follows: The same number of men (aged twenty-five to sixty-five years) that would give 1,000 deaths among all males (as a standard of comparison) would give 533 among the clergy, 563 among farmers, 1,642 among innkeepers and bartenders, 1,412 among steel grinders, etc.

When the mortality of persons in different occupations is distributed according to the causes of death, we find more specific results of the effect of such industries on the health of the employed. The highest mortality from cancer among occupied males is found among chimney-sweeps. For phthisis the lowest mortality is found among clergymen, railway engineers and stokers, farmers and coal miners; and the highest among steel grinders, lead miners, costermongers, and hotel servants. Pneumonia causes a low mortality among teachers and the clergy, and a high mortality among hotel servants, dock laborers, iron workers, and coal heavers. Diseases of the liver cause low mortality among the clergy and railway porters, and high mortality among lawyers, brewers, physicians, and publicans.

The following table* is interesting as showing the effects of dust-laden air in different occupations:

Occupation.	Phthisis and diseases of the respiratory system.	Occupation.	Phthisis and diseases of the respiratory system.
Agriculturist	100	Agriculturist	100
Iron miner	133	Quarryman	261
Carpenter	148	Zinc worker	266
Coal miner	166	Iron and steel worker	292
Corn miller	166	Gunsmith	294
Baker	177	Copper miner	307
Blacksmith	177	Copper worker	317
Wool worker	202	Lead miner	319
Tin worker	204	Glass worker	335
Carpet and rug maker	213	File maker	373
Bricklayer, mason	215	Tin miner	400
Cotton worker	244	Cutler, scissors maker	407
Lead worker	247	Potter, earthenware maker	453
Chimney-sweep	249		

This table is to be read as follows: In each 100 deaths of agriculturists out of a given number employed in such occupations, there would be 133 deaths of iron-miners employed in that occupation, etc. Dr. Ogle points out that the dust of coal and wood is least injurious, that of metals and stone most injurious, while flour dust and that of textile factories occupy an intermediate position in their effects upon health.

Lead Poisoning.—The mortality of all males from lead poisoning being taken as 1, that of printers is 3, lead miners 5, gasfitters 6, coachmakers 7, copperworkers 8, glassmakers 12, potters 17, painters and glaziers 18, plumbers 21, file-makers 75, and lead workers 211.

Alcoholism.—The returns under this head are usually imperfect, but since the intemperate use of alcoholic drinks damages most of the viscera, the excess of deaths from nervous diseases, phthisis, kidney diseases, gout, and suicide in different occupations forms an index of the effect of alcoholism upon health.

In the following table the mortality of occupied males between twenty-five and sixty-five years of age from each cause of death is taken as 100, and the mortality in each industry is reduced to a figure proportional to that standard:†

	Alcoholism and diseases of the liver.	Alcoholism.	Diseases of the liver.	Gout.	Diseases of the nervous system.	Suicide.	Phthisis.	Diseases of urinary organs.
Occupied males	100	100	100	100	100	100	100	100
Coachman, cabman	153	215	122	300	100	143	124	132
Costermonger	163	277	107	150	170	100	239	171
Coal heaver	165	223	137	....	120	50	116	122
Fishmonger	168	215	144	150	109	150	86	120
Musician	168	223	141	450	135	164	174	141
Hairdresser	175	269	130	400	109	250	149	78
Dock laborer	195	400	96	150	139	157	176	166
Chimney-sweep	200	454	78	....	100	221	141	144
Butcher	228	269	207	300	128	164	105	117
Brewer	250	315	219	500	152	121	148	190
Innservant	420	815	230	550	132	179	257	188
Innkeeper	733	708	744	600	195	229	140	220

THE CAUSES OF DEATH.—These are usually stated either in proportion to the number of deaths from all causes or as a ratio of the living population. The latter is the preferable method.

The first plan may be adopted when it is desired to ascertain the proportional share of any given cause of death in the total mortality, but for general purposes the population should be the standard of comparison.

For a half century or more diseases have been classified in most English-speaking countries in accordance with the plan proposed by Dr. William Farr, about the middle of the last century. The principal groups of this system were termed the zymotic, constitutional, local, developmental, and violent classes of disease or causes of death. The progress of medical science, however, has demanded a change, and the Bertillon system of classification has in many countries superseded the system of Dr. Farr. According to this new system, the groups of causes of death are as follows: (1) General diseases; (2) diseases of the nervous system; (3) diseases of the circulatory system; (4) diseases of the respiratory system; (5) diseases of the digestive system; (6) diseases of the genito-urinary system; (7) childbirth; (8) diseases of the skin; (9) diseases of the locomotor system; (10) malformations; (11) early infancy; (12) old age; (13) violence; (14) ill-defined diseases.

* Newsholme's "Vital Statistics," third edition, p. 183.
† Newsholme's "Vital Statistics," third edition, p. 184.

These changes in classification do not in the least interfere with the study of separate causes of death, when it is desirable to compare their present and past incidence upon the population.

A general consideration of the principal infectious diseases shows, in nearly all nations or communities in which registration records are kept, a remarkable decrease, while the diseases of special organs, or local diseases as they have usually been termed, together with cancer, have shown a decided increase. In Massachusetts, for example, the group of diseases embracing smallpox, measles, scarlet fever, diphtheria, typhoid fever, cholera infantum, consumption, whooping-cough, dysentery, and the diseases incident to childbirth had decreased from a mean of 81.7 per 10,000 living in the five-year period 1856–60 to 50.5 per 10,000 in the five-year period 1891–95; while, on the other hand, the group embracing pneumonia, kidney diseases, heart diseases, brain diseases, and cancer had also increased from a mean of 27.7 per 10,000 in the five-year period 1856–60 to 68.8 in the period 1891–95.

Longstaff, in his "Studies of Statistics," shows that similar changes have taken place in England.

Tuberculosis.—This disease, which until a quite recent period has been for at least a half-century and probably much longer the most destructive disease of the human race, has shown a steady decline in mortality in those countries where records have been kept. In England this decrease has been from a mortality of 2,579 per million living among males in the period 1851–60 to 1,487 per million in 1901, and from 2,774 among females to 1,054 in the same time. This shows a greater fall among females than among males, and the same is true of Massachusetts, where the phthisis death rate fell among males from 3,166 per million in 1851 to 1,690 in 1902, and among females from 4,600 per million in 1851 to 1,504 in 1902. The death rate for both sexes from this cause declined still further to 1,595 per million in 1902.

Newsholme says, in treating of this remarkable decrease: "It is possible that, owing to more accurate statement of causes of death, there has been considerable transference from phthisis to diseases (other than phthisis) of the respiratory organs. The term phthisis is now not so loosely used as formerly, when any chronic chest affection received this name. But that this is by no means a complete explanation of the decrease in phthisis is evidenced by the fact that while the mortality from phthisis has decreased at all age groups, the mortality from respiratory diseases has only increased under five and over seventy-five years of age. Furthermore, the mortality from phthisis chiefly takes place between the ages of fifteen and fifty-five years, while that from respiratory diseases is very low during these years and greatest at the extremes of life."

A circular of the imperial board of health of Germany published in 1896 states that out of each thousand deaths during the wage-earning period of life (fifteen to sixty years) there were from tuberculous diseases in Vienna 459 deaths, in Paris 400, in Belgium 371, in Bavaria 359, in the German empire 322, in Denmark 297, and in England 223.

Typhoid Fever.—As an index of the sanitary condition of a community, the death rate from typhoid fever holds high rank, and especially as a proof of the purity of the public water supply. Since the general introduction of public water supplies in cities and towns, the death rate from this disease has steadily fallen.

Ages. The highest relative mortality from this disease is at the ages fifteen to thirty years in both sexes.

Seasons. Typhoid fever proves most destructive in the months of September, October, and November, the number of deaths from this cause in New England occurring after September 1st in each year being usually about as many as those which precede that date.

In those cities in which public water supplies have been introduced, the typhoid death rate has fallen from 21 per 10,000 in Munich to 6.3, in Dantzic from 9.9 to 2.4, in Berlin from 9.2 to 2.9, in Vienna from 12 to 2.1, in London from 10.2 to 4.5, and in Lawrence, Mass., from 13.4 to 1.6, the periods which elapsed varying from five to forty years. In Lawrence the death rate from this cause fell within a few weeks after the introduction of filtered water from 10.5 in 1892 to 4.8 in 1894, the filter being introduced in 1893.

The general decline in this death rate in Massachusetts is illustrated by the following diagram and table, in which the typhoid death rate is compared with the *percentage of the population not supplied with public water,* since it is among this portion of the population that typhoid fever largely occurs. Many people even in large cities still derive their water supply from polluted sources, wells, springs, and canals in manufacturing cities.

TYPHOID FEVER IN MASSACHUSETTS.

Period.	Death Rate from Typhoid Fever, per 100,000.	Percentage of Population Not Supplied with Public Water.
1856–65	92.9	75.4
1866–75	80.8	58.9
1876–85	47.4	31.7
1886–95	36.4	13.9
1901	19.5	8.5

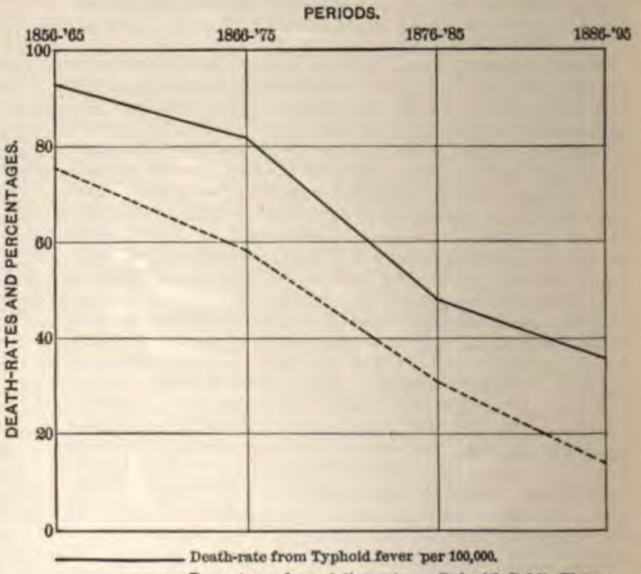

FIG. 5027.

carlet Fever.—This disease proves most destructive in second, third, fourth, and fifth years of life. Three es as many die of it in the first five years of life as in second five years, and about fifteen times as many as he period ten to fifteen years.

he death rate of the two sexes is nearly equal, and number dying in the first half of the year is consid- bly greater than those who die in the second half.

he death rate from this cause declined in England n over 9 per 10,000 in 1866–70 to 2 in 1891–95. It declined still further to 117 per million in 1899, ch was the lowest death rate in that country from cause on record. A similar decline has been observed nany other countries, and may undoubtedly be at- uted to the introduction of more efficient methods of tion and control of infectious diseases.

easles.—The deaths from this disease are also greatest umber in infancy and childhood, the mortality in the five years of life being eight or ten times as great as e second five years. The deaths of the two sexes this cause are nearly equal. (In Massachusetts in ty years there were 4,015 deaths of males and 3,984 males from measles.) The deaths from this cause in irst six months are usually greater in number than which occur in the last six months of the year. death rate from this cause has declined in most tries, but not so decidedly as in scarlet fever.

England it was 315 per million in 1899, or the low- ate recorded since 1881.

Massachusetts it was 159 per million in the twenty s 1856–75, and only 90 per million in the twenty 1876–95.

hooping-Cough.—This disease is more fatal in the first of life than in any succeeding year. More females f it than males, and the death rate from this cause liminished, the rate in England in 1899 having been er million, or the lowest yet recorded except that 895, which was 316. That of Massachusetts had de- l from 220 per million in the twenty years 1856–75, 0 in the twenty years 1876–95.

htheria.—The figures for diphtheria are now usu- onsidered together with those of membranous croup. nortality is greatest in the second, third, fourth, and years of life, that of the third and fourth years com- being slightly greater than those of the second and years. The death rates of the sexes are nearly the in diphtheria, but of the deaths registered as from those of males are slightly in excess.

effect of seasons upon the prevalence of this dis- s quite uniform and well marked, the lowest death usually occurring in midsummer (June to August), which the rate rapidly rises to November, and con- s at a high rate until January or February, after the decline is more gradual than the rise in the n. There is reason to believe that the rapid rise tumn as related to the opening of the schools is than a mere coincidence.

prevalence from one period to another for a long of years has been quite irregular as shown by the ing figures for Massachusetts, embracing the ies of 64,281 deaths from this cause:

ear s.	Deaths from diphtheria.	Death rate per 10,000 living.	Five-year periods.	Deaths from diphtheria.	Death rate per 100,000 living.
0...	2,949	4.9	1881–1885....	8,944	9.5
5...	7,710	12.8	1886–1890....	8,857	8.4
0 .	3,664	5.3	1891–1895....	7,652	6.4
5...	5,036	6.4	1896–1900....	6,331	4.7
0...	13,676	15.8			

h reference to the fatality of this disease (ratio of to cases) a marked change has taken place since neral introduction of antitoxin treatment in 1894– revious to its introduction the fatality of diphtheria l from 25 to 40 per cent. in different localities. In Massachusetts it was 28.3 per cent. for the four years 1891–94, but this percentage has been cut down to 13.1 per cent. for the seven years 1895–1901, and in 1901 it was only 10.5 per cent. The meaning of these figures, according to the Thirty-third Annual Report of the State Board of Health of Massachusetts is a saving, in the seven years, of 10,697 lives, and even if all sources of error were to cut down this figure by one-half "the result would be the saving of more than 5,000 lives by the use of antitoxin in the seven years 1895–1901."

There has also been a decided reduction in the death rate from dysentery and from puerperal fever and the diseases incident to childbirth, these latter being coincident with the introduction of antiseptic methods in the management of the lying-in chamber.

In Prussia the death rate of women in childbirth has been diminished from 81.8 per ten thousand births in the five years 1856–60 to 43.3 in the three years 1891–93, or nearly one-half. These figures are the results of observations upon over 44,000,000 cases of labor, and 296,-867 deaths in childbirth.[*]

Smallpox.—The statistics relating to this disease and its relation to the practice of vaccination may be found fully stated in the article on *Vaccination.*

Other causes of death from which the death rate has increased. The foregoing causes of death in which the death rate has fallen during the past half-century are of the infectious class, and are mainly the diseases of children and young adults. Had the death rate from all other causes remained stationary this decided fall in that of infectious diseases would have caused a material reduction in the general death rate, an observation which applies to most countries where vital statistics are carefully recorded. But the death rate from most of the diseases, usually known as local diseases, has increased in a ratio nearly equal to the decline in infectious diseases. For example, Longstaff in his "Studies of Statistics," p. 280, presents the following table, which may be termed the balance of mortality:

ENGLAND.

The death rate from each of the following diseases per million inhabitants has fallen from the five years 1850–54 to the five years 1875–79, as follows:		The death rate from each of the following diseases per million living has risen, 1850–54 to 1875–79, as follows:	
Phthisis	694	Lung diseases	1,218
Developmental diseases	617	Heart diseases	698
Fever (mostly typhoid)	569	Brain diseases	378
Dropsy	405	Kidney diseases	229
Convulsions	342	Liver diseases	32
Cholera	287	Cancer	191
Smallpox	197	Diphtheria	69
Scarlet fever	173	Tabes mesenterica	65
Tuberculous meningitis	111	Whooping-cough	45
Sudden death (cause unknown)	101	Rheumatism	45
Diarrhœa	85		2,963
Disease of stomach and intestines	68	Balance, a fall per million of	1,049
Measles	64		
All other causes	299		
	4,012		

There are several points of interest in the foregoing table:

1. Most of the destructive infectious diseases are found in the column of those in which the death rate has fallen, while the local diseases, or diseases of special organs, are found in the other column of causes in which the death rate has risen.

2. The former class, including phthisis, are chiefly diseases of children and young adults, while the latter, the local diseases and causes, are diseases of advanced life.

3. The decided fall in some instances may be taken as an evidence of more exact diagnosis of disease, as in the case of "dropsy," a symptom only which is now more commonly certified under its correct title of heart, kidney, or liver disease, hence the lessened number of cases atttributed to this indefinite cause.

---

[*] Dr. H. B. Brennecke. in Vierteljahrsschrift f. öff. Gesundheitspflege, 1897, p. 81, vol. xxix.

4. The fall in the death rate from typhoid fever "is without doubt," as Longstaff states, "the great triumph of the sanitary reformers." Undoubtedly, a large share of the fall in phthisis, smallpox, scarlet fever, and measles may reasonably be attributed to the same cause.

5. The steady rise in the death rate from cancer has given occasion for comment and investigation in all countries where registration of deaths is made.

The following figures show the increase of cancer in the countries and cities named:*

Various Countries.

In Germany, while the population increased from 1890 to 1900 14.18 per cent, cancer increased in 10 states in a shorter period (1892-93 to 1898-99) 24.56 per cent.
In Ireland cancer increased with a diminishing population from 5.8 per 10,000 in 1897 to 6.5 in 1901, or in absolute numbers, 2,635 to 2,893 deaths.
In Austria from 5.4 per 10,000 in 1891 to 7.0 in 1900.
" Bavaria from 8.9 per 10,000 in 1891 to 9.9 in 1900.
" Holland from 7.9 per 10,000 in 1891 to 9.3 in 1900.
" Italy from 4.3 per 10,000 in 1891 to 5.2 in 1900.
" Norway from 6.1 per 10,000 in 1891 to 9.2 in 1900.
" England from 5.1 per 10,000 in 1880 to 8.3 in 1899.
" Switzerland from 11.4 per 10,000 in 1889 to 13.2 in 1898.
" 250 cities of France from 8.4 per 10,000 in 1887-90 to 11.0 in 1900.

New England States.

" Maine from 6.1 per 10,000 in 1891 to 7.6 in 1900.
" New Hampshire from 5.6 per 10,000 in 1891 to 7.1 in 1900.
" Vermont from 5.5 per 10,000 in 1891 to 8.5 in 1900.
" Massachusetts from 6.1 per 10,000 in 1891 to 7.1 in 1900.
" Rhode Island from 5.1 per 10,000 in 1891 to 6.8 in 1900.
" Connecticut from 5.2 per 10,000 in 1891 to 6.6 in 1900.

Various Cities.

" Boston from 6.9 per 10,000 in 1891 to 8.1 in 1900.
" Brussels from 3.4 per 10,000 in 1891 to 4.4 in 1900.
" Breslau from 8.6 per 10,000 in 1891 to 10.8 in 1900.
" Copenhagen from 13.6 per 10,000 in 1891 to 13.9 in 1900.
" Munich from 12.7 per 10,000 in 1891 to 11.9 in 1900 (14.8 in 1897).
" New York from 5.4 per 10,000 in 1891 to 6.7 in 1900.
" Paris from 10.0 per 10,000 in 1891 to 10.5 in 1900.
" St. Petersburg from 9.9 per 10,000 in 1891 to 10.0 in 1900.
" Vienna from 10.4 per 10,000 in 1891 to 12.1 in 1900.

The Relation of Seasons to the Death Rate.—Seasons have an influence upon the mortality of populations. In temperate climates, having a wide difference between the temperature of summer and winter, a very cold winter usually increases the mortality of aged people, while an unusually hot summer increases the infant mortality. The effect of seasons may be shown by dividing the year into four quarters and stating the death rate in each. For this purpose the Registrar-General of England re-estimates the population for each quarter, allowing for increase. Dr. Böckh, of Berlin, makes a new estimate for each month in stating a monthly death rate.

MONTHLY DEATHS IN NINETY CITIES AND LARGE TOWNS IN MASSACHUSETTS IN 1901.

	Deaths in each month.	Deaths per day.	Monthly ratio.		Deaths in each month.	Deaths per day.	Monthly ratio.
January	3,742	120.7	108.8	August	3,683	118.8	107.1
February	3,517	125.6	113.2	September	3,514	117.1	105.6
March	3,832	123.6	111.4	October	3,178	102.5	92.4
April	3,406	113.5	102.3	November	3,127	104.2	94 0
May	3,063	98.8	89.1	December	3,296	106.3	95.9
June	2,886	96.2	86.7				
July	3,250	104.8	94.5		40,494	110.9	100.0

In order to show the relative incidence of disease in each month, the writer has adopted the following method, which corrects the effect of the varying length of the months.

Divide the whole number of deaths in the year by 365, to obtain a daily standard (in leap year 366).

Also divide the number of deaths in each month by the number of days in the month.

Divide the daily number of deaths in each month by the daily number for the whole year and multiply by 100.

By this method the intensity of the death rate in each month may be compared with that of the year, and with that of each of the other months.

By quarters of the year the highest mortality in the German Empire, Austria, Switzerland, and France was in the first quarter, but in Italy the highest mortality was in the third quarter. In Massachusetts during the forty years (1856-95) the highest mortality was in the third quarter.

With reference to the different diseases or causes of death considerable variations are found when these causes are compared with each other.

The following table presents the relative monthly incidence in the mortality from eight different diseases in Massachusetts for the twenty years 1876-95. These observations are made from 291,222 deaths from the specified diseases which occurred during the period named (1876-95).

TABLE SHOWING THE COMPARATIVE MORTALITY BY MONTHS OF EACH OF EIGHT DISEASES IN MASSACHUSETTS (1876-95).

	Measles.	Scarlet fever.	Diphtheria.	Typhoid fever.	Dysentery.	Cholera infantum.	Consumption.	Pneumonia.
January	94.8	143.2	124.0	79.2	17.9	5.2	104.9	171.4
February	103.4	121.0	106.1	67.3	19.4	4.7	104.2	153.8
March	116.1	129.1	89.4	64.6	19.7	5.3	109.5	158.8
April	166.7	121.5	90.4	67.7	19.8	6.0	110.4	154 5
May	182.9	120.1	92.4	62.8	23.7	9.4	105.6	115.1
June	169.0	91.9	83.7	56.8	35.2	39.5	94.6	60.7
July	128.7	63.9	68.3	64.7	187.9	382.8	93.7	39.0
August	55.2	56.0	65.8	125.0	416.5	443.8	94.2	32.1
September	33.7	55.7	86.3	190.8	282.5	216.2	95.8	39.5
October	30.3	78.8	125.1	181.3	115.5	56.2	95.8	61.8
November	49.7	105.3	134.7	136.4	35.0	12.9	93.8	88.0
December	70.6	114.7	134.1	102.3	18.8	5.5	97.5	128.2
Mean	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0

These figures are to be read as follows: Assuming a monthly standard mean of 100 throughout the year, there were 94.8 deaths from measles in January, 103.4 in February, 116.1 in March, etc.

Vital Statistics as Tests of the Comparative Healthfulness of Communities.—1. The general death rate is the test most commonly applied for determining the comparative health of different communities. It, however, has certain limitations. It may be trusted for comparing the health of a city, town, or district for any given year with that of the same community for a preceding year or period. But when comparison with other districts, cities, or towns is to be made, erroneous conclusions may be drawn.

(*a*) Because of differences in the age and sex distribution of the population of the places compared with each other (see page 250).

(*b*) There may be public or private institutions in the city or town in which deaths of persons other than residents occur. Correction for these should be made. For example, in a small town in Massachusetts in 1900 having a population of 3,683, the deaths were 453, giving the enormous death rate of 123 per thousand of the population; 402 of these deaths occurred in a state institution, leaving for the town a death rate of about 19 only.

(*c*) Occupation and social conditions have a decided effect upon the death rate. In the manufacturing communities in which different industries are conducted, one in which the wages are high and the other in which they are low, the death rate of the well-paid population is usually comparatively low.

2. The death rate from the principal infectious diseases is often quoted as an index of sanitary condition, the diseases embraced in such a general statement being measles, diphtheria, scarlet fever, whooping-cough, typhoid

---

* The figures are from the Mittheilungen aus Kaiserlichen Gesundheitsamte, vii., p. 120, and "Uebersicht über Verbreitung der Krebskrankheit am Ende des 19. Jahrhunderts in einigen ausserdeutschen Gebieten," by Dr. Rahts, and from the Registrar-General's Report upon Cancer in Ireland, Dublin, 1903.

fever, cholera infantum, and tuberculosis. In consequence of the different methods by which such diseases are spread the methods of prevention also differ, and are more susceptible of application in some diseases than they are in others.

For example, a high death rate from typhoid fever in a town would indicate a greater neglect of sanitary precautions than a high death rate from influenza. In presenting the death rates from preventable or communicable diseases it is better to state the death rate of each one separately than to give an average of several, since the latter method is apt to conceal the effects of epidemics from special causes.

3. The infant mortality constitutes a delicate test of sanitary conditions, but should not be quoted as the only test or index. It should always be based upon the number of births, and not upon the census enumeration (see page 251).

4. A more exact method when all the data are complete is to construct a life-table by which the expectation of life may be compared in different districts, as well as among different classes of population. Those of insurance companies may be compared with each other, or with a general average of several companies; but these are obtained from a large number of lives selected by individual examination, and should theoretically give more favorable results than those constructed from the general population. The difference, however, between the expectation of insured lives and that of the general population at the same ages is less than might at first thought have been expected.

These tests of the health of a community, and especially the general death rate, are most trustworthy when the experience of a given community or district for a certain year is compared with its experience in a previous year or number of years, and least trustworthy when comparing its experience with that of other communities or districts.

Effect of Sanitary Improvements upon the Death Rate.—The most convincing proof of the effect of sanitary measures in lowering the death rate is shown in the Reports of the Registrar-General of England, as well as in the Ninth Report of the Privy Council of the same country. In the Registrar's Report for 1881 he says: "There is nothing in the series of reports issued by this office that comes out more distinctly and unmistakably than the wonderful effect which the sanitary operations of the last decade have had in saving life. The Public Health Act came into operation in 1872. The average annual death rate for the immediately preceding ten years (1862–71) had been 22.6, and there were no indications whatsoever of any tendency of the rate to fall lower. Indeed, in 1871, the final year of this period, the rate was exactly the average, viz., 22.6. The act came into force, and at once the rate began to fall, and continued to fall year by year with almost unbroken regularity, until in 1881 it was no more than 18.9. Once only in the ten years that had elapsed since the act came into operation was the rate as high as the average of the previous decades. . . .

"Had the fall in the death rate been limited to a single year or to two years, or even to three, it might have been argued by sceptical persons that the improvement was due to a succession of seasons favorable to health, or to other causes unconnected with sanitary administration, and that the setting in of the fall, coincidently with the coming into operation of public health measures was no more than casual; but, in face of a fall, lasting for ten years in succession and increasing each year in amount, no one can seriously maintain such a position. There can be no real doubt that the saving effected in life was the direct product of the money and labor expended in sanitary improvements."

A similar effect has been observed in many large cities following the introduction of purer water supplies and other sanitary improvements, notably in Hamburg, Paris, Munich, Vienna, Berlin, Chicago, and in Lawrence.

Fallacies in Vital Statistics.—For the purpose of avoiding serious errors in the use and interpretation of vital statistics Quetelet has proposed the following excellent rules:

1. Never have preconceived ideas as to what the figures are to prove.

2. Never reject a number that seems contrary to what you might expect, merely because it departs to a great extent from the apparent average. (Any unusual departure from an apparent average, however, should lead the statistician to make a careful revision of his figures with the object of correcting possible errors.)

3. Be careful to weigh and record *all* the possible causes of an event, and do not attribute to one what is really the result of the combination of several.

4. Never compare data which have nothing in common.

Errors from paucity of data often occur in medical writings where statistics are employed. A small number of observations is not sufficient to establish a conclusion. The degree of approximation to the truth may be estimated by means of Poisson's formula:

μ = the total number of cases recorded in two groups.
m = the number in one group.
n = the number in the other group.
Hence $\mu = m + n$.

The extent of variation in the proportion of each group to the whole will vary within the proportions represented by $\frac{m}{\mu} + 2\sqrt{\frac{2\,m\,n}{\mu^3}}$, and $\frac{n}{\mu} - 2\sqrt{\frac{2\,m\,n}{\mu^3}}$.

The larger the number of the total observations (μ) the less will be the value of $2\sqrt{\frac{2\,m\,n}{\mu^3}}$, and the less will be the limits of error in the simple proportion $\frac{m}{\mu}$.

Thus, out of 150 cases of diphtheria 18 died, a fatality of 12 per cent. The possible error is determined by the second half of the above formula,

$$= 2\sqrt{\frac{2 \times 18 \times 132}{150^3}} = 2\sqrt{\frac{4,752}{3,375,000}} = 0.0756,$$

i.e., the possibility of error = 0.0756 of unity or 7.56 per cent. In other words, in a second series of cases of diphtheria under the same conditions as the foregoing, the fatality may vary from 4.44 to 19.65 per cent., an indefinite result which indicates that the first series cannot be depended upon as establishing more than a *prima-facie* case in favor of any special method of treatment that may have been adopted. If 15,000 cases and 1,800 deaths are taken the limits of error are comparatively small.

The steady decrease in the limits of possible error as the number of recorded facts increases is shown in the following table, where in the first line there are 7 recoveries (70 per cent.) out of 10 cases, and in the last line 700,000 out of a million cases. In the first instance the absurdity of drawing conclusions from a small number is shown, since the possible recoveries are actually greater than the whole number of cases:

Total number of cases.	Number of recoveries.	Possible number recovering out of 100,000 cases according to Poisson's formula.
10	7	29,020 or 110,980.
100	70	57,000 or 73,000.
1,000	700	66,000 or 74,000.
10,000	7,000	68,700 or 71,300.
100,000	70,000	69,600 or 70,400.
1,000,000	700,000	69,870 or 70,130.

An instance illustrating this fallacy occurs in a recent work upon vaccination, in which the author makes the following statement:

A certain Society for the Relief of the Blind publishes the names of fifty people seeking relief, and states the causes of their blindness: "One of these people was blind from having had smallpox. Smallpox hence appears to occasion two per cent. of the blindness at the present time."

The fallacy of this statement appears upon the application of the foregoing rule, since the limits of error allow a variation of 5.6 per cent. in either direction, or from − 3.6 to + 7.6 per cent., which renders the observation comparatively valueless. If, on the other hand, the number of the blind were 500,000, and those out of this number whose blindness was caused by smallpox were 2 per cent., or 10,000, the limits of error would only be 0.00056 in either direction, or 0.056 of one per cent., leaving a variation of 9,720 to 10,280 only.

Errors from Incomparability of Data.—The data to be compared should be strictly of a comparable nature. The conclusion that a certain remedy is valuable in the treatment of some definite diseases is not demonstrated by the fact that the fatality in a series of cases thus treated is six per cent., while in another series treated without this remedy it is twelve per cent., unless it is shown that the ages and other previous conditions of the patients in the two cases are not widely different, and unless the numbers constituting the series are sufficiently great to avoid the fallacy due to paucity of data.

Errors from the Composition of Rates.—These are among the most common of all statistical errors, and show the fallacy of dealing with average rates by any shorter method than that of dealing with the sums of the numbers to be compared.

For example, the death rate of Boston in the census year 1900 was 20.81 per one thousand. That of Chelsea was 19.02, of Revere 14.14, and of Winthrop 7.59.

If these death rates are averaged as follows:

20.81
19.02
14.14
7.59
4)61.56
15.39

the resulting death rate of these four municipalities (Suffolk County) is 15.39, and very many instances are to be found in which this erroneous method is employed.

The only correct method of obtaining the combined death rate is as follows:

Cities and towns.	Populations.	Deaths, 1900.
Boston	560,892	11,671
Chelsea	34,072	648
Revere	10,395	147
Winthrop	6,058	46
	611,417	12,512

Therefore $\frac{12,512 \times 1,000}{611,417}$ = 20.46, the true death rate of the County.

The error arises from the fact that the largest city in the group is given, in the first calculation, only as much prominence in obtaining the result as each of the others, namely, one-fourth of the whole, whereas its population constitutes over ninety-three per cent. of the whole.

Errors from Stating Deaths as a Ratio of the Total Deaths.—There is nothing erroneous *per se* in stating the deaths at any age as a percentage of the total number of deaths, or the deaths from any special cause as a percentage of the deaths from all causes. It is a useful and, in fact, the only method practicable when it becomes necessary to state the proportion of one of these to the other. But beyond this such method cannot be trusted. For example, the proportion of fatal accidents in Massachusetts, in 1900, among boys under five years of age was 14.5 per cent. of all fatal accidents among males, and that of girls of the same age was 24.3 of all fatal accidents of females. From these figures, however, it cannot be inferred that girls are more liable to fatal accidents than boys, since the contrary is the fact, the actual numbers being 205 such deaths among boys under five, and 126 among girls. The only reasonable conclusion is that at higher ages females are much less subject to fatal accidents than males. When stated as a ratio of the living population of the same ages, the deaths by accident of boys under five were fourteen per ten thousand, and those of girls of the same age were only nine per ten thousand.

Life Tables.—The usefulness of life tables is twofold. They constitute the basis of life insurance, and serve as an index of the sanitary condition of the community out of whose data they are constructed.

Life tables differ for the same group of population from year to year, and they also differ when calculated from the statistics of different portions of a group of inhabitants, as, for example, those of a large city, compared with those of any of the outlying districts beyond its borders.

The work of constructing a life-table for any American State or city is necessarily less satisfactory in its results than the work of making a similar table for any of the civilized nations or communities of Europe, since most foreign populations are more stationary than those of America.

The essential data for constructing a life-table are the number, ages, and sexes of the living, and the same data for the dying.

1. Theoretically, the best method of constructing a life-table would be to observe a large number of children, all born on the same day, through life, entering in a column (headed l_x) the number who remain alive at the end of each successive year, until all have died; and in a second colume (d_x) the number dying before the completion of each year of life. Therefore, d_x represents the number out of l_x persons, attaining the precise age x, who die before reaching the age $x + 1$. Therefore $d_x = l_x - l_{x+1}$, and the number dying between the ages x and $x + 1$ is equal to the difference between the numbers living at the ages x and $x + 1$. It is not practicable to observe a body of children throughout life in this manner, so that other methods must be adopted.

2. It is not necessary to assume, as in the preceding case, that all the persons have been born on the same day. If we could trace a large number of children throughout life, without reference to the dates of birth, a life-table could be constructed, if the number of the living and dying in each year of life were known.

The great life insurance companies employ a method somewhat similiar to this, in which tables are constructed from the results of watching a large number of insured lives from the time of insurance to death. These, however, differ from the general population, in that they are selected lives, among whom unfavorable risks are weeded out by medical examination. The result of this process does not, however, present such striking differences from the general population as might at first sight be expected.

3. The common method of constructing a life table consists in taking the experience of several years and comparing the numbers of deaths of persons at different ages with the living at the same ages as determined by the census. For example, in the United States, and especially in States where reliable registration of births and deaths is made, the results of the decennial census enumerations may be employed together with the deaths occurring in the intervening years. By this means the disturbing effect of an epidemic year may be minimized. By this method results are obtained which, being wholly based upon recent observations, are more correct than if a million persons were observed from birth to death; since in the latter case the conditions which determined the rate of mortality might, before the whole series became available, have undergone very great changes, which for practical purposes would render the table valueless.

Dr. Farr's English life table No. 3 was based upon the registered deaths in England during the seventeen years 1838–54, and on the two census enumerations of 1841 and 1851. Many other life tables of English cities and districts have been made since that time and were constructed upon similar principles.

The life table constructed by the writer upon the experience of the population of Massachusetts was based upon the deaths which occurred in the five years 1893–

97, and upon the State census of 1895, the middle year of this period.

There are certain conditions which affect the accuracy of life tables, and particularly American life tables, which may be enumerated as follows:

1. *The Influence of Migration.*—The increase or decrease in the population depends upon two factors, migration and the difference between the numbers of births and deaths. In many of the States the gain by immigration is much greater than the gain by natural increase of births over deaths. Moreover, the increase by immigration is not uniform from year to year, nor is it equally distributed at the different age periods, fully one-half of the immigrants being between fifteen and thirty years of age, while the numbers at the extremes of life are comparatively small.

2. *Defects of the Census.*—Mr. H. Gannett, in a paper contributed to the American Statistical Association (Publications, vol. iv., p. 99) estimates a "shortage in the census of 1890 of negro children of about a quarter of a million," and of native white children "about the same." If this be correct, the entire shortage in the total population, including that of foreign whites, must leave a million unaccounted for in the United States. In States with complete registration it is possible to supply the deficiency for the first four or five years of life with a reasonable degree of accuracy from the registered births.

3. *The Practice of Incorrectly Reporting the Ages of the Living and the Dead.*—This error is of two kinds: (*a*) Greater numbers of persons are reported at the even ages, 20, 30, 40, etc. (both living and dead) than at 19, 21, 29, 31, etc., in consequence of the common habit of using round numbers instead of accurate ages. This may be partly eliminated by employing the periods 25–35, 35–45, etc., instead of 20–30, 30–40, etc. (*b*) The habit especially among unmarried females of understating the ages of the living. This appears to a greater or less degree to be a common practice in all countries where census enumerations are taken.

4. *Defects in Birth and Death Registration.*—These defects depend upon the want of thoroughness with which the laws relating to birth and death registration are executed, and also upon the efficiency of such laws to secure the desired results. In some of the older States the birth and death returns are undoubtedly collected with a reasonable degree of completeness, and in such States life tables may be made from the returns of the whole population.

The following statement by Newsholme in the chapter on vital statistics in his "Hygiene and Public Health" presents in a condensed manner the general principles involved in the construction of a life table:

"It is usual to start with 1,000,000 or 100,000 children at birth and to make a separate table for the proportionate number of males and females at birth. Thus in Brighton in 1881–90 these were in the proportion of 51,195 × 48,805. Starting with 51,195 male infants at birth, and multiplying this number by .84608, the probability of surviving one year, we obtain 51,195 × .84608 = 43,315. For the second year of life the probability of surviving was .93398; hence the number of survivors is 43,315 × .93398 = 40,452, etc. The general arrangement is shown in the preceding example of a life table, which only presents the data at or near the two extremes of life, the intermediate figures having been omitted from considerations of space.

BRIGHTON LIFE TABLE, MALES.

(Based on the mortality of the ten years 1881–90.)

Age. x.	Dying in each year of life. d_x.	Born, and surviving at each age. l_x.	Sum of the number living, or years of life lived at each age, $x+1$, and upward to the last age in the table. $\Sigma l_x + 1$.	Mean after life time (expectation of life) at each age. e_x°.
0	7,880	51,195	2,206,174	43.59
1	2,863	43,315	2,162,859	50.43
2	996	40,452	2,122,407	52.96
3	733	39.456	2,082,951	53.29
4	440	38,723	2,044,228	53.29
..	....	......	....	....
..	....	......	....	....
97	12	29	43	1.60
98	7	17	26	1.53
99	4	10	16	1.48

The 43,315 males surviving to the end of the first year of life out of 51,195 born will each have lived a complete year in the first year, or among them 43,315 years. Similarly the 40,452 males will live among them 40,452 further complete years, and so on, until all the males started with become extinct at age 105. Evidently, therefore, the total number of complete years lived by the 51,195 males started with at birth will be 43,315 + 40,452 + 39,456 + 38,723 + . . . + 10 + 6 + 4 + 3 + 2 + 1 = 2,206,174 years, this sum being obtained by adding together the numbers living at each age beyond the age in question down to its last item. This number of years is lived by 51,195 males. Hence the number of complete years lived by (*i.e.*, the expectation of life of) each male $= \frac{2,206,174}{51,195} = 43.09$ years. This is termed the *curtate expectation of life*. It deals only with the complete years of life, not taking into account that portion of life time lived by each person in the year of his death, which may be assumed to be, on an average, half a year. Hence the complete expectation of life according to the above table is 43.59 years.

The materials for the construction of a life table are illustrated in the following table, from which the Massachusetts Life Table (1893–97), published in the Thirtieth Annual Report of the State Board of Health for 1898, was constructed:

POPULATION OF MASSACHUSETTS, 1885, AND DEATHS, 1893–97.

Age periods.	POPULATION, 1895.			DEATHS, 1893–97.		
	Total.	Males.	Females.	Total.	Males.	Females.
0 to 5..........	*235,647	*118,453	*117,194	78,779	42.710	36,069
5 to 10..........	224,119	112,296	111,823	6,730	3,345	3,385
10 to 15..........	202,900	101,574	101,326	3,460	1,655	1,805

85 to 95..........	6,123	2,180	3,943	7,105	2,713	4,392
Over 95..........	308	77	231	559	152	407
Age unknown...	3,014	1,554	1,460	496	378	118
Total..........	2,500,183	1,214,701	1,285,482	......	......	......

* The population figures in this line (0–5) were not used in the construction of the life table, but the figures employed were estimated from the registered births and the deaths under five years of age.

In the English life tables it has been customary to estimate the population at the middle of a given year for life-table purposes, the census being taken on April 1st. In Massachusetts the census has usually been taken so near the middle of the year (about June 1st), that the slight error arising from the difference between this date and the middle of the year may practically be disregarded.

The deaths in any year are distributed throughout the year, and it is plain that the deaths registered at any age x will not have occurred at the precise age x, but some will have just attained that age, and others will have been close upon $x + 1$. Now it is assumed that these deaths at age x occur at equal intervals throughout the ensuing year, an assumption which is approximately correct except for the first two years of life. It is therefore customary to distribute the deaths in the first year of life by months, and then to calculate the mean from this distribution.

MASSACHUSETTS LIFE TABLE.

(Based on the Mortality of the Five Years 1893-97.)

Table No. 1.—Males.

Age.	Dying in each year of age.	Born and surviving at each age.	Population or years of life lived in each year of age.	Years of life lived in and above each year of age.	Expectation of life at each year of age.

One hundred thousand infants, followed through their first year of life (in the period 1893–97) in Massachusetts, yielded 90,250 years of life. To obtain this mean of the infants living throughout the first year, the following method was employed:

All of the deaths of infants under one month old which occurred in the years 1893–97 were tabulated from the mortality returns in the office of the secretary of state, also those of infants who died in the second and the third months of life separately, then those of infants who died in the three succeeding months of life (fourth to sixth) in one group, and then those who died in the succeeding six months in another group. From these data, and from the births registered in the five years ending with June 30th, 1897, the figures for the first year of life were calculated after the method shown by Dr. Farr in his life table No. 3, page xxiii.

The foregoing mean, 90,250 (46,343 males and 43,907 females) (the arithmetical mean of the series l_0, $l_{\frac{1}{12}}$, $l_{\frac{2}{12}}$, . . . l_1), is used as the first term of column P (see foregoing table, p. 260). All of the succeeding terms in the column for the years 1, 2, 3, 4, etc., are the means of the terms in the preceding column l_x, using the formula,

$$P_x = \frac{l_x + l_{x+1}}{2}.$$

In these tables Column x presents the ages from birth up to one hundred years.

Column d_x presents the numbers of those dying in each age of life.

Column l_x, Table 1, presents the survivors out of 51,350 males at birth at each age of life. (The females were 48,650, which added to the number of males makes 100,000.)

Column P_x presents the population maintained by the numbers in column l_x, beginning with 46,343 males (and 43,907 females), in all 90,250 persons.

Column Q_x shows the aggregate number of years which the persons at each age in the table will live, until their extinction by death.

Column $E_x = \frac{Q_x}{l_x}$ is the mean future life time of the persons living at each age in the table, the expectation of life.

In the third table, the mortality column presents the mortality per unit of the population at each age of life, the figures being obtained by dividing the deaths at each age by population at such ages, the proper corrections and interpolations having been made, either by the analytical method described by Dr. Farr in his English Life Table, No. 3, p. xxv., or by the less accurate method known as the graphic method described by Mr. George King in the *Journal of the Institute of Actuaries* (October, 1883) and in Newsholme's "Vital Statistics," 3d edition, p. 266. From this column (m_x) the probability of living at each year of age (p_x) is obtained by the formula $p_x = \frac{2 - m_x}{2 + m_x}$ applied to each year of the series.

Column l_x is obtained by the formula $l_x \times p_x = l_x + 1$, and column P_x is obtained by the formula $\frac{l_x + l_{x+1}}{2}$.

From these tables it appears that, out of 100,000 children born alive in Massachusetts during the years 1893–97, 16,000 or nearly one-sixth die before arriving at the age of one year; 78,963 or nearly four-fifths attain the age of three years; 77,051 survive the age of five years, or seventy-seven per cent.; 50,124 or a little more than one-half attain the age of fifty-three years; 24,993 or nearly one-fourth live to the age of seventy-two years.

These figures present very decided differences as compared with those which were published for the same State in 1855 by Mr. E. B. Elliott.* In that report it was shown that the numbers dying before the close of the first year out of 100,000 born were 15,510, or nearly the same as those for the year 1895 for the same age. At the end of three years the survivors were only 74 per cent instead of 79 per cent. as in 1895, and one-half had died before the close of the forty-first year, instead of surviving to the fifty-third as in 1895.

Since the numbers of each sex are unequal at birth, the males continue in greater numbers until the fifty-third year, when the greater death rate of the males has reduced their number below that of the females, and the females continue in excess throughout the remainder of life. Observing the tables more closely, it appears that the comparative intensity of the death rate of the sexes varies at different points of the table. For the first five years the death rate of males exceeds that of females. From age five to age nineteen inclusive the rate of females exceeds that of males, and from age twenty to the end of life the death rate of females is less than that of males.

In table 3 are presented two columns, in which are shown the probability of living one year from each age and the mortality per unit of the population at each year. At birth the probability of living a year is for males 0.82569 and for females 0.84939, that of boys at birth being about the same as for men of eighty-six, and that of girls about the same as that of women at eighty-six or eighty-seven. The probability of living a year is at its highest point for boys at age twelve (0.99722) and for girls it is about the same for age eleven as for age twelve (0.99695 and 0.99693).

A comparison of death rates at different periods presents certain points worthy of notice.

e death rate of children under five, and especially ose under one year of age, has not undergone very ed changes, but that of all ages from five to forty ery perceptibly diminished, while that of ages above has increased. This result has been produced by great reduction in the number of deaths from infec- diseases, including consumption, which occur in the period of life, from two years up to thirty. By means a much larger ratio of the population than erly survives to live throughout the useful and earning period of life. This causes a material increase in the number of years lived at the later ages of life.

These persons being spared from the diseases incident to childhood naturally increases the relative mortality from the diseases of adult life and old age.

This decided increase in the number of survivors throughout the useful ages of life has a marked effect upon the vitality of the population. It is undoubtedly due in no small degree to the increased attention which has everywhere been given in the past twenty-five years to public hygiene.

The accompanying diagram represents the numbers of survivors at the different ages of life in Sweden, England, Spain, and Massachusetts out of 10,000 at birth. Those of Massachusetts are presented for two periods 1893-97 and 1855, showing the marked changes which have taken place. Sweden is selected because it has a low death rate and is often selected as a standard of a healthy population. Spain, on the contrary, has a high death rate, which is chiefly due to excessive mortality in the early years of life. (See table on p. 264 and diagram on p. 262.)

VITILIGO.—This affection of the skin, which is likewise known by the name of leucoderma, consists in the development of whitened areas upon various portions of the body, but especially upon the face, neck, and hands. It is due to localized loss of pigment in rounded or ovoid patches of various size, having sharply defined margins and surrounded by more or less deeply pigmented skin which gradually shades off into the normal. The characteristic features of the whitened spots are, that their border is usually convex, giving the impression that they extend into their darkened surroundings, or that, in their advance, they drive the pigment before them; that there is no change in the structure, sensations, or secretions of the affected areas; and that their tendency is to persist and to increase in extent, being little affected by any treatment. It is an acquired condition which comes on usually in youth or early adult life without previous ill health or prodromes, although in some instances it has been known to follow local injury; and sometimes it develops in the neighborhood of a pigmented mole. The dark-skinned races are rather more subject to vitiligo than those of fair skin and light hair, and it is not so very rarely seen in the negroes of this country, in whom the contrast between the perfectly white spots and the normal skin produces a striking effect. I have seen instances in which much discomfort of mind was occasioned by the fact that the white patches were merging into each other until extensive regions of the body had lost their pigment, and the negro was fearful that he was "turning into a white man." The hair may lose its pigment in the same way as the skin, and rounded or irregular tufts of gray may appear upon the head. In white races the affected regions are often more noticeable in the summer time, when the surrounding pigmentation becomes deeper

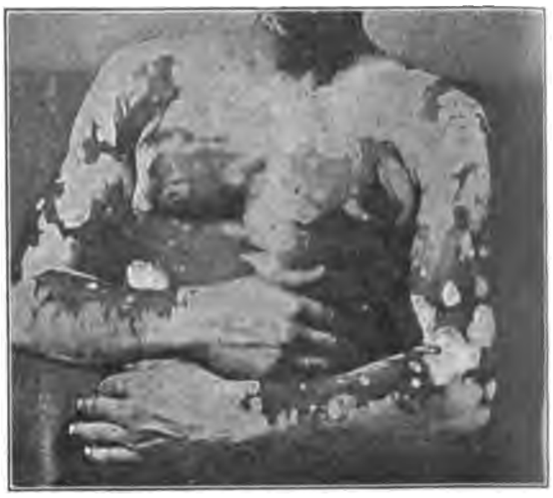

FIG. 5029.—Vitiligo.

The *diagnosis* of vitiligo is not difficult, although it is liable to be confounded with morphœa, chloasma, tinea versicolor, syphilitic pigmentations, macular leprosy, and albinism. One chief point by which it is distinguished from other conditions is the normal condition of the skin, apart from its loss of pigment. In morphœa there are structural changes. In tinea versicolor the patches are inflammatory and itchy, and from them there can be scraped scales which show, under the microscope, the characteristic groups of spores, although, when circumscribed areas of healthy white skin are enclosed in the brownish patches of this disease, vitiligo may be closely simulated; but the margins will be found irregular instead of clean-cut. In chloasma there is increased pigmentation of the patch itself and the circumference is the part which appears white. The distinction has been made that in vitiligo the margin of the white area is convex toward that which is pigmented, while in chloasma it is concave; but in some instances the patches run together in such a way that this distinction becomes more theoretical than apparent. Syphilitic pigmentations, especially about the neck in women, may persist after other manifestations have disappeared and may, in some instances, be mistaken for vitiligo. In the macular form of lepra the patches of white skin have an irregular outline, not so abrupt as in vitiligo, and the tinge is rather grayish than dead white; then, too, the skin is either thickened or atrophied and anæsthesia or impaired sensation is present. Finally, in albinism we have, as in vitiligo, an absence of normal pigment, but in the former it is a congenital defect and the whole surface of the body, including the hair and eyes, may be devoid of pigment

The *pathology* of vitiligo is obscure. Leloir has de- ribed a parenchymatous neuritis in which the axis linder had disappeared, the myelin sheath had broken own, and the nerve fibre had become transformed into n empty primitive sheath, whose nuclei had prolife- ted. The affection begins as a hyperpigmentation in eas which run into one another and assume a poly- clic character, the pigment becoming absorbed from the ntre and deposited in excess in the marginal epidermis, e connective-tissue cells, and about the vessels and hair llicles.

The *ætiology* of vitiligo is not well understood, but the use of the condition is usually ascribed to perverted in- rvation. It is probable that the disappearance of the gment from one spot and its increased deposit in a ighboring part is due to atrophy in the former and to pertrophy in the latter, both changes being effected rough the agency of the sympathetic nervous system. metimes, though rarely, the proper proportion of pig- entation is spontaneously restored, but in the majority instances the affected areas tend to increase in extent d the condition to assume marked chronicity. When rge areas of surface are involved the term leucoderma comes appropriate.

The *treatment* is unsatisfactory. Some reports of suc- ss from electricity have been made. Local applications r the removal of surrounding pigmentation are resorted with the view of rendering the white regions less ticeable. The internal administration of nerve tonics, pecially strychnine and arsenic, has been advised. istering the patches to excite a deposit of pigment has en tried, but the results are not brilliant. If the spots e located upon the face or other exposed part, artificial aining may be employed, and dyes used to restore the lor of the hair. *Charles Warrenne Allen.*

VITREOUS BODY OR HUMOR.—ANATOMY.—The treous body is a transparent, semifluid, colorless mass, soft gelatinous consistence, subglobular in form, which ls the posterior four-fifths of the interior of the eyeball; is bounded by the optic-nerve entrance and retina be- nd, by the retina on each side, and in front by the lens d its suspensory ligament which fit into a depression own as the patellar fossa. It serves as a support to e tunics of the eyeball, and, of lesser importance, as a ar refractive medium; its index of refraction is slightly ater than that of distilled water. Chemically, it con- ts of 98.5 per cent. water and 1.5 per cent. solids.

There has been much discussion regarding the struct- e of the vitreous. When the fresh substance is own upon a muslin filter, the greater part passes ough as a watery liquid, a very small proportion re- ining behind—demonstrating the existence of a *sup- rting framework* and a fluid portion. It is quite gener- y held that there is a very delicate fibrillar *reticulum*, which are scattered a few round or branched cells of connective-tissue type, most abundant in the periph- , and often a variable number of migratory leucocytes. e cells are known as *vitreous corpuscles*; they are often ult to recognize; they are peculiar in exhibiting large uoles which push the nucleus to one side, and in pre- ting a number of budlike swellings (Fig. 5030).

The vitreous body is enclosed in a delicate, structure- glassy membrane, the *hyaloid membrane*, which lies lose apposition with the entire inner surface of the ina; it can be readily separated from the latter, except teriorly where the retinal vessels of fœtal life have ered, and anteriorly at the patellar fossa. At the ora ata, the hyaloid membrane splits into two layers: the t, the hyaloid membrane proper, exceedingly delicate, ich is continued over the anterior surface of the vitre- body; and the second, which blends with the poste- layer of the suspensory ligament of the lens.

he central portion of the vitreous body is penetrated a channel (*hyaloid canal, canal of Stilling, canal of uet, central canal*); this is filled with fluid, is limited a wall of extremely delicate homogeneous membrane, extends from the disc to the posterior pole of the lens; it is about 2 mm. in diameter, with a slight dilatation at both ends. This canal conveys the hyaloid branch of the central artery to the lens during fœtal life; in the adult it forms part of the posterior lymph passages of the eyeball, having its outlet in the lymph spaces of the optic nerve.

The adult vitreous has no blood-vessels, its nourishment being received from the surrounding structures, particularly the uvea; hence diseases of the retina, choroid, and ciliary body almost always implicate the vitreous. Vitreous humor is never regenerated after loss; the diminution in volume is compensated for by the addition of aqueous. If the escape of vitreous is small, no injurious effects follow; if large, the consequences are serious—the globe softens, shrinkage results, and sight is lost.

DISEASES OF THE VITREOUS BODY.

CONGENITAL ANOMALIES.—1. *Persistent Hyaloid Artery.*—During fœtal life the hyaloid artery, a branch of the central artery of the retina, passes through the central canal of the vitreous from the optic-nerve entrance to the posterior pole of the lens; it usually begins to shrivel during the sixth month and has generally disappeared at the end of fœtal life. Sometimes this process of obliteration fails, and a greater or lesser remnant of the artery persists during life. This can be seen with the ophthalmoscope as a grayish cord or thread which arises from the optic disc and stretches into the vitreous for a variable distance; it may terminate by a free extremity in the vitreous, or may traverse the latter and be attached to the posterior pole of the lens, the attachment to the lens being marked by a small opacity (congenital posterior polar cataract); or the thread may be attached to the lens with its free end floating in the vitreous; or the vestige may be represented by an irregular, minute deposit of connective tissue upon the disc. In rare instances the persistent artery continues to carry blood. Vision is generally good, but sometimes such eyes are amblyopic or present other congenital defects.

2. *Opacity of the Walls of the Hyaloid Canal.*—In unusual instances the walls of the hyaloid canal are abnormally opaque, causing some interference with central acuteness of vision; this anomaly is visible with the ophthalmoscope as a grayish, tubular cord extending from disc to lens.

HYALITIS (*Inflammation of the Vitreous*).—This term includes two types: first, a purulent inflammation (*suppurative hyalitis*), and second, a form characterized by the occurrence of *opacities in the vitreous*. As will be readily understood by considering the avascular and almost structureless nature of this tissue, inflammations of the vitreous are rarely primary; they generally accompany or are the result of inflammation of the retina and uveal tract.

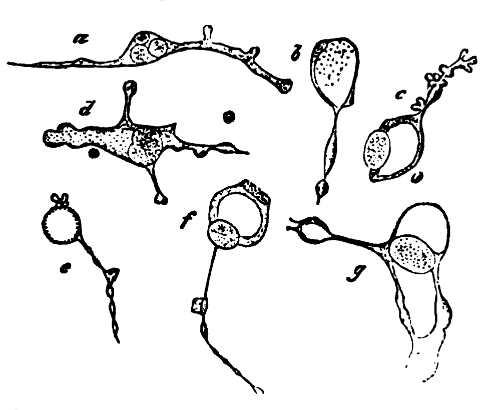

FIG. 5030.—Cells of the Vitreous Humor. (Schwalbe.) *a* and *d* without vacuoles; *b, c, e, f, g*, vacuolated.

Suppurative hyalitis is an infective inflammation of the vitreous, which is generally merely part of a purulent choroiditis or panophthalmitis. It is caused by *infection*, the result of a penetrating wound, a foreign body, or an iridochoroiditis following an operation upon the globe; it may arise in the course of the exanthemata, erysipelas, relapsing fever, meningitis and cerebro-spinal meningitis, infective blood diseases, and lengthy debilitating fevers; it may follow metastatic choroiditis after inflammation of the cord in the newly born child.

Since the affection is generally secondary to inflammation of other structures, symptoms of the primary disease will be present, such as posterior synechiæ and other evidences of iridocyclitis. If the media are clear, the purulent exudate is readily seen as a yellowish reflex shining through the pupil, and the ophthalmoscope detects the presence of an opaque mass which may be circumscribed, but is usually diffuse.

When it is more or less circumscribed, the condition presents appearances which are very much like those of glioma of the retina, and as a matter of fact it is known as *pseudoglioma*. It can generally be distinguished from a true glioma by the history of the case, by the presence of the signs of iritis or uveitis, and by the diminished tension. The disease tends to run a chronic course. In rare instances, when circumscribed, and especially when of traumatic origin, purulent hyalitis may leave a more or less useful eyeball. But in the great majority of cases, and in every instance in which panophthalmitis exists, sight is lost; the retina becomes detached, the soft eyeball shrinks, and an atrophied globe results; enucleation then becomes necessary, especially if the shrunken organ menaces the safety of the other eye. No method of treatment will prevent such a result. If, during the course of a debilitating fever, suppurative hyalitis is detected early, it may be possible to save some vision in the affected eye by vigorous supporting treatment of the general condition. Intra-ocular injections of chlorine water have been recommended (Berry).

OPACITIES IN THE VITREOUS may be fixed, but they are usually movable. They vary in size from fine dustlike deposits (*hyalitis punctata*) to large masses. They may have any shape: dust, specks, threads, flakes, bands, or irregular membranous masses. They may be entirely free or may present one or more attachments to enveloping tunics. In the great majority of instances the affection is secondary to diseases of neighboring structures.

The opacity causes an impairment of the transparency of the vitreous. It can be detected with the ophthalmoscope held at a distance, the patient moving the eye in various directions and then fixing it. Under such circumstances the opacity, if movable, will be seen as a dark object behind the pupil, upon the red background of the fundus, and will disappear from view as it falls to the bottom of the vitreous. The rapidity of movement depends upon the consistence of the vitreous. If this is normal, the movement is slow; if it is fluid, the movement is rapid. By placing a +4 D. lens in the sight hole of the ophthalmoscope and getting closer to the patient, then increasing the strength of the lens to +16 D. and simultaneously approaching the eye, successive depths of the vitreous chamber can be focussed and explored. With minute or very delicate opacities, faint illumination and the plane mirror of the ophthalmoscope should be employed.

Opacities of the vitreous are distinguished from opacities of the cornea and lens by their depth, their mobility, the gradual settling after the eye has been moved and is then steadied, and by the fact that they cannot be seen by oblique focal illumination. Patches of choroidal pigment are differentiated in like manner by dissimilarity in shape, and by difference in depth as measured by their refraction.

If the symptoms due to disease of the surrounding structures be excluded, the subjective manifestations of opacity of the vitreous are the occurrence of one or more spots in the field, and more or less impairment of vision, the degree of the latter depending upon the size, situation, and density of the opacity; patients may merely complain of motes but slightly more pronounced than the muscæ volitantes of normal eyes, or the vision may be almost or completely abolished. When the opacity is situated deeply in the vitreous, the annoyance of the patient is increased by the shadow which the opacity throws upon the retina. Very often the patient will cast the opacity out of the line of vision by a sudden movement of the eyes or head, and thus obtain unobstructed vision for a moment; in other cases vision will be improved after the eyes have been kept quiet for a time, thus allowing the opacity to settle. The disease must not be confounded with muscæ volitantes; the latter are described below.

Opacities in the vitreous are very common. In most instances they depend upon some disease of the choroid, ciliary body, or retina. They are frequently found in high degrees of myopia associated with choroidal disease, and are then often seen as flakes and threads. They are not uncommon in syphilitic chorioretinitis and cyclitis, in such cases being usually dustlike, with or without threadlike or shredlike additions. They result from hemorrhages into the vitreous, and when thus produced they may constitute membranous masses; occasionally the latter are attached to the retina and are accompanied by the formation of new blood-vessels, constituting *retinitis proliferans*. In some cases errors of refraction are found in the eyes which are the seat of opacities of the vitreous; but there is no evidence that the two anomalies bear any etiological relationship except in myopia. Very often the condition results from retinal or choroidal disease, depending upon some disturbance of the general health, of which the following are the most common examples: Disturbances of menstruation, disorders of the liver, debilitating diseases, endarteritis, gout, malaria, and the effects of the prolonged use of arsenic. Finally, it is not uncommon to find opacities of the vitreous, of various shapes and sizes, in apparently normal eyes of healthy individuals; in such cases no cause can be assigned. *Asteroid hyalitis* is the name given by Benson to a very rare condition, probably congenital, in which the vitreous is filled with minute, light-colored spheres.

Treatment consists in an attack upon the causative disease. In syphilitic cases the usual treatment of this infection, especially if the mercury be given hypodermically, will often cause a clearing up. Disturbances of the system should be corrected by appropriate means. High myopia requires proper correction with glasses, and careful attention to general and ocular hygiene. Where no cause can be assigned, good results sometimes follow the use of iodides, with or without mercury in small doses. Small quantities of jaborandi or pilocarpine, or larger hypodermic doses of the latter, are useful, followed by hot baths, so as to produce diaphoresis, if the patient is able to tolerate such vigorous treatment. Abstraction of blood from the temples and the local application of the galvanic current have been reported of benefit.

Large membranous deposits that persist after every other method of treatment has failed, may sometimes be divided with a narrow knife or a knife-needle, providing no active disease of neighboring parts exists and there is no blood-vessel formation. The instrument is inserted in front of the equator of the eyeball, just below the lower border of the external rectus muscle. In some cases the result of this operation has been to cause a shrinking of the opacity and an improvement of vision.

While in syphilitic cases, in examples of hemorrhages of small size, and in a few others in which the opacities are of limited extent and of delicate consistence, complete absorption takes place after some months, in most of the instances of this condition disappearance is incomplete or the opacities are permanent. There exists also a tendency to recurrence after complete or incomplete absorption. Not uncommonly, when extensive opacities are attached to surrounding structures, shrinkage takes place, the retina becomes deprived of its natural support and becomes detached.

MUSCÆ VOLITANTES (*Myodesopsia*) are the black specks or motes often seen in the field of vision, especially when the eye is directed toward the light or a bright surface. They are most often complained of by myopes. They are caused by the shadows which the cells and migratory leucocytes of the vitreous cast upon the retina. These shadows usually have the shape of dots or small bubbles, isolated or collected into strings or clusters; less frequently they are of larger, fantastic shapes. Any movement of the eye sets them in motion. After the eye ceases to move, they continue to float across the field, gradually settling out of the line of vision. This phenomenon may be produced entopically by partially closing the lids or by looking through a small opening in a card, and by facing the light or a white surface. It is often seen while looking into the tube of a microscope.

Muscæ are not true opacities of the vitreous, and consequently cannot be detected with the ophthalmoscope. They are normal phenomena, occurring in healthy eyes, perfectly transparent, and not disturbing to vision. Present in all eyes, they are usually disregarded. When noticed they cause annoyance and often anxiety, which is apt to be aggravated by the habit of the patient of searching for them. Neither must they be confounded with scotomata, which are blind spots in the field of vision, due to a loss of function of certain portions of the retina.

Many of the patients who complain of muscæ have some error of refraction. The correction of the latter often gives relief. In any case the patient should be assured that the occurrence is devoid of significance. He will then cease to look for the shadows, and in consequence will no longer be annoyed by them.

Blood-vessel Formation in the Vitreous (*Retinitis Proliferans*).—Occasionally we observe dense grayish or bluish-white membranes, provided with new blood-vessels, which have no apparent connection with the retinal vessels, attached to the retina in the situation of the optic-nerve entrance, projecting into the vitreous, and hiding a portion of the fundus. These represent the sequels of previous pathological processes—either hyalitis, or hemorrhages, or chronic retinal inflammation. Examples of the last cause have been associated with general disease (syphilis, nephritis, diabetes, gout). The pathology is obscure. There is interference with vision, the degree depending upon the density, size, and position of the membrane. The tissue is incapable of absorption.

HEMORRHAGES INTO THE VITREOUS.—These are usually due to rupture of some of the vessels of the ciliary processes or of the choroid, less frequently to a break in the retinal vessels, in consequence of injury, vascular disease, or alterations in the blood. Anæmia, nephritis, diabetes, arteriosclerosis, myopia, glaucoma, and menstrual disturbances are predisposing factors. There are also some examples, generally in young male adults, in which hemorrhage into the vitreous occurs *spontaneously*, and often repeatedly. Such cases have been attributed to irregularities of the circulation and to gout.

If the hemorrhage be recent and slight, a bright red reflex is seen with the ophthalmoscope; if greater, dark red masses are observed, which may appear red at the margins; if considerable, a large part or all of the vitreous chamber is filled, and no fundus reflex is obtained. There is always impairment of vision, but the degree varies with the amount and situation of the extravasation. With large hemorrhages sight is immediately reduced to perception of light.

Small hemorrhages are often absorbed after some weeks or months with restoration of good vision. Not infrequently, however, the process of absorption is incomplete and opacities remain. Large extravasations usually leave dense membranous opacities which cause serious impairment of vision. Such hemorrhages necessarily produce considerable disorganization of the vitreous structure, followed by fluidity, and not infrequently by detachment of the retina.

If these hemorrhages are seen early, treatment consists in absolute bodily rest with the head in an elevated position, cold compresses on the closed lids, the administration of cardiac sedatives and ergot, and abstraction of blood from the corresponding temple. Subsequently small doses of potassium iodide and mercury, pilocarpine sweats, saline cathartics, hot compresses to the closed lids, and subconjunctival injections of saline solution may be used to promote absorption. Attention to the general health, avoidance of the stooping posture, and rest of the eyes are also indicated. Large membranous, non-vascular opacities may be cut with a knife-needle or a narrow knife after all inflammation has subsided and no tendency to recurrence of hemorrhage appears to exist.

DEGENERATIONS OF THE VITREOUS comprise: (1) Synchysis; (2) sparkling synchysis; (3) fatty degeneration; (4) detachment; (5) ossification.

Synchysis (*fluidity of the vitreous*) is a softened or fluid condition of the vitreous. This can be diagnosticated with certainty only when vitreous opacities exist and move with undue rapidity during motions of the eyeball. The condition is often accompanied by tremulousness of the iris; but this symptom may exist without fluid vitreous, and is no proof of the existence of synchysis. It is merely an evidence that, owing to relaxation or rupture of the suspensory ligament, the iris has been left without the support of the lens upon which it usually depends. The tension of the eyeball is commonly diminished, but it may be normal, or even increased, as in certain cases of glaucoma.

Synchysis occurs with high degrees of myopia, with or without complicating choroiditis and posterior staphyloma; with extensive vitreous opacities; after ocular injuries with extensive hemorrhage into the vitreous; and with degenerative processes of the eye in general. In such cases the loss in consistence depends upon an impairment of nutrition. Advanced age is a predisposing factor. Fluid vitreous is not infrequently present in eyes that have never suffered from any disease, and in which no definite cause can be assigned.

No treatment is of any avail. Recognition of the condition is of practical importance when an operation upon the globe, such as cataract extraction, or iridectomy for glaucoma is contemplated, since it forms a complicating circumstance and increases the liability to loss of vitreous.

Synchysis scintillans (*sparkling synchysis*) is the name given to a fluid vitreous which presents numerous small crystals of cholesterin and tyrosin. These are seen to move rapidly whenever the eye moves, reflecting the light of the ophthalmoscope, and giving rise to a beautiful picture which resembles a shower of brilliant sparks. These crystals are supposed to represent a degenerative change of blood effused into the vitreous at some previous period, or else decomposition of the wandering cells. The condition is not of common occurrence. It is usually found in old persons, and is said to be more common among alcoholics, in those suffering from some general disease of nutrition, and in choroiditis. But clinically it is met with most frequently in eyes which are apparently healthy in other respects. There is usually little or no reduction of vision if the eye is otherwise normal. Such individuals sometimes complain of seeing glittering flashes when the eye is moved. The condition is not amenable to treatment.

Detachment of the vitreous is a serious condition which, if it ever exists alone, cannot be recognized clinically. The support which the vitreous usually gives is withdrawn, and the retina becomes detached. This condition follows traumatism, especially perforating wounds, also cataract extraction, choroiditis, intra-ocular hemorrhages, intra-ocular growths, high degrees of myopia, and extensive staphylomata. After loss of a considerable portion of the vitreous from any cause, there is shrinkage, detachment of the hyaloid, followed by that of the retina. Detachment is not amenable to any form of treatment. If the eye remains quiescent, no interference is called for. If symptoms of irritation, pain, or sympathetic disease set in, enucleation is indicated.

Fatty degeneration of the vitreous is occasionally met with as an evidence of senile decay. The patient complains of muscæ volitantes, and the ophthalmoscope reveals numerous white glistening spots evenly distributed through the vitreous and having a very limited amount of motion when the eye is moved. There is some reduction in the acuteness of vision. The condition does not call for any special treatment.

Ossification of the vitreous has been described by Wittich and Virchow as a rare form of degeneration, always associated with phthisis bulbi following a suppurating process or hyalitis. The vitreous body changes into a solid fibrous mass of cord-like shape, enlarged at either end. The osseous tissue is developed in the anterior end of this cord. The occurrence of this change is doubted by many authorities.

PARASITES IN THE VITREOUS.—The presence of entozoa in the vitreous is exceedingly rare except in north Germany. In nearly every instance the parasite has been the *cysticercus cellulosæ*. The filaria sanguinis hominis has been seen in the vitreous, with certainty, in only a single instance. The parasite found in the vitreous is the scolex of the *tænia solium*, the eggs of which enter the circulation from the stomach, and are deposited in the eye between the choroid and the retina. Perforating the latter it escapes into the vitreous.

When still situated between the choroid and the retina it can be seen with the ophthalmoscope as a bluish-gray opacity resembling detachment of the retina. After entering the vitreous, if still alive, it appears as a pale bluish or bluish-gray cyst from which there projects a short white neck and a head. The latter is provided with minute suckers, which can sometimes be seen to move. When this picture is found, particularly when the head is observed to move independently of motions of the eyeball, the diagnosis can be made with certainty. Very often, however, opacities of the vitreous are present and render the diagnosis more difficult. After the death of the parasite it becomes covered with lymph and thus hidden from view with the ophthalmoscope.

Unless removed while still beneath the retina, there is gradual loss of sight and finally destruction of the eyeball. When discovered early, before the entozoon has escaped into the vitreous, it may be removed by forceps through an incision in the sclera. Quite a number of such operations have been successful and have resulted in the preservation of good vision. After the parasite has entered the vitreous it may also be removed, but then the preservation of sight cannot be hoped for. If the attempt at removal be unsuccessful, enucleation is indicated. *Charles H. May.*

VIVISECTION.—According to the definition given in the Century Dictionary, vivisection is the "dissection of a living body; the practice of anatomizing alive, or of experimenting upon living animals for the purpose of investigating some physiological function or pathological process which cannot well be otherwise determined. Vivisection strictly includes only cutting operations; but the term is extended to any physiological experimentation upon living animals. . . . Vivisection in competent and humane hands, under proper and reasonable restrictions, is fruitful of good results to the sciences of physiology and pathology."

The necessity for resorting to this mode of experimentation depends on the fact that physiology, pathology, therapeutics, and bacteriology deal with the phenomena of life, and in order to study them successfully the necessary investigations must be made during the life of the animal upon which experiments are made.

The valuable results which have been attained by such experiments constitute a large share of the actual knowledge now possessed in these departments of medical science. The study of the functions of circulation, respiration, digestion, the nervous system, the investigation of infectious diseases, the reproduction of bone, the action of drugs and poisons and their uses and antidotes have all been greatly facilitated by means of vivisection.

The discovery of the true nature of rabies, of anthrax, glanders, tuberculosis, the Texas cattle fever, and of hog cholera, is due very largely to the assistance afforded by animal experimentation. In the production of a constant supply of diphtheria antitoxin (which has saved thousands of human lives), animal experimentation must necessarily be resorted to. At a hearing before a legislative committee in 1901, which was considering the propriety of legislation to restrict this practice, a witness said: "No father whose child had been saved by such means would care how many lives of animals had been sacrificed in the discovery. We cannot use the rabbit as a unit in estimating the value of our children's lives."

In a lecture before the Royal Society of England, Huxley stated "that the discoveries made by Pasteur alone by means of experimentation upon living animals would have sufficed to pay the war indemnity paid by France to Germany." By means of inoculations practised as the result of Pasteur's experiments, the loss from anthrax in France alone had diminished from ten per cent. in sheep and five per cent. in cattle to less than one per cent. in sheep and one-fourth of one per cent. in cattle.

Galen, Harvey, John Hunter, and others made use of this method in early times, but it has come largely into use in the last half of the nineteenth century.

Like very many practices vivisection is liable to abuse, but, as Bishop Lawrence, of Massachusetts, stated before a legislative committee in 1900, the subject "can be left, with perfect confidence on the part of the community, to a profession that has shown itself worthy of such confidence in its attitude toward humanity, as well as toward the lower animals."

Within the past thirty years vigorous opposition has been made, either to prevent vivisection or to restrict it by law. Scarcely a year now passes in which such restrictive legislation is not proposed in some form or other in one or more States of the Union.

In order to obtain an expression of opinion with reference to the practice of vivisection, a circular was issued by the American Humane Association in 1895, and sent to many prominent physicians, clergymen, educators, and others, and the replies from these sources were classified as follows:

REPLIES FROM PHYSICIANS.

	Total number.	Per cent.
For vivisection without restriction	220	19.1
For vivisection restricted by utility	513	44.6
For vivisection without pain	186	16.2
For total prohibition of vivisection	207	18.0
Obscure or evasive	24	2.1
Total	1,150	100.0

REPLIES FROM OTHER PROFESSIONAL MEN.

	Clergymen.	Educators.	Authors, editors, etc.	Per cent.
For vivisection without restriction	0	34	4	4.7
For vivisection restricted by utility	189	84	63	41.2
For vivisection without pain	116	49	26	23.5
For total prohibition of vivisection	144	52	30	27.7
Obscure or evasive	6	16	2	2.9
Total	455	235	125	100.0

Thus far, while much legislation upon this subject has been proposed, not very many laws have been enacted. After a parliamentary investigation in England a law was enacted in 1876 entitled "An Act to Amend the Law Relating to Cruelty to Animals" (Chapters 77, 39, and 40, Victoria). This act has twenty-two sections, and prohibits the performance of painful experiments on animals except under restrictions; with penalties of not over £50 for the first offence and not over £100 for the second offence.

y Section 3 of this act it is provided that:
. The experiment must be performed with a view to
advancement of science by discovery of physiological
wledge, or of knowledge which will be useful for the
ing or prolonging of life or of alleviating suffering.
. The experiment must be made by licensed persons.
. The animal must be under the influence of an anæs-
ic.
The animal must be killed if pain is likely to con-
e, or if serious injury is done to the animal.
The experiment is not to be performed in illustration
ctures.
It is not to be performed for the purpose of attain-
manual skill.
y Section 4 the use of urari is prohibited.
y Section 5 restriction is made as to experiments upon
s, cats, horses, mules, and asses.
y Section 6 public exhibition of such experiments is
e illegal.
ther sections relate to the registration and licensing
ersons desirous of making experiments and the
od of instituting legal proceedings.
he provisions of the act do not apply to invertebrate
als.
several definite exceptions the restrictions in Section
auses, 1, 3, 4, and 5, are very much modified.
a recent suit for libel, in England, it was shown
Dr. Bayliss, professor of physiology at London
ersity, was charged by Hon. Stephen Coleridge
cruelty in the conduct of certain physiological ex-
nents. Dr. Bayliss was licensed to perform such
riments under the English act here referred to. Dr.
iss sued Mr. Coleridge for libel, won his suit, and
awarded £2,000 damages (*Boston Medical and Surgi-*
ournal, November 26th, 1903).
though legislation has been proposed in many States,
are but three in which the statutes contain any refer-
to vivisection. These are New York, New Jersey,
alifornia. The law of New York respecting cruelty
imals runs as follows:
f any person shall torture, torment, deprive of nec-
y sustenance . . . or needlessly mutilate or kill, or
or procure" the same to be done, to "any living
ure, every such offender shall for every such offence
ilty of a misdemeanor."
llowing this section there is a paragraph relating to
ection:
othing in this act contained shall be construed to
bit or interfere with, any properly conducted scien-
experiments or investigations, which experiments
be performed only under the authority of the
ty of some regularly incorporated medical college or
r-ity of the State of New York."[1] In California
w is substantially the same.[2]
-truing these sections together, according to a
ar legal principle, the law in New York and Cali-
regarding vivisection may be stated as follows:
ection is lawful when performed under the author-
entioned and when "properly conducted." If im-
rly conducted, that is, with the infliction of needless
justifiable suffering, the offender would be guilty of
demeanor, which is punishable in New York by fine
prisonment, or both, the maximum penalty being
ar in the county jail, including thirty days of soli-
onfinement, and a fine of $250. In California, also,
nd imprisonment may be imposed for this offence.
ction undertaken without the authority prescribed
statutes is punishable in like manner.
New Jersey the law and the penalty are substan-
the same, except that the authority under which
ction may there be performed, if "properly con-
l," is that of any "incorporated medical society of
ate."[3]
ll the other States, with few exceptions—and the
ions, doubtless, will soon disappear—there are laws
t cruelty to dumb animals. In these States, there-
ivisection—at least such vivisection as is performed
t the use of anæsthetics—might or might not be adjudged to come within the statute. In each case there would be a question whether suffering had been inflicted needlessly or cruelly, and each case would be decided according to its own circumstances and to the views of the particular tribunal before which it came. In the interest both of the medical profession and of dumb animals, it is to be hoped that the statute of New York will be copied by all the States, and it would be well if the law were somewhat extended. In Great Britain the buildings in which vivisection may be performed are licensed, and there is an inspector to see that the provisions of the statute are carried out. In this way, additional precautions are taken. It is scarcely necessary to point out that such regulations do not hamper the competent and conscientious surgeon, and that they tend to make vivisection legally possible everywhere, because they render it free from objection in the view of the people generally.

VOMITING OF PREGNANCY.—By way of introduction it may be assumed that no more common source of discomfort, distress, and even danger besets the condition of pregnancy than the symptom which serves as the subject of this article. It may be asserted, also, that very few who have not experienced it have any adequate idea of how distressing it may, and often does, become. It is doubtless a fact that the nausea accompanying, or at times taking the place of, the actual vomiting is of such intensity, is of such a sickening and depressing character, is so much worse than the ordinary and commonplace nausea due to other causes, as to be to many the hardest to bear of all the trying experiences of the process of maternity.

At other times, it must be admitted, the vomiting is easy, accompanied by little if any nausea, and it is a noticeable fact that even in some cases in which vomiting has been frequent and persistent for months the patients have held their flesh and strength to a wonderful degree. In these latter cases the body must hold its own with a very meagre supply of food, for to a casual observer it would appear that none is retained.

It has been customary to draw a line of demarcation between the slight and the severe cases, or between those which are rebellious to treatment and threaten life and those which do not. The former have been called the "physiological" or "simple" vomiting of pregnancy; the latter the "pernicious," or "incoercible," or "uncontrollable" vomiting of pregnancy. The correctness of these descriptive terms will be called in question elsewhere.

On the other hand, Dr. Graily Hewitt has very properly pointed out the important distinction which exists between the vomiting *of* pregnancy and the vomiting *dur-*

ing pregnancy, the latter being merely an accidental occurrence in the course of pregnancy, while the former is a direct result from the fact of pregnancy.

As regards the history of this troublesome complication, it is probably the history of the human race, for from the nature of the case it must have been a frequent symptom during pregnancy at a very early period in the history of the world. What Hippocrates and other ancient worthies have to say upon the matter, however, is of far less importance than the fact that so many men in the present day show plainly by their writings how little they understand either the cause or the treatment of the trouble. The very multiplicity of theories as to the cause, and of remedies for working a cure, serves as a sufficient commentary upon the unsettled state of medical opinion upon one of the most common and important symptoms which the physician is called upon to treat. It does not seem right that so simple and every-day an experience as the vomiting of pregnancy should remain at the present day a matter of mystery, and that its treatment should continue so unsatisfactory, uncertain, and often futile. The writer believes that most cases may be explained according to a very simple theory, and his experience demonstrates that treatment along that same line may be confidently expected to give prompt and complete relief in the vast majority of cases.

Symptoms.—The most common form of this complaint is the occurrence of one or more attacks of vomiting directly after rising from bed in the morning. This may end the attack for the day, or the vomiting may recur during breakfast as well as at intervals throughout the day. So frequent is this experience on rising that the affection has come to be universally known as "morning sickness."

At times vomiting is absent, but the patient experiences attacks of nausea instead. Either the nausea or the vomiting may begin before rising, at times even awaking the patient from her sleep, and may then recur as above stated.

In the severer forms of pregnancy vomiting every attempt to take food is followed by fresh paroxysms, and indeed, not infrequently, vomiting is wellnigh constant, irrespective of anything which is taken into the stomach. The symptoms may be so urgent that sleep is prevented, nutrition wholly fails, loss of flesh and strength is rapid, elevation of temperature, small and rapid pulse, delirium and death supervene, all in the course of a few weeks.

It has been customary to divide these severe cases, commonly known as the pernicious vomiting of pregnancy, into three stages. During the first stage the symptoms develop with more or less rapidity, as a rule giving no indication of the gravity of the situation which is to follow until, after a period varying from a few days to several weeks, the vomiting becomes so frequent and so urgent as materially to affect the patient's strength. The threatening aspect of the case now visibly augments from day to day. Nothing whatever is retained upon the stomach, and, in default of food or drink, vomiting of mucus, bile, and even blood continues at short intervals.

No one can now overlook the serious nature of the complication. Suffering and anxiety are plainly depicted in the patient's face, the pulse has already become markedly accelerated, and then, with the advent of fever, is ushered in the second stage,

In this stage the temperature remains persistently above 100° F., the pulse varies from 100 to 140 per minute, the skin is hot and dry except that in some cases the extremities remain cold and clammy. Thirst is a prominent symptom, the mouth is parched and dry, the tongue may be cracked, and sordes may appear upon the teeth. Ptyalism and jaundice are commonly present. The urine is scanty, often albuminous and tinged with bile. As a rule, diarrhœa exists.

With the onset of the third stage most of these symptoms abate, the patient being able once more to take and retain small amounts of food. The friends and even the physician may be deceived, thinking convalescence about to be established, while in fact this is merely the period of grave disturbance of the nerve centres preceding death. Delirium is present, with loss of one or more of the special senses. Neuralgic pains are commonly present. The pulse remains between 120 and 140. Coma gradually supervenes and continues until death.

The period of pregnancy at which nausea or vomiting most frequently occurs is during the first six or eight weeks, though they may appear at any time up to delivery. One case is reported in which the patient was married on Monday, began vomiting on the following Saturday, and was delivered normally at such a time as to establish the fact that conception immediately followed marriage. It is probable, however, that discomfort is first noticed, in the majority of cases, somewhere near the end of the first month of pregnancy. Beginning as a slight nausea on rising in the morning, or at the breakfast table, it may go on to the serious train of symptoms described above, or after a few days may wholly disappear. Usually the experience is one of annoyance rather than of actual suffering, and rarely continues after the fourth month.

Diagnosis.—The points involved in the diagnosis are, *first*, to determine the fact of pregnancy; *second*, to decide whether the vomiting is due to the pregnancy or is simply incidental to it—in other words, whether we have to deal with the "vomiting *of* pregnancy" or the "vomiting *during* pregnancy"; and perhaps I may be permitted to add, *third*, to ascertain the local cause of the vomiting.

It is by no means easy to establish the fact of pregnancy at an early stage, and indeed it is often impossible. Until after the first catamenial period has passed it must be chiefly a matter of inference, based upon the opportunity which has been afforded for pregnancy to occur, and upon the possibility or otherwise of the vomiting being due to other causes. As soon as one menstrual period has passed, or when other signs of pregnancy have been discovered, the diagnosis may be made to rest upon a surer basis.

The difficulties in the way of deciding the second point in diagnosis are usually less marked. The peculiar characteristics of pregnancy vomiting are usually sufficiently well marked; yet in some cases it may be necessary to avail one's self of an eliminative diagnosis, making careful examination for disease of stomach, liver, kidney, or other organ which might be productive of the symptoms, and failing to find such cause the diagnosis must rest upon the pregnancy as responsible.

The diagnosis of the abnormal conditions which serve as a cause for the vomiting will be considered under the next heading.

Cause.—Here we reach the great point of difference which exists between observers, and yet the point upon which it is most important that definite and correct views should exist, for upon it must rest the most successful treatment. It has been customary to attribute the vomiting to a reflex irritation proceeding in some mysterious way from the developing ovum, but more stress has commonly been laid upon the condition of the patient, whether as concerning her stomach or her nervous system, which made this irritation potent for evil, than upon the source of irritation itself. Moreover, as regards the nature of this irritation, men have held, and hold to day, most divergent views, though it is coming to be admitted more and more generally that its origin is to be found in some abnormal pelvic condition.

My own preference is to consider that a number of causes may operate in different cases, or even in the same case, to produce the symptoms, and these causes should be classified as predisposing and exciting.

As to the predisposing causes, the chief is undoubtedly that state of exalted nervous sensibility which shows itself in so many and in such unmistakable ways during pregnancy. It is a matter of universal observation that trifling emotions, whether of fright, grief, annoyance, or otherwise, produce in the pregnant woman results far surpassing those which she would ordinarily experience. Similarly, it is doubtless true that conditions giving rise to irritation of sensory nerve fibres may produce correspondingly exaggerated results in the way of reflex phenomena.

Undoubtedly an important factor in this connection lies hidden in racial conditions. In no other way can we adequately explain the fact that Carl Braun, in his enormous experience, has never met with a fatal result, nor even with a case sufficiently serious to require induced abortion, while in France, England, and America a fatal termination is far from being a rarity. Hirst, in his "System of Therapeutics," shows a mortality of ninety-five in two hundred and thirty-nine cases reported.

Other factors may possibly be found in the hydræmic condition of the blood; the condition of fear, or at least the state of introspection and anticipation in which so many newly pregnant women find themselves; the various functional perversions of taste, smell, appetite, and digestion; and lastly, and more generally, in the presence of gastric catarrh in more or less marked degree.

Far more important, however, are the exciting causes which, as has already been suggested, will usually be found in some abnormal condition of the pelvic organs.

The theory which has been held in favor the longest is perhaps that of Bretonneau, who considered that the distention of the body of the uterus by the growing ovum caused pressure upon or tension of the nerve filaments, so setting up a reflex irritation. To a superficial observer this serves as a very satisfactory explanation, yet it fails utterly in many cases and must be rejected as inadequate. This distention occurs in every case, and yet many escape the nausea altogether, while others have it in one pregnancy and not in another. Moreover, the symptoms cease in most cases while this distention is still going on, and often the cessation is sudden and complete.

Another theory rests upon the supposition of metritis; yet metritis is more common in those who have borne children, while the vomiting of pregnancy is more common in primiparæ.

Still others, notably Veit, believe that endometritis, pre-existing and aggravated by pregnancy, is the source of the reflex irritation. That this may be a factor in some cases is quite likely, but it can hardly explain the phenomena in most, or even in many, cases.

There are those who hold lacerations and erosions of the cervix responsible, but in most cases such lesions do not exist.

Coming now to the theory advanced and ably advocated by Dr. Graily Hewitt, I believe that we find here the chief, though not the only, cause. He is often quoted as teaching that anteflexion is the sole factor, but this interpretation is far from correct. He finds that "the alterations of the uterus proved by recorded cases to be most frequently present in cases of severe vomiting are:

"(*a*) Marked flexion forward and backward.

"(*b*) Rigidity of tissues of the cervix.

"(*c*) Impaction or detention of the uterus in the pelvis.

"These three factors are most frequently associated in various degrees of severity."

Upon these facts rests his theory that the reflex irritation consists in "undue pressure or tension of the nerve filaments distributed in the walls of the cervix, especially those in the vicinity of the internal os"; . . . "this pressure or tension may arise in any case in which that expansion process in the tissues of the cervix which is natural to pregnancy is delayed or obstructed by the condition of the cervix."

Now, if it be borne in mind that during the early weeks of pregnancy the uterus commonly gravitates toward the pelvic floor, it will at once be seen that any previously existing flexion must be exaggerated. If it be still further remembered that the normal condition of the uterus is one of moderate anteflexion, which our modern methods of dress, together with other injurious influences of civilization, too often make pathological anteflexion, the preponderance of cases of anteflexion in these statistics of vomiting of pregnancy will not be wondered at.

It will be noted, however, that flexion need not necessarily be present in order to explain the vomiting in accordance with this theory. If, by reason of a laceration of the cervix, with subinvolution and chronic metritis as a consequence, the tissues at and about the internal os have become so indurated as to prevent their normal and equable expansion, injurious tension of the nerve filaments is produced. If, again, the uterus be held down in the pelvis by firm adhesions, or by the added weight and bulk of a fibroid, impaction and injurious pressure are just as surely produced as in the case of a flexion. Other ingenious but less plausible theories have been advanced, but aside from admitting the general truth that almost any form of pelvic disease may in isolated and exceptional cases be a prominent factor, these theories need not be considered here.

My own belief is more liberal than is that of many who have written upon the subject, for while I hold most tenaciously to the general fact of a local cause to be found within the limits of the true pelvis, I yet admit most of the special theories above mentioned. Most prominently I should place Dr. Hewitt's explanation in its broadest interpretation, viz., anything that prevents the free and uniform expansion of the cervix, particularly in the immediate neighborhood of the internal os.

Following this are to be grouped indifferently the various factors of metritis, endometritis, lacerations and erosions of the cervix, and the sundry other forms of pelvic disease which may be operable in rare cases.

The above represented the best teaching of a dozen years ago, and it is as true to-day as when it was written; but careful observation and a considerable experience have in the mean time served to crystallize and confirm my beliefs. I find that in the vast majority of the cases anteflexion is present and the "impaction or detention of the uterus in the pelvis" is the result of contraction of the utero-sacra lligaments. Schultze has well described this contraction, due to parametritis posterior, which usually accompanies and aggravates anteflexion, but its influence upon the vomiting of pregnancy was, I believe, first pointed out by me some three years ago. I am convinced that in cases of this type, "the degree of the intractability of the vomiting and to a large extent the degree of its severity depend upon the degree of contraction in the utero-sacral ligaments."

Having now ascertained that, whatever the degree of pregnancy vomiting, it springs from some abnormal condition and not at all as a natural and inevitable result of pregnancy, we cannot escape the conclusion that there can be no such thing as "physiological" vomiting, and that, therefore, no difference save one of degree exists between the light and the severe cases. All vomiting during pregnancy, as at other times, is abnormal and must be so regarded and so treated.

TREATMENT.—It having been established that the chief factor in practically every case of vomiting of pregnancy is some abnormal condition of the pelvic organs, it follows naturally that the most effective treatment must be directed toward the removal or cure of such condition. And just here it should be urged that success in treating the vomiting will be in very close ratio to the accuracy of the diagnosis of the pelvic cause and the intelligence of the treatment applied to it. Let no one who has not good cause to consider himself competent correctly to map out the true condition of the pelvic organs rest content with the delusion that there is no pelvic cause for the vomiting because he can find none. In such a case no one but a well-trained gynæcologist is competent to pass final judgment, and it must be confessed that even he is fallible.

Most frequent in the list of abnormal pelvic conditions is anteflexion of the body or cervix, associated in most cases with more or less contraction of the utero-sacral ligaments. For this Graily Hewitt recommends gentle elevation of the base of the bladder and the superimposed fundus of the uterus with the finger. Failing thus he advocates the use of the air-ball pessary, which is to be inflated after insertion. This pessary must be perfectly spherical, and must, when distended, measure not over two and one-quarter inches in diameter, the size rarely needing to be over two inches.

Aseptic precautions are to be observed before and after insertion, the patient to maintain the horizontal position, and the pessary to be removed at the end of six or eight hours. It may be necessary to repeat this treatment daily until the position of the uterus becomes permanently improved. Care must, of course, be exercised to prevent the induction of abortion by too great or too prolonged pressure due to the presence of the pessary.

Personally I have used this method but once, in which case it did good service. I have preferred to rely chiefly upon the frequent use of the knee-chest position, digital elevation, and packing.

In fact, so common is this condition as a factor, and so effective is the first part of the treatment alone, that I am in the habit of prescribing it as a routine treatment in the ordinary cases of pregnancy vomiting as they present themselves in the hospital clinics and in private practice, and I do not hesitate to assert that relief is complete in eighty per cent. of the cases.

The patient is told to assume a position on her knees, her hips high in air, her chest touching the bed, *every band being loose about the waist*, and then, either by opening the vagina with the finger or by introducing a glass tube, to admit air to the genital tract. This is done regularly night and morning, and at any other time when nausea is felt.

This failing, I place the patient in the knee-chest position and pack; lightly at first, but more firmly as she becomes accustomed to it. At first it is well to pack wholly in front of the cervix, so as to straighten out the flexion, but later a few tampons are best placed behind the cervix for the purpose of stretching the utero-sacral ligaments and so breaking up the impaction. Wool is the only proper material for this packing, as cotton soon becomes matted and hard; and the wool carded in sheets is far more elastic and therefore better than the fine tampon wool. The first one or two pieces may be dipped in a ten-per-cent. solution of ichthyol in glycerin, or in any bland antiseptic solution. I am in the habit of having all the tampons tied in a continuous string, like a kite-tail, so that the patient may be able to remove them at the first sign of irritation, or in order to use a cleansing douche before the next visit.

In one of these ways most cases of pregnancy vomiting may be relieved, but there remain those cases in which other causes are operative.

Retroversion and retroflexion are to be corrected by the aid of the knee-chest position, bimanual manipulation, and packing placed as high up as possible *behind* the cervix and extending down to the perineum. Once replaced the uterus is to be retained by some form of pessary.

In cases presenting erosion of the cervix, and in not a few cases showing no such sign, relief has promptly followed the nitrate-of-silver treatment. Indeed, so successful has this treatment proved in some hands that it has long been a routine method in the Vienna clinics. It is applied as follows: The cervix is exposed by a cylindrical glass speculum, the end of which it just fills, and after a thorough cleansing enough ten-per-cent. solution of silver nitrate is poured in to cover the exposed surface. After ten minutes this is decanted and the mucous membrane is dried. A second, and even a third, application may be called for after an interval of two or three days.

Should inflammatory processes be present, either in or about the uterus, the ordinary measures of rest, hot douches, and vaginal medication are in order. It is probably in such cases that benefit is had from vaginal suppositories or dressings of belladonna, cocaine, and morphine

In all the more serious forms of the complication absolute rest in bed, in the horizontal position, is of much importance Besides its general therapeutic value it permits the uterus more easily to rise above the brim, and aids us in our endeavors to correct displacements and lesser impaction. Coitus, and whatever may tend to cause sexual excitement or otherwise to increase pelvic congestion, must be avoided.

First discovered accidentally, and then practised empirically, Copeman's procedure has an established place in the treatment of severe cases. This consists in the careful dilatation of the cervical canal up to, but not through, the internal os. The index finger is used by preference, though Wylie has used a steel-branched dilator. Whether this acts by separating constricting bands of tissue, by straightening flexion, by breaking up impaction, or by some less apparent means, is not as yet agreed, but in many cases in which abortion has not resulted, a cure has been obtained.

Personally I wholly disapprove of this treatment, believing it to be dangerous and irrational. The same object is much better attained by the methods already described.

Besides the local cause, however, it is usually desirable to treat the conducting apparatus by which the reflex stimulus is conveyed. In other words, it is well to endeavor to lessen susceptibility to reflex irritation by the use of nerve sedatives, such as bromide, valerian, chloral, and even morphine. Chloral in full dose by rectum, night and morning, sometimes gives great relief, as does also morphine, introduced hypodermically or placed dry upon the tongue.

Chapman's ice bag to the spine has occasionally been found of service.

Then comes the long list of drugs for lessening the real or fancied irritability of the stomach. These must always be of secondary importance, and yet where symptoms are trivial they may answer every purpose at a minimum of annoyance to the patient, and where the outlook is grave we cannot afford to lose any help, however trifling, which may tend toward a cure. While, then, such remedies may always be given a place, reliance should not be bestowed upon them to the extent of wasting valuable time, or to the neglect of more rational measures.

In not a few cases gastric catarrh plays a more or less important part and claims attention. The ordinary remedies may be used, particularly the alkaline salines, taken well diluted before rising. Cocaine in small doses frequently repeated; creosote, or creosote and compound tincture of iodine in equal parts, given in one-drop doses every half-hour; oxalate of cerium in five-grain doses alone or combined with bismuth; calomel and ipecac in minute doses; hydrocyanic acid; tincture of nux vomica; pepsin; ingluvin; champagne; hot water; ice—these and other empirical means may be employed for their direct effect upon the stomach. In recent years the washing out of the stomach has been tried with manifest relief in not a few cases.

The diet and the mental surroundings of the patient must be carefully guarded. Our endeavor must be to keep up the strength at the same time that we spare the stomach needless effort by giving the lightest and most digestible foods. These are best given in small and frequent portions, it being borne in mind that often food will be retained if given just after a paroxysm of vomiting has spent itself. It must be remembered also that a patient can sometimes retain and assimilate an article of food for which she experiences a marked longing, when seemingly more appropriate articles are at once rejected. The simple expedient of giving a light and easily digestible breakfast an hour before rising will sometimes solve the problem in those ordinary cases which are known as "morning sickness."

When, however, the stomach rebels to such an extent that the patient's strength perceptibly fails, resource must at once be had to rectal alimentation. Peptonized milk, eggs, and predigested beef form the best basis for these enemata, to which may be added, if necessary, a few drops of laudanum and half an ounce of whiskey. Four injections, of four ounces each, given within twenty-four hours, can generally be retained, provided that once daily the lower bowel be well emptied by a

ansing enema of warm suds. Life can be sustained
weeks in this way when all else fails.
Recognizing the fact that mental conditions play an
ortant part in some cases, the patient must be cheered
l encouraged at all times, and so far as possible all
ses of worry, anxiety, and undue care must be re
ved.
Ve now come to that class of cases which resists all
measures at our command. The patient has reached
second stage described above, and the question of
otying the uterus presents itself. Of course it is as-
ued that no one will lightly decide upon this last re-
without good and sufficient cause; yet, on the other
d, there is need to urge the danger of too long delay.
vided a faithful trial has been made of less radical
sures, and yet in spite of them the gravity of the
ptoms continues, let no time be lost in producing
rtion, preferably by emptying the uterus at one sit-
, under ether. The reason for thus urging against
y lies in the fact that even abortion may fail to avert
fatal issue if the third stage be permitted first to make
ppearance. *Rufus A. Kingman.*

ACONDA SPRING.—Mitchell County, Kansas.
ST-OFFICE.—Cawker City. Hotel and sanitarium.
CESS.—Trains on the Central Branch of the Missouri
fic Railroad stop within a few rods of the hotel.
his big spring is located within a fine curve of the
mon River, about three miles from Cawker City, and
elevation of about 3,500 feet above the level of the
The spring is contained in the centre of a huge,
lar mound composed of hard rock, which rises to a
ht of thirty feet above the surrounding surface.
spring is sixty feet in diameter, and is surrounded
natural platform of rock from eighty to one hun-
and fifty feet wide, and so nearly circular as to ap-
as if artificially cut. The diameter of the base of
mound is one hundred and seventeen yards from
to south and one hundred and nineteen yards from
o west, while its circumference is sixty-six rods. A
coping has been placed around the spring, and this
mounted by a light iron fence, to protect the water.
in ten rods of the spring a substantial hotel and sani-
n, supplied with all modern comforts and conven-
s, has recently been erected. The water from the
g is supplied to this building and is utilized for the
houses, where all varieties of hot and cold or vapor
will be found. The surroundings of this resort are
attractive, and the climate is of a bracing and salu-
character. The following analysis of the water
made by Prof. G. E. Patrick, of the University of
s, at Lawrence:
United States gallon contains (solids): Sodium
de, gr. 765.76; sodium bromide, gr. 0.23; sodium
ate, gr. 183.60; magnesium sulphate, gr. 85.28; so-
bicarbonate, gr. 26.92; magnesium bicarbonate, gr.
calcium bicarbonate, gr. 31.30; silicic acid and
s acid, traces; no organic matter. Total, 1,120.65
. Carbonic-acid gas, 91 cubic inches to the gallon;
c gravity, 1.017.
water has a strong saline taste, and when properly
nated is clear and sparkling. The analysis shows a
of great potency. It should be fully possessed of
alities found in the waters of this class. Taken in
doses it is said to stimulate the appetite, to tone
nervous system, and to invigorate the spirits and
l bodily condition to a remarkable degree. It may
ly recommended in all cases in which this class of
has been found useful. It is bottled and shipped
desired point. *James K. Crook.*

400.—(*Euonymus*, U. S. P.; Spindle tree, Burning
etc.) The dried bark of the root of *Euonymus*
rpureus Jacq. (fam. *Celastraceæ*).
plant is a graceful shrub or small tree of the Mid-
l Western States, and is frequently cultivated for its beauty. It is usually about eight to twelve feet high, with opposite, oval-oblong, pointed, serrate leaves, and small, regular, dark purple flowers in axillary cymes. Sepals, petals, and stamens usually four; the latter inserted on a disc which extends over the ovary; pistil one; ovary three- to five-lobed and three- to five-celled, with several ovules in each cell; pods deeply lobed, smooth, bright crimson, drooping on long slender peduncles.

The bark occurs in quilled strips or pieces of very irregular size, usually with a few fine hair-like roots adhering; bark 1–5 mm. ($\frac{1}{25}$–$\frac{1}{5}$ in.) thick; outer surface ashy or pale brownish-gray, usually with some small dark patches, shallowly fissured and ridged, with a somewhat scaly and soft, friable cork; inner surface whitish or slightly tawny, indistinctly short striate; fracture short, whitish, or the inner layer pale-brownish in bark which has been long kept; when it is slowly broken, the fractured ends are held together by fine, somewhat elastic fibres; odor distinct and characteristic, more or less saponaceous; somewhat gummy in the mouth, the taste sweetish, bitter, slightly acrid.

The stem bark, which is in long, tough strips, with a dark gray or blackish cork, should be rejected.

The constituents of wahoo are not very well made out. Several resins, oil, wax, and numerous more ordinary substances have been obtained from it, as well as a glucoside named *euonymin;* indeed, several "euonymins," of somewhat different characters, have been separated by as many chemists. From all of these, again, is to be distinguished the resinoid "euonymin" obtained by precipitating the tincture. Of the latter there are two forms: the "brown," made from the official bark, and the green, made from the stem bark, the latter being inferior.

USES.—Wahoo is a not very certain, usually gentle, but sometimes griping laxative, with a reputation as a cholagogue. It may be given in chronic constipation, or perhaps better in occasional attacks of constipation with dyspepsia, heaviness, and symptoms of diminished hepatic action.

Dose of the extract (*Extractum Euonymi*, U. S. P.), 1 or 2 dgm. (gr. i. ad iij.) in pill form once or twice a day.
Henry H. Rusby.

WALLERIAN DEGENERATION.—The degeneration which occurs in the peripheral portion of a severed nerve fibre is known as the Wallerian degeneration. It is due to the separation of this portion of the fibre from its corresponding ganglion cell, and is usually explained as resulting from a loss of trophic influences, the severed portion being cut off from the source of its nutrition. The fact that a nerve when separated from its trophic centre degenerates in the direction in which it normally carries impulses is known as the *Wallerian law of degeneration.* It is also true that the central portion of a severed nerve —that portion which retains its connection with the ganglion cells—undergoes retrograde changes; but these differ from the changes seen in the Wallerian degeneration, being more of the nature of a simple atrophy.

The first recognizable change in Wallerian degeneration is a loss of the translucency of the nerve fibre. This is followed by a breaking-up of the myelin. Under the microscope the medullary substance is seen to be fragmented into small lumps or segments which become separated from each other. This is followed by a complete degeneration of the medullary sheath in which the latter is distintegrated into small fat droplets, the process suggesting an emulsification. At the same time there is a great increase in the size and number of the nuclei of the sheath of Schwann. Formerly it was believed that the neuraxones degenerated secondarily to the changes in the medullary sheath; but it has been shown that the changes in the former occur coincidently with those of the sheath. The neurilemma finally becomes filled with the remains of the axis cylinder and medullary sheath, the fat droplets are taken up by fat granule cells, and the detritus is in time absorbed by the cells of the neurilemma. In the neighborhood of the injury the nerve nuclei become enlarged and show signs of proliferation. The neurilemma eventually disappears, but if the severed ends are again brought together, or if the distance between the ends is not too great, the old neurilemma sheaths may again become neurotized by new axis cylinders growing downward from the central cut end.

Aldred Scott Warthin.

WALLEY'S HOT SPRINGS.—Douglas County, Nevada.

POST-OFFICE.—Genoa. Hotel.

This resort, formerly known as Genoa Hot Springs, is located about fourteen miles from Carson City, the capital of the State. The situation is picturesque, having an altitude of about four thousand feet, with high mountains on the west and a beautiful valley on the east. The prevailing weather is clear and pleasant, the temperature seldom exceeding 90° F. in summer or falling below zero in winter. Mr. H. J. Walley furnishes us with the following analysis made by J. W. Phillips, analytical chemist at the Nevada Agricultural Experimental Station: One United States gallon contains (solids): Potassium sulphate, gr. 0.67; sodium sulphate, gr. 12.41; calcium sulphate, gr. 2.19; sodium hyposulphite, gr. 0.40; sodium bicarbonate, gr. 0.64; sodium biborate, gr. 1.45; sodium chloride, gr. 4.78; silica, gr. 2.85; alumina, gr. 0.02; and traces of iron sulphate, magnesium bicarbonate, ammonia, and organic matter. Total, 25.41 grains. Carbonic acid gas, 6.48 cubic inches.

The temperature of the several springs (six in number) varies from 136° F. to 160° F. The baths here are stated to be very efficacious in the treatment of renal and skin diseases and in rheumatism of long standing. The analysis shows a valuable thermal water of the saline class.

James K. Crook.

WART. See *Verruca.*

WASATKA MINERAL SPRING.—Salt Lake County, Utah.

This spring is located in the northern outskirts of Salt Lake City. "Wasatka," or the "Milk Spring," derives its name from the peculiar soft and milk-like flavor of the water. During the past three or four years this water has come into extensive use, and it is said to give ample evidence of remedial value, besides furnishing an excellent table beverage. The following is a recent analysis by Walter S. Haines, professor of chemistry at the Rush Medical College of Chicago:

One United States gallon contains (solids): Sodium chloride, gr. 230.88; potassium chloride, gr. 3.06; magnesium chloride, gr. 21.24; calcium chloride, gr. 11.92; lithium chloride, gr. 0.12; ammonium chloride, gr. 0.25; calcium sulphate, gr. 59.50; calcium carbonate, gr. 4.75; silica, gr. 0.75; iron and aluminum oxide, gr. 0.03; sodium borate and magnesium bromide, traces. Total, 332.50 grains.

The water possesses alterative, aperient, and diuretic properties, and is recommended by Utah physicians in functional diseases of the digestive organs, liver, and kidneys. It is bottled and shipped to many points in Utah and the adjoining States. *James K. Crook.*

WASHINGTON, D. C.—Washington city (latitude 35° 53′ 39″ north, longitude 77° 2′ 48″ west), the capital of the United States of America, is in the District of Columbia, on the east bank of the Potomac River, about one hundred miles from its mouth. The Anacostia River (or Eastern Branch as it is sometimes called), a small tributary of the Potomac, bounds the city on the south, separating it and the suburb, Anacostia. Rock Creek, another small stream, which flows through the western part of the city, was at one time the boundary between the cities of Washington and Georgetown, but this muni- istinction is now not made. Between these two an area of about eight square miles, having a itude of twenty to eighty feet above the level mac River. Upon this area the greater part of the city is built. Elsewhere the land rises to a general plateau, averaging from two hundred to three hundred feet above the river level, which also is practically sea-level.

The District of Columbia, originally styled "Federal Territory," was laid out in 1791 by commissioners appointed by President Washington, and in pursuance of an act of Congress, which gave the President the authority to select the site of the national capital. At the time of the selection, the District of Columbia was about the centre, geographically, of the original thirteen States of the Union. The original territory had an area of one hundred square miles, and was ceded, as equally as the nature of the site chosen admitted of, by the States of Maryland and Virginia. Subsequently, in 1846, the part given by the State of Virginia was ceded back to it by the national Government. The present area of the District is sixty-four square miles.

Washington has had no corporate existence apart from the District of Columbia since 1874. From 1802 to 1871 there was a municipal form of government, the chief executive being a mayor elected by the citizens. From 1871–74 the District and the city had a territorial form of government, the chief executive being a governor. Since 1874 the city and District have been governed by three commissioners, the Board of Commissioners of the District of Columbia, appointed by the President of the United States and confirmed by the United States Senate. These officials are appointed for terms of three years: two must be residents of the District for three years before appointment and of opposite political parties; the third must be an officer of the engineers, United States army, of a rank not lower than that of captain, and he must have served at least fifteen years in that branch of the military service. The Congress of the United States legislates directly for the District, and the commissioners execute the laws so enacted. There is thus in the capital of the greatest republic of history the spectacle of the citizens of that capital without direct representation in their own government. On the whole, however, the plan works well.

The population of the District of Columbia, according to the census of 1900, was 278,718, of which 191,532 were whites, 86,702 negroes or of negro descent, 455 Chinese, and 29 of all other races. Within what was the city of Washington as defined by its limits of 1874, there were 218,196 inhabitants, in what was Georgetown, 14,973, and scattered throughout the remainder of the District 45,973 inhabitants, mostly located in the suburbs known as Anacostia, Brightwood, Brookland, and Tenleytown. The average death rate of the District, including the city of Washington, for the last ten years is 17.57 per 1,000 for whites and 30 per 1,000 for negroes. The chief cause of mortality is tuberculosis. While there appears no undue prominence of any cause, contrasted with neighboring cities, there are certain conditions which, if removed, would greatly increase the longevity of the community. Typhoid fever has now a larger death rate than it will have when the contemplated water-filtration plant is in operation. Much improvement can be made in the sanitary requirements of house construction, especially in the matter of requiring ample initial air space in all dwellings, and in the prevention of overcrowding, particularly in the houses perniciously tolerated and still permitted to be erected in alleys and courts.

The water supply of the city is taken from the Potomac River about eighteen miles above the city, and is conveyed in a covered conduit to the distributing reservoirs. This conduit crosses a deep ravine on the famous cabin John Bridge, the largest single span stone arch in the world, two hundred and twenty feet from pier to pier, fifty-seven feet rise, and twenty feet wide. The distributing reservoirs being at a higher level than the greater part of the city, gravity is sufficient for household supply. However, there are several pumping stations for such parts of the city as cannot be fed by gravity. The quality of the water is soft, and during dry weather the water is clear. The water-shed is not thick-

populated, there being no cities of any size within the
a. So far, there has been no serious suspicion of
phoid or other infection emanating from the city water
pply. From the frequency of rains, and the conse-
ent turbidity, many persons object to using the city
ter on æsthetic grounds, and they resort to pumps
thin and to springs outside the city. There is reason to
ieve, from investigations made some years ago by the
dical Society of the District of Columbia, that these
ters are more dangerous than the less inviting Potomac
ter. Contracts have been awarded for gravity sand filter
ls, and when these are constructed and in operation the
r will have a water supply of unimpeachable purity.
ewage, both house and street, is removed by water
riage. At present there are several mains discharging
different points. Plans are in progress to converge
se mains to a central pumping station, from which a
nk sewer will convey the total sewage across Anacos-
River and thence along the Potomac, to be discharged
that stream some miles below the city.
he streets are wide, varying from sixty to one hun-
d and twenty feet, and are paved, with few excep-
s, with asphalt. The street plan is simple. The orig-
topographic map was designed by a French engineer
er, Major L'Enfant, into whose hands the work was
usted by President Washington. The centre of the
is the Capitol. Radiating from the Capitol are
e streets, one running north, called North Capitol
et, one running east, East Capitol Street, and one
ing south, South Capitol Street. West of the Capi-
line of parks extends to the Potomac River. These
ts and the line of parks serve to divide the city into
sections, denominated the Northeast, the Southeast,
Southwest, and the Northwest, respectively. What
distinctively named *streets* run east and west, and
h and south, intersecting each other at right angles;
her class, called *avenues*, intersect the streets and
other obliquely.
e east and west streets on each side of East Capitol
t and its westward park prolongation are designated
he letters of the alphabet (except that there are no J
X streets), and the north and south streets on each side
orth and South Capitol streets are designated by
bers. The avenues are named after the different
s of the Union. Streets and avenues receive in addi-
the names of the sections in which they are located.
city, however, has extended northward beyond the
nal street plan, and, as no provision had been made
niformity in naming the new east and west streets,
derable confusion has resulted. Efforts are now
ng to rectify the oversight. The intersections of the
ues and the streets afford many opportunities for
parks, laid out in triangles, circles, and small
ngles. There are a number of large parks; the total
ng area being somewhat over three thousand acres.
spicuous feature of Washington is the great num-
f trees ornamenting the streets, and so thick are
that their summer foliage shuts out the houses from

might naturally be expected the city has many
e buildings. The most imposing are the Capitol,
ibrary of Congress, the Treasury, the State, War
Navy building, the Interior Department, the Presi-
s House (or popularly the White House), and the
office. The many other public buildings are not
ecturally striking enough to be named.
Capitol, the largest and most noticeable structure,
length of 751 feet 4 inches, and a breadth varying
121 to 350 feet, and covers an area of 158,112 square
The central part of the building is surmounted by
n dome, 135 feet 5 inches in diameter at its base;
top is Crawford's bronze statue of liberty, 19½ feet
its crest towering 287 feet 5 inches above the earth.
ody of the central part of the Capitol is built of free-
the two wings of marble, and the dome, as above
of iron. The corner-stone was laid September
1793, by President Washington. The interior of
iginal building, at that time only the wings, was burned by the British in 1814. The present central structure was begun in 1818. The building as it exists at present was practically completed in 1865. The total cost has been somewhat in excess of $15,000,000. The Library of Congress, just east of the Capitol, is one of the most imposing structures to be found anywhere. It is built of granite, covers about three and three-quarter acres of ground, and cost $6,347,000.

Perhaps the most striking structure after the Capitol is the Monument, situated about a mile and a quarter west of the Capitol. This is a plain, rectangular, marble shaft, five hundred and fifty-five feet five and one-half inches high, and is the highest stone structure in the world. Its interior is hollow and is provided with a stairway and an elevator, both leading to a chamber just under the cap-stone. An excellent view of the city and surrounding country can be had from this point. Many small monuments and statues ornament the different parks. Educational advantages are excellent. There are ample public schools and the system of instruction is good. The Columbian University and the Georgetown University are old institutions, and offer first-class facilities for advanced instruction in all branches of study. The Catholic University of America, a comparatively new school, offers at present chiefly advanced instruction in theology and philosophy. The American University, a Methodist institution, is yet to be developed, but it promises to become a factor of educational importance. There are many smaller colleges and universities so called. The scientific work carried on in the different departments of the national Government gives exceptional opportunities for post-graduate work. The immense libraries—the library of Congress, that of the Surgeon-General's office, United States army, and of the other departments and bureaus of the Government—afford better facilities for gaining access to the literature of science than are to be found anywhere else in this country. There are a number of large and well-appointed hospitals. From a political and from a social view-point the advantages offered by the city, being the seat of the National Government, are obvious.

The facilities for living compare favorably with the other large cities of the country. The markets are well supplied the year round and prices are reasonable.

The climate is variable, but on the whole pleasant. A better idea can be had of it by consulting the table contained in the article on *Climate* in Vol. III.

W. F. R. Phillips.

WASHINGTON SPRINGS.—Washington County, Virginia.

POST-OFFICE.—Glade Springs. Hotel and cottages.

ACCESS.—Viâ Norfolk and Western Railroad to Glade Springs depot; thence two miles by hack or carriage to springs.

This resort is ensconced in a delightful location among the hills, at an altitude of 2,250 feet above the sea-level. The situation is opposite to and faces the White Top Mountain, one of the highest peaks in Virginia. Close by are the Chilhowee Sulphur Springs, Seven Springs, and Emory and Henry College. An excellent hotel, with provision in various ways for the comfort and amusement of the guests, is maintained. The springs are seven in number, and have an average flow of thirty gallons per hour. The water has a temperature of 51° F. We present analyses of the "Sulphur" Spring and the "Magnesia Soda-Iron" Spring, by W. H. Seamon, analyst of Crozet, Va.:

One United States gallon of the "Sulphur Spring" contains (solids): Iron carbonate, gr. 0.52; calcium carbonate, gr. 2.99; potassium carbonate, gr. 0.11; sodium carbonate, gr. 0.29; calcium sulphate, gr. 6.47; calcium phosphate, gr. 0.14; sodium chloride, gr. 0.09; strontium sulphate and arsenic chloride, traces. Total, 10.41 grains. The water also contains a certain amount of hydrogen sulphide.

One United States gallon of the Magnesia Soda-Iron Spring (Washington Spring) contains (solids): Calcium sulphate, gr. 0.10; magnesium sulphate, gr. 4.04; strontium sulphate, gr. 0.38; sodium sulphate, gr. 3.97; iron carbonate, gr. 1.95; calcium carbonate, gr. 13.66; sodium chloride, gr. 0.34; potassium chloride, gr. 0.24; silica, gr. 2.07; organic matter, gr. 1.03; aluminum sulphate, manganesium carbonate, and phosphoric acid, traces. Total, 27.78 grains. These waters have a useful application in debilitated states, especially when attended by intestinal torpor. They have rendered good service in anæmia and general debility. *James K. Crook.*

WATER (H_2O).—Even after it had ceased to be considered elementary, there was much ignorance concerning the composition of water. Thus when for the first time it was decomposed by the action of the electric battery, an acid was observed to form at one pole and an alkali at the other, in addition to the gaseous products oxygen and hydrogen. This acid and the associated alkali were supposed to be intimately related with the two gases in the structure of water, until Humphry Davy, by a series of brilliant experiments, showed that the acid and alkali were entirely adventitious and that water consisted of oxygen and hydrogen alone. Demonstration of its composition was also made synthetically by the explosion of a mixture of the two gases, such mixture being in the ratio of one volume of oxygen to two volumes of hydrogen.

Considered physically, an important property of water is its very great solvent power, and it is also noteworthy as the basis for specific gravity and specific heat. Moreover, it is employed as the metric unit of weight, the "gram" being the weight of 1 c.c. of water at the temperature of its greatest density, 39.2° F.

Chemically considered, the graphic formula for water, H—O—H, known as the "water type," constitutes the starting-point of the two great series of compounds known as "hydrates" and "oxides," the first being formed by the replacement of half the hydrogen of the "water type" by a metal (R—O—H), and the latter by its entire replacement (R—O—R). For our present purposes, however, it is the more practical and sanitary side of the question of "water" that should claim our attention; in other words, we should undertake some consideration of the wide field of inquiry covering *water supply*.

From remote antiquity the highest value has been set upon an abundant and pure water supply. Centres of population sprang up in ancient times around those points where it was readily available, and great expenditures of labor and treasure were made to carry it to places where it was not naturally plenty. Not only was a generous daily *per capita* allowance sought for, but we note in the centuries gone by unmistakable evidences of a keen appreciation of the dangers lurking in a polluted supply; and upon this point many of the ignorant consumers of our own day and generation would be benefited did they consult the wisdom of the past.

When considering the sources of water supply available for public or private use, we very properly first turn to such bodies of "stored water" as may be within reachable distances.

Nature provides enormous quantities of water stored up in lakes and ponds ready for human consumption, and man frequently supplements this by impounding surface and deep-seated waters in artificial basins when the natural reservoirs of the district are unavailable or are insufficient in size.

Lakes of such magnitude as to be properly considered inland seas—the Great Lakes of North America, for instance—furnish water of quite constant composition, free from the considerable vegetable contamination so frequently met with in small lakes and ponds.

Large as these Great Lakes are, the influence of the sewage from cities upon their shores is nevertheless beginning to be seriously felt. For instance, the pollution of Lake Michigan by the sewage of Chicago is a widely known fact, and the intakes, situated as they are miles from shore, are frequently reached by the ever-swelling volume of the city's refuse.

	Lake Superior, near Duluth, 40 miles out from shore, March, 1896.	Lake Erie, near Erie, Pa., 14 miles out from shore, October, 1897.
Free ammonia	0.03	0.045
Albuminoid ammonia	.02	.112
Chlorine	1.0	3.500
Nitrogen as nitrates	0.0	.080
Nitrogen as nitrites	0.0	Trace.
Required oxygen	1.15	1.250
Total solids	54.0	134.000

Much opportunity is given in large lakes for sedimentation to come into full play, and settlement is, in consequence, a very great item in the process of the natural purification of their waters; but so far as the American "Great Lakes" are concerned, a difference must be noted in this respect between Lake Erie and the other members of the group. Lake Erie is comparatively shallow and is stirred to its bottom by every gale. Therefore sedimentation advantages are at a minimum therein.

In small lakes and storage reservoirs vertical circulation commonly ceases below a depth of twenty feet, that being the usual distance to which wind and wave agitation extends. Fitzgerald found that Lake Cochituate, which has an area of seven hundred and eighty-five acres, is not affected by wind and wave action below twelve feet from the surface. Should a lake be protected from the wind, the aerated layer may extend temporarily only ten feet from the surface, and below this level the cold, stagnant water rests, until such time as the chilling of the upper layer increases its gravity to and beyond that of the lower layer upon which it floats. When this point is reached, readjustment of relative position is immediately instituted, in accordance with the change in specific gravity, and the water of the lake "turns over."

The formation of this stagnant layer begins in April in this latitude, and circulation is partly re-established in October and completely so in November. With the advent of freezing weather a second period of stratification is inaugurated, which continues until the surface thaws again in the spring. Vertical circulation then progresses until the warm sun of later April renders the surface water so light as to float upon the colder layers beneath, when summer stagnation again begins.

Whenever the lower stagnant layer is brought in contact with decomposing organic matter, as is the case in reservoirs with bottoms from which the vegetation has not been removed, the dissolved oxygen present is quickly used up; quantities of extractive matters pass into solution and the water becomes foul in odor and dark in color.

Even though the bottom of a lake or reservoir be perfectly clean and sandy, the dissolved oxygen must surely diminish in the lower layers of water, for no water is without some oxidizable contents, but it will not be reduced to zero, nor will the water become damaged in quality.

Uniform experience goes to prove that good water may be preserved in properly constructed reservoirs without deterioration for indefinite lengths of time. It must be remembered, however, in this connection, that to keep a ground water in good condition it is necessary to cover the reservoir. Such waters are usually charged with mineral matter suitable for plant food, and the higher organisms will be very likely to grow therein unless light be excluded. Reservoirs used for storing filtered surface waters should be likewise dark, for the same reason.

Algæ depend for their development upon material furnishing nitrogen. Water containing a moderate amount of this element washed from natural sources will maintain but a small growth of such plant life, but where nitrogen is present in great quantity as nitrates, as is frequently the case in deep-seated waters, the development of algæ is often excessive during reservoir storage, and the resulting smell and taste given to the water may cause widespread complaints.

It is true that no relation has ever been established between the occurrence of disease and the presence of the bad tastes and smells occasioned by abundant growth of algæ, but the results directly traceable to such growths will not be tolerated by the public, and the water purveyor constantly finds himself much more open to criticism through difficulties of that kind than through pollution of the supply by drainage from pathogenic sources.

Properly to conserve a water, to put it tersely, it may be said that if it be from a dark source it should be stored in the dark, and *vice versa ;* filtered water being the exception and requiring dark storage irrespective of its source.

If dark storage be not practicable, then a water from an underground source should be delivered for use at the earliest moment possible to avoid the growths which the presence of light will encourage. With surface waters, on the other hand, open storage is always of benefit if the reservoir be clean.

It is an error to suppose that "stagnation" in a properly prepared reservoir is of itself harmful to the quality of water. Quite the contrary is true, and it is scarcely too much to say that rest rather than motion is the condition commonly leading toward the greatest amount of "self-purification."

Pathogenic bacteria tend to diminish by storage, both by reason of settlement and because of conditions which are adverse to their requirements for life; hence we note the beneficial value of the time element when dealing with impounded waters. Running streams, on the other hand, lessen the opportunities for sedimentation and their rapid flow hastens the delivery of the yet living disease germs to the unsuspecting consumer.

Let it not be thought, however, that the popular belief in the purification value of thorough aeration is based entirely upon error. Gases dissolved in the water and giving it objectionable odor—as the sulphureted hydrogen, for instance, in the artesian supply of northern Florida—are driven out by thorough exposure to air; and even algæ growths are often impeded by vigorous agitation. To such extent, therefore, falls and rapids and reservoir fountains are of advantage for the improvement of water; but the really serious item of pollution, namely, sewage admixture, cannot be disposed of by so simple a method as direct atmospheric oxidation, and any hopes that are based upon the supposed efficiency of such action will be doomed to disappointment.

A very large number of cities derive their water supplies from purely surface sources, such as rivers and streams—in Europe after careful filtration, but in America usually without such purification.

One of the important things for the consumer of such a water to bear in mind is that sudden and great changes in the character of the water are to be expected. Much will depend upon the weather and the amount of surface wash which naturally flows toward the drains of the district. A river which is clear to-day may be muddy and less fit for use to-morrow, and the turbidity will persist, even after its direct cause has ceased, until the river and its tributaries shall have emptied themselves into the sea. For it must be noted that the clearing of running streams has little to do with sedimentation and is almost wholly dependent upon a running out of the roily waters.

Another change, slow in operation but serious in results, is that induced by the establishment of sewerage systems in river towns, through the growth of a population which naturally sewers into the river. The difficulty is twofold. Not only does pollution increase with the multiplication of the people producing it, but the partial soil purification of the contents of the village cesspool is entirely eliminated when the sewers of the growing town turn the sewage in the raw state into the river.

It is not unusual to find a city damaging its own water supply by its sewage outflow. Tidal action may carry the refuse of a town up stream from the sewer outfalls until the water works intake is reached; or else the currents produced in a lake by weather changes may accomplish the same result, as is noticed at Chicago.

The self-purification of streams is a topic which has been very fruitful of discussion. Pettenkofer held that sewage might be safely turned into any stream whose volume was fifteen times greater than the volume of the sewage, and whose velocity was not less than that of the sewage inflow. This is but an *ex-cathedra* statement of a rather widely spread belief in the ability of running water to purify itself after a comparatively short flow. That efficient purification by such means is far from being an established fact is attested by the many instances that might be quoted of typhoid infection having been carried many miles from the point of pollution to the city intake below.

How far such infection may be carried is uncertain and is governed by the velocity of the current, but the distance has been shown to be many miles. The germs of such a disease as typhoid fever do not find conditions suitable for their development in river water, hence they do not multiply therein and after a time they die out without causing disturbance, provided that they be not caught up by some down-stream intake before their death be accomplished. Hence the value of the element of time in rendering a polluted water again fit for consumption. Not infrequently an acceptable water may be found flowing from a lake of no great size, while the stream tributary to its other end may be distinctly polluted; the lapse of time and the advantages of sedimentation having united their efforts toward the promotion of purity.

While space cannot be here given to detailed accounts of the ravages that have been caused by infected water, yet a glance at a single instance may serve for general illustration.

The cities of Hamburg, Altona, and Wandsbeck are practically one and are separated by only imaginary boundaries which a stranger could not locate. In 1892 Asiatic cholera broke out in Hamburg with exceeding severity, the reported cases having been 17,020 with a death list of 8,605. The disease marched up to the invisible boundary lines and there stopped, confining itself almost exclusively to Hamburg. In one street, which for a long way forms the boundary, there was cholera on the Hamburg side, whereas the Altona side was practically exempt. There was one detectable difference, and only one, between the conditions obtaining in these adjacent cities—they had different water services. Hamburg took raw water from the polluted Elbe River; Altona used the same river water, still more polluted by the Hamburg sewage, but carefully purified it by sand filtration; Wandsbeck possessed an entirely different supply. How cholera located the boundary is best shown by a "spot map" of the reported cases. (Fig. 5031.)

Freezing is a means of natural purification of water upon which the popular mind lays great stress, and to a certain extent the general confidence in its efficiency is not misplaced. Ice is certainly purer than the water from which it is formed, often very greatly purer. The ice cake grows from the surface downward, the crystals as they form pushing away from them the material suspended in the water, bacteria included, and freeing themselves also from no small amounts of even dissolved impurities. Naturally some floating objects become entangled in the thickening mass, particularly so if the underlying water be shallow, and all must of necessity pass into the ice cake if the entire depth of water be frozen. An excellent idea of the exclusive action of the crystals may be had by examining a cake of artificial ice. It will be observed that the last part frozen, namely, the centre of the cake, shows marked inferiority, due to the floating objects having been driven inward by the forming ice, only to be at last caught by the final solidification of the central portion.

When ice is formed on a polluted but deep water, a large river, for instance, the amount of bacterial purification amounts to over ninety per cent., commonly over ninety-five per cent., and a further element of safety lies in the fact that storage in ice-houses during the months elapsing between the winter "harvest" and the summer distribution tends still further to reduce the number of germs present in the ice cake. Be that as it may, however, there is small excuse for the too common practice of cutting ice from grossly polluted waters, for with even a high percentage of exclusion some germs do enter the ice, and it has been shown that typhoid germs are at times capable of surviving a three months' imprisonment therein.
